AUTHOR INDEX

1960

Abdullaev, A. Estimates, Based on Usage, of the Service Life of Contact Apparatus - 175
Abdullaev, A. A. and I. A. Nabiev. Automatic Telemetry System for Oil-Well Flow - 183
Agababyan, M. M., see Sarkisyan, E. P. - 563
Aizerman, M. A., L. A. Gusev, L. I.Rozonoer, I. M. Smirnova, and A. A. Tal'. Finite Automata. I. - 156
Aizerman, M. A., L. A. Gusev, L. I. Rozonoer, I. M. Smirnova, and A. A. Tal'. Finite Automata II. - 248
Aizerman, M. A., L. A. Gusev, L. I. Rozonoer, I. M. Smirnova, and A. A. Tal'. On Methods for Realizing a Finte Automaton whose Cyclical Nature is Determined by the Variation of the Input State - 1126
Alimov, Yu. I. Lyapunov Functions for Relay Control Systems - 500
Andreev, N. I. Determining Pulse System Optimum Weighting Function which Ensures the Extreme of a Functional - 322
Andreeva, E. A. Calculation of Static Characteristics of "Nozzle-Baffle" Elements - 691
Andryushchenko, V. A. Electrets and the Prospects of Their Use in Automation. (Survey) - 93
Anisimov, I. A., see Aronovich, V. V. - 575
Aronovich, V. V., I. A. Anisimov, M. I. Lyudmirskii, and R. S. Patushinskaya. Control of Chemical Production Processes by Indicators of Product Quality - 575

Baikovskii, V. M. On the Noise Immunity of the Discrete-Incremental Method of Information Transmission - 239
Bamdas, A. M., V. A. Kulinich, V. A. Somov, V. A. Suchkov, S. V. Shapiro, A. O. Shmidt, and Ku Shen-ku. New Electromagnetic Executive Organs for Automatic Control Systems - 639
Baranova, V. S. and A. A. Pervozvanskii. Parametric Phenomena in the Simplest Continuous Extremal Control Systems - 881
Barashin, E. A. An Estimate of the Maximum Deviation for a Given Trajectory - 945
Barbashin, E. A. Estimating the Mean Square Deviation from a Given Trajectory - 661
Baverman, E. M. Certain Problems in the Design of Machines which Classify Objects According to an Identifying Feature which is not Specified A Priori - 971
Belya, K. K. On the Stability of the Periodic Motion of Piecewise Linear Automatic Control Systems - 799
Belaya, T. P. An Investigation of Some Types of Matrix Decoders with a Relay Output - 924
Belyavskii, V. F. and Yu. M. Shamaev. Designing Circuits which Contain Cores with Rectangular Hysteresis Loop Characteristics - 838
Berezovets, G. T. and Chou, Ching-leng. Experimental Investigation of Rubber-Fabric Membrane Characteristics - 224
Blokh, A. Sh. Equivalent Transformations of Sequential Machines - 1057
Blokh, Z. Sh. Transient Responses in Control Systems with Lags - 493
Bogomolov, V. N. Contactless DC Automatic Potentiometer with a Transformer Based on the Hall Effect - 90
Boguslavskii, I. A. On Unbiased Estimates of Signals which Depend Nonlinearly on Unknown Parameters - 27
Boguslavskii, I. A. On a Drive Scheme with a Given Equation of Motion - 236
Bol'shakov, I. A., see Tikhonov, V. I. - 765
Boyarchenkov, M. A. and M. A. Rozenblat. Reversive (Duodirectional) Magnetic DC Amplifiers of Increased Efficiency - 1066
Brik, V. A. Error Accumulation Digital Computations - 412
Burovoi, I. A. and S. V. Emel'yanov. On the Control of Certain Industrial Processes by Means of Minimum Changes of the Controlling Inputs - 810
Butkovskii, A. G. and A. Ya. Lerner. The Optimal Control of Systems with Distributed Parameters - 472

Chang Jen-wei. Stability of a Controlled System with Two Nonlinear Elements - 897
Chang Jen-wei. The Stability of a Certain Nonlinear Controlled System - 1047
Cherepanov, A. I. Analysis of a Two-Position Compensating Control System under Constant Prolonged Disturbances - 215
Cherepanov, A. I. Letter to the Editor - 384
Chernetskii, V. I. An Interpolation Method for Analyzing Automatic Control System Accuracy under Random Stimuli - 333
Chilikin, M. G. and I. I. Petrov. Scientific and Engineering Problems of Automated Electric Drives During the Current Seven-Year Period - 107
Chinaev, P. I. On the Principles of Synthesizing Automatic Systems with Many Controlled Quantities - 529
Ching-leng, Chou, see Berezovets, G. T. - 224

Chugin, Yu. I. Noise Stability of a Frequency Telemetering System for Weak Pulse Noise - 62

Dashevskii, L. N., see Glushkov, V. M. - 617
Dekabrun, I. E., N. P. Kozlov, and I. M. Krassov. Electromagnetic Control-Element Dynamics - 348
Dekabrun, L. L. On Amplifiers of Error Signals of Electrical Automatic Control Systems - 71
Devyatov, B. N. Determination of Dynamic Characteristics of Chemical Engineering Apparatus as Well as the Relevant Criteria of Persistence and Controllability - 544
Diligenskii, S. N. Differentiation of Slowly Varying Signals - 353
Doganovskii, S. A. Automatic Operating Mode Optimization of a Class of Systems with Respect to Statistical Performance Criteria - 779
Dubnikov, E. E., see Gadzhiev, M. Yu. - 936
Dzhelyalov, A. R., see Gadzhiev, M. Yu. - 936

Emel'yanov, S. V. and A. I. Fedotova. Constructing Optimal Second-Order Automatic Control Systems Using Limiting Values of Control Loop Element Gains - 37
Emel'yanov, S. V., see Burovoi, I. A. - 810
Eskin, M. G. Automatic Control of the Turbine Drilling Process by Means of Adaptive Systems - 552

Fedotova, A. I., see Emel'yanov, S. V. - 37
Fel'dbaum, A. A. Statistical Theory of Gradient Systems of Automatic Optimization for Objects with Quadratic Characteristics - 111
Fel'dbaum, A. A. Dual Control Theory I - 874
Fel'dbaum, A. A. Dual Control Theory II - 1033
Fialko, G. M. Use of Electrothermal Isodrome Devices for the Interconnected Control of Production Processes - 568
Fitsner, L. N. Two Types of Optimum-Extremal Systems - 786

Gadzhiev, M. Yu., F. B. Gul'ko, A. R. Dzhelyalov, E. E. Dubnikov, V. D. Kazakov, I. A. Litovchenko, K. B. Norkin, and N. L. Prokhorov. The Seventh Scientific-Technical Conference of Young Scholars of the Institute of Automatics and Remote Control of the Academy of Sciences of the USSR - 936
Gashkovets, I. and N. P. Vasil'eva. Questions of Stability of Operation of Closed (or Lengthy) Schemes Constructed of Certain Types of Logical Elements - 628
Glushkov, V. M., L. N. Dashevskii, and A. I. Nikitin. Use of Electronic Computers for Bessemer Process Automation - 617
Gol'traf, V. I. Hydraulic Servomotor Motion in Automatic Control Systems with a Jet Amplifier - 863
Gordon, M. M. Complex Automation of an Open-Hearth Furnace with Gas Heating - 596
Gorskaya, N. S. Effect of Rate Feedback on Loaded Relay Servomechanism Dynamics - 416
Gul'ko, F. B., see Gadzhiev, M. Yu. - 936
Gusev, L. A., see Aizerman, M. A. - 156
Gusev, L. A., see Aizerman, M. A. - 248
Gusev, L. A., see Aizerman, M. A. - 1126
Gusev, M. I. Determining the Effect of Regular Signal Dynamics in the Statistical Linearization Method - 1093
Gutovskii, I. G. Selection of the Most Suitable Circuit for a Photoelectric Fluxmeter - 989
Guzenko, A. I. Plotting Logarithmic Frequency Responses for Servosystems with Combined Control - 1101

Il'in, V. A. On the Reliability of Schemes for Connecting Dispersed Objects - 364
Il'in, V. A. Remote Control of Several Objects Located at Different Places - 826

Karibskii, V. V. On the Errors of an Interpolating Device for a Given Circular Motion - 220
Kazakevich, V. V. Theory of Ideal Models of an Extremal Controller - 338
Kazakov, I. E. The Dynamics of Self-Adaptive Systems with Extremal Continuous Adjustment of the Compensating Network in the Presence of Random Disturbances - 1040
Kazakov, V. D., see Gadzhiev, M. Yu. - 936
Kazakov, V. D. and O. P. Kuznetsov. List of Foreign Works Published in 1958 on the Theory of Relay Actions and Finite Automata - 941
Kerbnikov, F. I. The Theory of a Magnetic Modulator with Crossed Fields and a Fundamental Frequency Output - 1062
Khokhlov, V. A. Forced Periodic Motion of a Hydraulic Actuating Mechanism with a Positional Load - 654
Kilin, F. M. Transient and Steady-State Processes in an Automatic Range Finder. II. Range Finder with an Operational Amplifier - 146
Kislov, B. D. Reduced Equivalent Amplification Factor of a Nonlinear Element in the Presence of Noise - 804
Kislyakov, V. S. Application of the Krylov-Bogolyubov Method of Constructing Asymptotic Approximations to the Investigation of Systems with Lags - 307
Kislyakov, V. S. Foundations for the Application of the Harmonic Linearization Method to an Investigation of Periodic Oscillations in Systems with Lag - 1051
Klempner, K. S., see Vasil'ev, A. G. - 169

A translation of Avtomatika i Telemekhanika, a publication of the Academy of Sciences of the USSR

Russian Original Dated January, 1959

Vol. 21, No. 1, pp. 1-106

August, 1960

CONTENTS

	PAGE	RUSS. PAGE
Optimal Control of a Nonlinear system. Sun Tszyan'	2	3
The Reduction of Nonlinear Control System Equations to Their Simplest Form. E. N. Rozenvasser	9	15
The Relationship between Linear Systems' Transient Responses and Their Laplace Transforms. N. S. Kochanov	12	20
A Generator of Random Processes from Their Given Spectral Density Matrices. I. Matyash and Ya. Shilkhanek	18	29
On the Stability of Servo-Controlled Systems with Random Stimuli. P. S. Landa	23	36
On Unbiased Estimates of Signals which Depend Nonlinearly on Unknown Parameters. I. A. Boguslavskii	27	42
Synthesizing Control Systems with Monotonically Decreasing Gains by the Root-Locus Method. Ya. I. Rubinovich	31	48
Constructing Optimal Second-Order Automatic Control Systems Using Limiting Values of Control Loop Element Gains. S. V. Emel'yanov and A. I. Fedotova	37	56
On One Particular Case of a Sampled-Data System with Variable Parameters which Change by Jumps. V. I. Teverovskii	42	64
On Methods of Simulating Rational-Fraction Transfer Functions without the Use of Differentiating Elements. B. Ya. Kogan	47	72
On Constructing Bridge Circuits by the Short-Circuit Method. A. Ya. Tolchan	54	82
Noise Stability of a Frequency Telemetering System for Weak Pulse Noise. Yu. I. Chugin	62	93
On Amplifiers of Error Signals of Electrical Automatic Control Systems. L. L. Dekabrun	71	106
Determination of Magnetic Conductance with Geared Stator and Rotor. L. A. Sribner	75	112
The Effect of Nonuniformity of Magnetization on the Static Characteristics of Cores. I. G. D. Kozlov	80	119
Contactless DC Automatic Potentiometer with a Transformer Based on the Hall Effect. V. N. Bogomolov	90	135
Note on the Properties of a Simple Extrapolator with a "Switch." L. Prouza	91	137
Electrets and the Prospects of Their Use in Automation. (Survey). V. A. Andryushchenko	93	139
LETTERS TO THE EDITOR		
A Note to a Paper of Yu. S. Sobolev, "On the Absolute Stability of Certain Controlled Systems," [1]	96	143
CHRONICLE		
Seminar on the Engineering Applications of Mathematical Logic (1958-1959)	98	145
BIBLIOGRAPHY

Automation and Remote Control

A translation of Avtomatika i Telemekhanika, a publication of the Academy of Sciences of the USSR

Russian Original Dated February, 1960

Vol. 21, No. 2 **October, 1960**

CONTENTS

	PAGE	RUSS. PAGE
Scientific and Engineering Problems of Automated Electric Drives During the Current Seven-Year Period. M. G. Chilikin and I. I. Petrov	107	161
Statistical Theory of Gradient Systems of Automatic Optimization for Objects With Quadratic Characteristics. A. A. Fel'dbaum	111	167
A Statistical Method for Determining Dynamic Characteristics of Industrial Objects in the Presence of Noise and for Analyzing Infralow-Frequency Random Processes. Yu. P. Leonov and L. N. Lipatov	119	180
Method of Investigating the Accuracy of Essentially Nonlinear Automatic-Control Systems by Means of Equivalent Transfer Functions. K. A. Pupkov	126	191
Processes of Finite Duration in Pulse-Width Systems. I. V. Pyshkin	141	201
Transient and Steady-State Processes in an Automatic Range Finder. II. Range Finder with an Operational Amplifier. F. M. Kilin	146	209
Determination of the Second-Order Moments of Various Coordinates of Automatic-Control Systems by the use of Electronic Analog Computers. L. A. Tel'ksnis	153	220
Finite Automata. I. M. A. Aizerman, L. A. Gusev, L. I. Rozonoer, I. M. Smirnova, and A. A. Tal'	156	224
A Universal Function Generator based on the Principle of Quadratic Approximations. A. A. Maslov and Yu. G. Purlov	164	237
Reliability Criteria for Automatic Relay Devices with Radioactive Emitters. A. G. Vasil'ev, I. S. Zhitomirskii, and K. S. Klempner	169	245
Estimates, Based on Usage, of the Service Life of Contact Apparatus. A. Abdullaev	175	254
A Numerical-To-Electrical Converter. A. K. Zavolokin	179	260
Automatic Telemetry System for Oil-Well Flow. A. A. Abdullaev and I. A. Nabiev	183	266
BIBLIOGRAPHY	189	271

Automation and Remote Control

A translation of Avtomatika i Telemekhanika, a publication of the Academy of Sciences of the USSR

Russian Original Dated March, 1960

Vol. 21, No. 3, pp. 195-302 November, 1960

CONTENTS

	PAGE	RUSS. PAGE
Estimating the Effect of Quantization by Level on the Processes in Automatic Digital Systems. Ya. Z. Tsypkin	195	281
Determination of the Optimal Impulsive Response Function in the Presence of Internal Noise. P. S. Matveev	198	286
On the Autooscillations of a Dynamic Table Platform. G. P. Miroshnichenko	204	293
Phase-Lock Automatic Frequency Control Operation in the Presence of Noise. V. I. Tikhonov	209	301
Analysis of a Two-Position Compensating Control System under Constant Prolonged Disturbances. A. I. Cherepanov	215	310
On the Errors of an Interpolating Device for a Given Circular Motion. V. V. Karibskii	220	317
Experimental Investigation of Rubber-Fabric Membrane Characteristics. G. T. Berezovets and Chou Ching-leng	224	323
Optimal Frequency Control of Asynchronous Electric Motors. Yu. P. Petrov	232	333
On a Drive Scheme with a Given Equation of Motion. I. A. Boguslavskii	236	340
On the Noise Immunity of the Discrete-Incremental Method of Information Transmission. V. M. Baikovskii	239	344
Finite Automata. II. M. A. Aizerman, L. A. Gusev, L. I. Rozonoér, I. M. Smirnova, and A. A. Tal'	248	359
A Visual-Matrix Method for Minimizing Boolean Functions. A. D. Zakrevskii	255	369
Generalized Proportionality Conditions of Electromagnetic Systems (Geometry of Electromagnetic Systems). A. S. Tulin	259	374
Relay Winding Overheating and Heat Transmission Coefficient as Functions of Ambient Air Temperature. M. I. Vitenberg	266	384
Certain Questions in the Theory of Magnetic Amplifiers Loaded by DC Drives. L. V. Safris	273	393
The Use of Hall Pickups in Magnetic Heads. Yu. A. Vasilevskii	279	402
A Voltage Deflection Pickup Based on Semiconductor Elements. S. V. Kulikov	284	409
Regarding the Theory of Third-Order Linear Systems. Yu. G. Zarenin	290	417
Determination of the Interval of Positiveness of the Real Frequency Characteristic from the Graph of the Transient Response. L. P. Shiniberov	292	420
Processing Experimental Frequency Characteristics. G. I. Monastyrshin	294	422
INFORMATION		
The ÉMU-8 Electronic Analog Computer	301	429

Automation and Remote Control

A translation of Avtomatika i Telemekhanika, a publication of the Academy of Sciences of the USSR

Russian Original Dated April, 1960

Vol. 21, No. 4 **November, 1960**

CONTENTS

PAGE RUSS. PAGE

Analytical Controller Design. A. M. Letov 303 436
Application of the Krylov-Bogolyubov Method of Constructing Asymptotic Approximations to the Investigation of Systems with Lags. V. S. Kislyakov 307 442
On Steady-State Modes in Automatic Control Systems. B. V. Shirokorad 316 456
Determining Pulse System Optimum Weighting Function Which Ensures the Extreme of a Functional. N. I. Andreev 322 465
The Effect of Stationary Random Processes on Automatic Control Systems Containing Essentially Nonlinear Elements. G. I. Pyatnitskii 328 474
An Interpolation Method for Analyzing Automatic Control System Accuracy under Random Stimuli. V. I. Chernetskii 333 481
Theory of Ideal Models of an Extremal Controller. V. V. Kazakevich 338 489
Electromagnetic Control-Element Dynamics. I. E. Dekabrun, N. P. Kozlov, and I. M. Krassov 348 506
Differentiation of Slowly Varying Signals. S. N. Diligenskii 353 513
Choice of Frequency Range for Industrial Pulse-Frequency Telemetry System Devices. A. M. Pshenichnikov 361 525
On the Reliability of Schemes for Connecting Dispersed Objects. V. A. Il'in 364 530
On the Question of Relay-Contact Device Reliability. K. P. Kurdyukov 366 533
Rectified Voltage Regulator. O. G. Malkina 372 542
Stabilizing the Temperature of Heated Thermistors. G. K. Nechaev 376 548
Use of Heater Resistances for Current and Voltage Stabilization. V. S. Popov 381 555
Letter to the Editor. A. I. Cherepanov 384 558

[This issue of AVTOMATIKA I TELEMEKHANIKA contained an article commemorating the 90th anniversary of the birth of V. I. Lenin. Since that article did not discuss either the present state of Soviet research in automation or its historic development, and as a matter of fact, contained no information of scientific interest, it was omitted from the translation.]

Russian Original Dated June, 1960

Vol. 21, No. 6 December, 1960

CONTENTS

PAGE RUSS. PAGE

The Approaching First Congress of the International Federation of Automatic Control 455 657
A Message from the President of the IFAC. 457 659
Analytical Controller Design. III . A. M. Letov 458 661
Investigation of Probability Stability Using Example of Automatic Control of Aircraft Course. V. S. Novoselov 462 666
The Problem of Shaping Filters and Optimal Linear Systems. Yu. P. Leonov 467 674
The Optimal Control of Systems with Distributed Parameters. A. G. Butkovskii and A. Ya. Lerner . 472 682
Theory of Certain Indirect Control Systems with Several Essential Nonlinearities. R. A. Nelepin . . 478 692
On the Theory of Oscillations of Quasi-Linear Systems with Constant Lags. S. N. Shimanov 490 706
Transient Responses in Control Systems with Lags. Z. Sh. Blokh 493 710
Lyapunov Functions for Relay Control Systems. Yu. I. Alimov 500 720
The Application of the Method of Small Parameters in the Investigation of Systems of Automatic Control with Delay. Yu. A. Ryabov 507 729
The Application of Lyapunov's Method to Problems in the Stability of Systems with Delay. B. S. Razumikhin 515 740
Some Questions Concerning Coordinated Control Systems. E. M. Syuzyumova 521 749
On the Principles of Synthesizing Automatic Systems with Many Controlled Quantities. P. I. Chinaev 529 761
A Method for Obtaining Transfer Functions of Automatic Control Systems Operating on Alternating Current. N. P. Vlasov 538 772
Determination of Dynamic Characteristics of Chemical Engineering Apparatus as Well as the Relevant Criteria of Persistence and Controllability. B. N. Devyatov 544 779
Automatic Control of the Turbine Drilling Process by Means of Adaptive Systems. M. G. Éskin . . . 552 791
Adaptive Automatic Control System for Obtaining Aluminum by the Electrolytic Process Using a Computing Device. É. P. Sarkisyan, M. M. Agababyan, and P. S. Saakyan 563 806
Use of Electrothermal Isodrome Devices for the Interconnected Control of Production Processes. G. M. Fialko 568 812
Control of Chemical Production Processes by Indicators of Product Quality. V. V. Aronovich, I. A. Anisimov, M. I. Lyudmirskii, and R. S. Patushinskaya 575 821
Development of Apparatus for the Automatic Control of Boiler Aggregates. V. D. Mironov 584 833
Methods of Increasing Reliability and Response Speed of Steam Turbine Control. V. N. Veller . . . 589 840
Complex Automation of an Open-Hearth Furnace with Gas Heating. M. M. Gordon 596 849
A Paper-Making Machine as an Object of Control and Some Ways Toward its Complex Automation. A. S. Shamson 602 857

CONTENTS (continued)

	PAGE	RUSS. PAGE
Automation and Centralization of a Copper Mine. V. V. Kryuchkov	610	867
Use of Electronic Computers for Bessemer Process Automation. V. M. Glushkov, L. N. Dashevskii, and A. I. Nikitin	617	877
New Method and Universal Measuring Device for Active Inspection on Metal-Cutting Machines. G. L. Perfil'ev	622	884
Questions of Stability of Operation of Closed (or Lengthy) Schemes Constructed of Certain Types of Logical Elements. I. Gashkovets and N. P. Vasil'eva	628	892
On One Method of Constructing Analog-to-Digital Transformers. A. K. Zavolokin and G. I. Kurakhtanov	635	902
New Electromagnetic Executive Organs for Automatic Control Systems. A. M. Bamdas, V. A. Kulinich, V. A. Somov, V. A. Suchkov, S. V. Shapiro, A. O. Shmidt, and Ku Shên-ku	639	907
Design of Transducers with Force Compensation. S. M. Zasedatelev and V. A. Rukhadze	646	918
Forced Periodic Motion of a Hydraulic Actuating Mechanism with a Positional Load. V. A. Khokhlov	654	929

CONTENTS

PAGE RUSS. PAGE

Estimating the Mean Square Deviation from a Given Trajectory. E. A. Barbashin. 661 941
Investigation of the Periodic Behavior of Relay Systems with Extremum Regulation. I. S. Morosanov. 668 951
Continuous Extremum Control Systems in the Presence of Random Noise. A. A. Pervozvanskii. 673 958
Investigation of a Servosystem with an Electromagnetic Induction Clutch Which Operates with Low Null Currents. P. F. Klubnikin. 678 964
The Maximum Dynamic Characteristic Values of Servomechanism Components of Servosystems. I. G. A. Nadzhafova. 685 973
Calculation of Static Characteristics of "Nozzle-Baffle" Elements. E. A. Andreeva. 691 982
Dynamic Characteristics of a "Jet Amplifier – Servomechanism" System. B. D. Kosharskii 701 997
Determination of Maximum Error of a Binary Multiplier. Yang Hsi-zeng. 709 1007
Exponential Converters with a Logarithmic Transformation Law. A. I. Novikov. 714 1015
Transformer Distance Transmission by Means of Two Phase Contactless Induction Potentiometers. Yu. M. Pul'er. 722 1026
Contactless Semiconductor Switching Elements. E. V. Miller. 728 1035
Calculation and Construction of Induction Clutches. M. S. Mirenskii. 736 1046
Effect of Magnetization Irregularity on the Static Characteristics of Cores. II. G. D. Kozlov 744 1057
A Transistorized Magnetic Amplifier. R. A. Lipman and M. V. Ol'shvang. 755 1073
A New Method of Spectral Measurements by Means of Photosensitive Layers. W. Lueck. . 762 1084

LETTERS TO THE EDITOR

An Error in the Article "Effect of Fluctuations on the Simplest Parametric Systems" by V. I. Tikhonov. I. A. Bol'shakov 765 1088

DISCUSSION

On the Book "Elements of Structural Synthesis of Relay Control Circuits" by V. N. Roginskii. V. I. Shestakov 767 1090
Reply to V. I. Shestakov's Critical Review of the Book "Elements of Structural Synthesis of Relay Control Circuits" by V. N. Roginskii. V. N. Roginskii. 771 1094

Erratum. 775 1098

OPTIMAL CONTROL OF A NONLINEAR SYSTEM

Sun Tszyan'

(Moscow)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 1, pp. 3-14, January, 1960)
Original article submitted May 26, 1959

The paper considers transient responses, optimal as concerns speed of response, in control systems containing a rotary amplifier and a dc motor. The motor's excitation voltage is considered as a second independent control parameter. Methods are suggested for the synthesis of an optimal controlling device. An example is given of the synthesis of simplified second- and third-order systems.

Electrical control and regulation systems containing rotary amplifiers and dc motors have found wide application. The various systems in use today are ordinarily constructed on the basis of the linear theory. Control of the motor is effected on the side of the rotary generator's control winding, wherein the controlling signals are proportional to a combination of the error (the discrepancy between input and output) and its derivatives. The motor's excitation voltage is ordinarily fixed. These systems can also contain other connections, introduced for the purpose of compounding or compensation. In all these systems, the signal applied to the rotary generator's control winding is the sole control parameter. However, a second possible control parameter – the motor's excitation voltage – exists in these systems. With a variable motor excitation voltage, the system can manifest better quality indications, for example, higher speeds of response.

A system with two control parameters is nonlinear, as will become obvious in the sequel. The analysis and synthesis of such optimal systems are very difficult variational problems. Today, the problem of synthesizing such optimal systems can be solved on the basis of the work of L. S. Pontryagin, V. G. Boltyanskii, and R. V. Gamkrelidze [1-3]. In these works, the variational maximum principle is proven to be a necessary condition for optimality of control. However, in many cases, the maximum principle, in conjunction with other information about a system, permits one to solve completely the problem of synthesizing an optimal system.

1. Equation of System Motion

We consider the electrical control system containing a rotary amplifier whose block schematic is shown on Fig. 1. With the nomenclature used on this figure, we can write the following system of equations:

$$\begin{aligned} &\frac{dX_1}{dt} = \zeta\Omega, && J\frac{d\Omega}{dt} = k_3 I_a I_e + M_{st}, \\ &T_1\frac{dI_c}{dt} + I_c = k_1 U_1, && T_2\frac{dI_e}{dt} + I_e = k_2 U_2, \\ &T_3\frac{dE_g}{dt} + E_g = k_4 I_c, && E_g - c\Omega I_e = I_a R_a. \end{aligned} \tag{1}$$

Here, ζ, k_1, k_2, k_3, and k_4 are constant gains, T_1, T_2, and T_3 are the time constants of the rotary amplifier's control winding, in the motor's excitation winding and in the transverse circuit of the rotary amplifier, respectively. In our further transformations of system of equations (1) we shall made the following assumptions: the load's static torque is small in comparison with the load's inertia; time constant T_1 of the rotary amplifier's control winding is small in comparison with T_3. System (1) will then, after some transformation and after conversion to dimensionless units, have the following form:

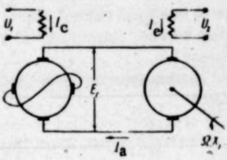

Fig. 1.

$$\begin{aligned} &\frac{dx}{dt} = \zeta_0\omega, && \frac{d\omega}{dt} = \frac{\eta}{1-\mu} i_e e_g - \omega i_e^2, \\ &\frac{de_g}{dt} = -\beta_1 e_g + \beta_1 u_1, && \frac{di_e}{dt} = -\beta_2 i_e + \beta_2 u_2. \end{aligned} \tag{2}$$

In these equations,

$$x = \frac{X_1}{X_{1\max}}, \quad e_g = \frac{E_g}{E_{g\max}}, \quad i_e = \frac{I_e}{I_{e\max}},$$

$$i_a = \frac{I_a}{I_{a\,nom}}, \quad \omega = \frac{\Omega}{\Omega_{nom}}, \quad u_1 = \frac{U_1}{U_{1\max}},$$

$$u_2 = \frac{U_2}{U_{2\max}}, \quad \beta_1 = \frac{T_{em}}{T_3}, \quad \beta_2 = \frac{T_{em}}{T_2},$$

$$T_{em} = \frac{JR_a}{k_3 C I_{e\max}^2}, \quad \eta = \frac{E_{g\max}}{E_{g\,nom}} > 1,$$

$$\mu = \frac{I_{a\,nom} R_a}{E_{g\,nom}} < 1.$$

The time t in system (2) of equations is also dimensionless; as the basic quantity we take the electromechanical time constant T_{em}. For convenience, we retain the previous notation for time.

In actual systems there are four essential limitations: limitations on the control and excitation voltages u_1 and u_2, limitations on armature current, and limitations on the motor's rotational speed. The last two are limitations on coordinates of the system. The analysis and synthesis of optimal systems when limitations on coordinates are taken into account are complicated mathematical problems requiring special study. However, the coordinate limitations in practice are quite simple. In many cases, quite simple considerations permit one to find the optimal processes with coordinate limitations taken into account [5]. In this paper we shall only consider limitations on the controlling parameters, as the case most studied from the point of view of the variational calculus. In relative units, the limitations imposed on u_1 and u_2 are expressed by the following inequalities:

$$|u_1| \leqslant 1, \quad 0 < \lambda \leqslant u_2 \leqslant 1. \tag{3}$$

The lower limit for the motor excitation voltage λ is defined by the condition that the motor not enter a separation mode of operation for small static loads.

We shall investigate the optimal transient responses in the processing of original errors. In this case, the magnitude of an original error does not effect the structure of the optimal controlling portion. When the input stimulus varies linearly in time, the problem is solved analogously, but a more complicated structure (design) is obtained since, in this case, the velocity at which the input stimulus varies will enter into the equation of motion. Let the input stimulus be $g(t) = A_0$, where A_0 is an arbitrary constant. We introduce new coordinates, related to the old coordinates in the following way:

$$x_1 = A_0 - x, \quad x_2 = \frac{dx_1}{dt} = -\zeta_0\omega,$$
$$x_3 = -e_g, \quad x_4 = i_e. \tag{4}$$

By substituting the new coordinates in Eqs. (2), we get the definitive system of equations:

$$\frac{dx_1}{dt} = x_2, \quad \frac{dx_2}{dt} = \alpha x_3 x_4 - x_2 x_4^2,$$
$$\frac{dx_3}{dt} = -\beta_1 x_3 - \beta_1 u_1, \quad \frac{dx_4}{dt} = -\beta_2 x_4 + \beta_2 u_2. \tag{5}$$

Expressions (3) for the limitations on u_1 and u_2 also hold for equations in the new coordinates.

2. Optimal Processes and Optimal Equations

Let the initial state of the system be given, i.e., at the initial moment of time let the four coordinates of system of equations (5) be given. It is required to choose controls $u_1(t)$ and $u_2(t)$ which will take the system to the null state in minimal time. We first consider the phase space X of system (5). Each point of this space, called a representative point, defines one state of the system. The system's null state is characterized by the point with coordinates $\{0, 0, 0, \gamma\}$, where $\gamma (0 < \lambda < \gamma < 1)$ is some fixed number. The system's motion will be considered as a trajectory of the representative point $\{x_1, x_2, x_3, x_4\}$ in phase space X. The general point in X is denoted by the letter x.

Limitations (3) form a closed rectangle U on the control plane, whose coordinates axes are u_1 and u_2. The control vector with coordinates u_1 and u_2 we shall denote by the letter u. A vector function u(t) is called admissible if all its values lie in U. In the sequel we shall assume that u(t) is an admissible piecewise-smooth function with no more than a finite number of first-order discontinuities. Each such fixed control uniquely defines one continuous trajectory which passes through the given initial point in phase space.

With this notation, the system of equations in (5) can be replaced by one vector equation

$$\frac{dx}{dt} = f(x) + Bu. \tag{6}$$

Here, B is the rectangular matrix

$$B = \begin{pmatrix} 0 & 0 \\ 0 & 0 \\ -\beta_1 & 0 \\ 0 & \beta_2 \end{pmatrix}.$$

The optimal control problem can be formulated as follows: In phase space X the point x(0) is given, and it is required to find an admissible control $u(t) = \{u_1(t), u_2(t)\}$ which will carry point x(0) over into null point $\xi_0 = \{0, 0, 0, \gamma\}$ in minimal time.

In accordance with the theorems of the maximum principle [3], we set up the system of differential equations which is adjoint to system (5) with the new variables $\psi = \{\psi_1, \psi_2, \psi_3, \psi_4\}$:

$$\frac{d\psi_1}{dt} = 0, \quad \frac{d\psi_2}{dt} = -\psi_1 + x_4^2\psi_2,$$
$$\frac{d\psi_3}{dt} = -\alpha x_4 \psi_2 + \beta_1 \psi_3, \tag{7}$$
$$\frac{d\psi_4}{dt} = (2x_2x_4 - \alpha x_3)\psi_2 + \beta_2\psi_4.$$

Here, ψ is a covariant vector whose components are computed by the usual formula

$$\frac{d\psi_i}{dt} = -\sum_{\alpha=1}^{n} \frac{\partial f_\alpha}{\partial x_i} \psi\alpha \quad (i = 1, 2, 3, 4).$$

We now set up the Hamiltonian function, which is here the scalar product of the vector ψ by the velocity vector dx/dt. We denote by H the Hamiltonian function:

$$H(x, \psi, u) = \left(\psi, \frac{dx}{dt}\right)^{*} = \psi, f(x) + Bu) =$$
$$= (\psi, f(x)) + (\psi, Bu). \tag{8}$$

---

[*] We shall use parentheses to denote the scalar product of two vectors.

With this notation, we formulate the necessary condition for the optimality of control u(t) in the following way [3]. Let u(t) be an optimal control and x(t) the corresponding optimal trajectory. There then exists a nonzero continuous vector function $\psi(t)$ such that

$$H(\psi(0),\ x(0),\ u(0)) \geqslant 0,$$

the functions $\psi(t)$, x(t), and u(t) satisfy systems (5) and (7) of equations, so that along the trajectory, at any moment of time, the Hamiltonian function is a maximum with respect to u, i.e.,

$$H(\psi(x),\ x(t),\ u(t)) = \sup_{u\in U}(\psi(t),\ f(t)+Bu)$$

and

$$H(\psi(t),\ x(t),\ u(t)) = \text{const} \geqslant 0. \qquad (9)$$

We note that the quantity in the first parentheses in the rightmost member of (8) does not depend on u. Consequently, the expression in the second parentheses attains a maximum simultaneously with Hamiltonian function H. The necessary condition for optimality leads to the condition

$$(\psi(t),\ Bu(t)) = \sup_{u\in U}(\psi(t),\ Bu). \qquad (10)$$

We now write (10) in expanded form:

$$(\psi,\ Bu) = -\psi_3(t)\beta_1 u_1 + \psi_4(t)\beta_2 u_2.$$

If an optimal control exists, it is easily seen that it is defined by the following relationships:

$$u_1(t) = -\operatorname{sign}\psi_3(t),$$
$$u_2(t) = \begin{cases} 1 \text{ for } & \psi_4(t) > 0, \\ \lambda \text{ for } & \psi_4(t) < 0. \end{cases} \qquad (11)$$

This means that if the optimal control exists, it consists of a certain number of intervals, in each of which u_1 and u_2 assume one of their limiting values.

Controls u_1 and u_2 change their values by a jump each time $\psi_3(t)$ and $\psi_4(t)$ pass through zero. This is the state of affairs in all nonlinear systems where the controlling parameters enter linearly and if the corresponding components of the covariant vector do not vanish identically in any finite interval of time.

We now give the solution of system (7) of equations for the vector $\psi(t)$

$$\psi_1(t) = \psi_{10} = \text{const},$$

$$\psi_2(t) = e^{\int_0^t x_4^2(\tau)\,d\tau}\left[\psi_{20} - \psi_{10}\int_0^t e^{-\int_0^\tau x_4^2(s)\,ds}\,d\tau\right],$$

$$\psi_3(t) = e^{\beta_1 t}\left[\psi_{30} - \alpha\int_0^t x_4(\tau)\,\psi_2(\tau)\,e^{-\beta_1\tau}\,d\tau\right],$$

$$\psi_4(t) = e^{\beta_2\tau}\left[\psi_{40} + 2\int_0^t (x_2(\tau)\,x_4(\tau) - \alpha x_3(\tau))e^{-\beta_2\tau}\,d\tau\right]. \qquad (12)$$

It is clear from (12) that $\psi_3(t)$ goes through zero no more than once. Consequently, if $x_4(t)$ does not change sign, $\psi_3(t)$ goes through zero not more than twice and, in the general case, $u_1(t)$ consists of three intervals.

These consequences are useful for the solution of the synthesis problem. To be assured of the possibility of constructing an optimal system, it is nice to know the following theorem on the existence of optimal controls: For each point of the phase space given by (5), there exists an optimal control which takes this point to the point $\xi_0 = \{0,\ 0,\ 0,\ \gamma\}$ in minimal time.

The proof of this theorem for the system of (5) can easily be carried through by modifying the well-known scheme of the proof of the similar theorem for linear systems which has been given by R. V. Gamkrelidze [2]. This may be done because the nonlinearity in (5) enters only into the coefficients of the corresponding equations.†

Concrete analysis shows that one can expect the optimal control in our case to be unique.‡ This means that, for a given point of phase space, there exists a unique control which takes this point over into point ξ_0 in minimal time. We shall make use in the sequel of the existence and uniqueness theorems for optimal controls.

3. Some Properties of the Field of Optimal Trajectories

In this section we give a brief presentation of some of the properties of optimal trajectories. As was stated earlier, we can assume existence and uniqueness of the optimal controls for the system being studied, i.e., for any point of phase space there exists a unique optimal trajectory joining the given point to the null point ξ_0. To each point of phase space there corresponds just one duration of the optimal transient response. The time T is a single-valued function of the phase-space points. We now consider the set S_T of points with the same duration of the optimal transient response. All these points lie on some hypersurface with equation

$$T(x_1,\ x_2,\ x_3,\ x_4) = C. \qquad (13)$$

The entire space is filled by the optimal trajectories. In the direction of point ξ_0 these trajectories can only converge, not diverge. On each optimal trajectory from a remote point there lies only one point which is in the set S_T.

---

† The theorem on the existence of optimal controls is proved in [7] for nonlinear nonstationary systems with linear controls and for certain additional limitations.

‡ What we have in mind here are the concrete constructions of optimal processes on planes and in three-dimensional space. So far as the author knows, the literature contains no proof of the existence theorem for an arbitrary nonlinear system.

It may be proved** that the point set S_T is a closed convex hypersurface. Moreover, this hypersurface is everywhere continuous and almost everywhere differentiable, i.e., except for a set of points of "area" (measure) zero, there is a tangent plane at every point of S_T. Following A. Ya. Lerner [5], we call S_T an isochrone. All points inside S_T have a duration of the transient response less than T. An isochrone continuously widens with increasing time. As $T \to \infty$, S_T fills the entire finite phase space.

The function $T(x_1, x_2, x_3, x_4)$ forms a scalar potential field in phase space. Equation (13) defines an equipotential hypersurface. Since hypersurface S_T is differentiable almost everywhere, field T generates a vector gradient field, which is the field of external normals to hypersurface (13). One may easily remark the relationship between the field of external normals and the covariant vectors ψ, which is noted in L. S. Pontryagin's maximum principle. It turns out that the vector ψ forms a vector field in phase space X, with the exception of the set of points of the space where the hypersurface S_T is not differentiable. This can be written in the form of a vector equation

$$\operatorname{grad} T(x_1, x_2, x_3, x_4) = \sigma(x_1, x_2, x_3, x_4)\,\psi(x_1, x_2, x_3, x_4), \tag{14}$$

where σ is some function of the points of space X.

Equation (14) gives rise to several partial differential equations which, in some of the simplest cases, can be integrated, giving the function T in explicit form. It may also be shown that there is a continuous dependence of the optimal control on the original position of the point,†† i.e., points which are close in phase space have "close" optimal controls. This fact was established for linear systems by F. M. Kirillova in [6].

4. The Synthesis of an Optimal Controlling Device

As is well known, the task of synthesis reduces to the finding of the optimal control in the form of a function of the points of phase space $u_i(x_1, x_2, x_3, x_4)$ $(i = 1, 2)$ or, what amounts to the same thing, to finding the switching hypersurface for the controls u_1 and u_2 since, according to expression (11), the optimal control has the form of a relay function. If the optimal control functions cannot be found exactly by analytic means, then the switching hypersurface can be found approximately. Optimal trajectories always consist of a finite number of segments of curves of four families, corresponding to the controls $u_1 = \pm 1$ and $u_2 = 1, \lambda$. With this, the entire space is divided into regions, in each of which u_1 and u_2 have definite values. The boundaries of these regions are also the switching hypersurface. Two methods can be proposed for finding the switching hypersurfaces approximately. In the first method, one sets up, on an analog computer, a model whose time runs in the reverse direction of system (5). Then, all the optimal trajectories leaving point ξ_0 will have the reverse direction. We also construct the conjugate model in accordance with system of equations (7), but with time t replaced by −t. We then connect these two models as in Fig. 2. Since each initial condition $\psi(0)$ defines one optimal trajectory, we can, by giving various values of $\psi(0)$, obtain a set of optimal trajectories. With this, the pulse generator sends a command at the moments of switching of u_1 and u_2 which causes the recorder to write the values $\{x_1, x_2, x_3, x_4\}$. Thanks to the linearity of Eqs. (7) in ψ_i $(i = 1, 2, 3, 4)$, $\psi(0)$ can be chosen so as to satisfy the condition:

$$\psi_{10}^2 + \psi_{20}^2 + \psi_{30}^2 + \psi_{40}^2 = 1.$$

For each trajectory we record the times of switching and the corresponding system coordinates at the moment of switching. By continuing this for a sufficient number of times, we obtain an approximate representation of the switching hypersurface in the form of a table. Using the tabular data, one can carry out the synthesis of the optimal controlling device by the method cited in [9].

If it is impossible to measure the system's parameters with sufficient accuracy, it is then advantageous to use another method for the determination of the optimal control function, wherein one uses the relationship between the gradient field of the duration of the optimal transient response and the vector field of the function $\psi(x_1, x_2, x_3, x_4)$. The isochrones for various durations of the optimal transient response can be constructed approximately by means of a machine of the type of the automatic optimizer which was developed under the direction of A. A. Fel'dbaum at the Institute of Automation and Remote Control of the Academy of Sciences, USSR. The algorithm for solving this problem on the automatic

---

** The proof of the following assertion, which we omit here, depends essentially on the specific features of nonlinear system (5), and is therefore of a concrete, nongeneral character. It is different from the well-known proof for linear systems.

†† A continuous dependence here has the mathematical meaning of continuity of the norm. If $u^1(t)$ and $u^k(t)$ are two optimal controls which take points ξ^1 and ξ^k to the null point then, as ξ^k tends to ξ^1, the integral $\int_0^T [u^1(t)-u^k(t)]^2 dt$ tends to zero, where $T = \max(T_1, T_k)$.

optimizer was developed by R. L. Stakhovskii. By constructing the isochrone hypersurfaces we can, using Eqs. (14), determine the distribution of the signs of the functions $\psi_3(x_1, x_2, x_3, x_4)$ and $\psi_4(x_1, x_2, x_3, x_4)$, and thereby find the switching hypersurface.

For certain limiting cases, when the order of Eqs. (5) can be lowered, the synthesis problem can also be solved analytically. We give below the results of synthesis for two limiting cases: for the case when the generator's time constant and the motor's excitation winding time constant are negligibly small in comparison with the electromechanical constant, and for the case when only the second of these can be neglected. In the first case, we can substitute $\beta_1 = \infty$ and $\beta_2 = \infty$ in system of equations (5). The equations will then have the form:

$$\frac{dx_1}{dt} = x_2, \qquad \frac{dx_2}{dt} = -u_2^2 x_2 - \alpha u_1 u_2. \quad (15)$$

As before, the limitations imposed on the system have the form given in (3). For this limiting case, the maximum principle turns out to be sufficient for the determination of all optimal trajectories and the switching lines of controls u_1 and u_2.

We now set up the conjugate (adjoint) system of differential equations for the functions $\psi_1(t)$ and $\psi_2(t)$:

$$\frac{d\varphi_1}{dt} = 0, \qquad \frac{d\varphi_2}{dt} = -\varphi_1 + u_2^2\varphi_2. \quad (16)$$

We then set up the Hamiltonian function:

$$H(x, \varphi, u) = \varphi_1 x_2 + \varphi_2(-u_2^2 x_2 - \alpha u_1 u_2). \quad (17)$$

For the essentially nonlinear system (15), it is not known, in general, if there is an optimal control for any arbitrary initial conditions and, if there is one, whether or not it is unique. But, since system of equations (15) is a limiting case of system (5), one may expect that system (15) also possesses these properties. The results of the synthesis substantiate this assumption.

We now write the solution of system of equations (16):

$$\varphi_1(t) = \varphi_{10} = \text{const},$$

$$\varphi_2(t) = e^{\int\limits_0^t u_2^2(\tau)\,d\tau}\left[\varphi_{20} - \int\limits_0^t \varphi_{10} e^{-\int\limits_0^\tau u_2^2(s)\,ds}\,d\tau\right]. \quad (18)$$

We notice that $\psi_2(t)$ cannot change sign more than once. We now turn our attention to the Hamiltonian function (17). Within the parentheses there, α is a positive number and u_2 is always positive. Then, in accordance with the requirement of the maximum principle,

$$u_1 = -\operatorname{sign}\varphi_2(t). \quad (19)$$

To elicit the optimal law for control $u_2(t)$, we rewrite the Hamiltonian function in another form:

$$H(x, \varphi, u) = \varphi_1 x_2 + \varphi_2\left[-x_2\left(u_2 + \frac{\alpha u_1}{2x_2}\right)^2 + \frac{\alpha^2 u_1^2}{4x_2}\right]. \quad (20)$$

Let us consider separately the two possible cases.

a) $\psi_2(t) < 0$. In this case, $u_1 = 1$. For $x_2 > 0$, u_2 must assume its greatest value, equal to unity. On the lower half-plane, where $x_2 < 0$, the optimal control u_2 is defined as follows:

$$u_2 = \begin{cases} 1, & \text{if } \left|\frac{\alpha}{2x_2}\right| \geqslant 1, \\ \frac{\alpha}{2x_2}, & \text{if } \lambda \leqslant \left|\frac{\alpha}{2x_2}\right| \leqslant 1, \\ \lambda, & \text{if } \left|\frac{\alpha}{2x_2}\right| \leqslant \lambda. \end{cases} \quad (21)$$

b) $\psi_2(t) > 0$, $u_1 = -1$. On the upper half-plane, where $u_2 > 0$, the optimal control u_2 is defined by the expression

$$u_2 = \begin{cases} 1 & \text{for } \frac{\alpha}{2x_2} \geqslant 1, \\ \frac{\alpha}{2x_2} & \text{for } \lambda \leqslant \frac{\alpha}{2x_2} \leqslant 1, \\ \lambda & \text{for } \frac{\alpha}{2x_2} \leqslant 1. \end{cases}$$

On the lower half-plane, $u_2 = 1$.

It is thus clear that in the general case u_1 consists of two intervals, in each of which u_1 assumes the value 1 or −1. Control u_2, which is the motor excitation, consists of four intervals. In one of these intervals, u_2 continuously sweeps through the segment $[\lambda, 1]$. On the succeeding segment u_2 can only assume its maximum value, 1, since otherwise the function H would not be a maximum at the endpoint, where $x_1 = x_2 = 0$. It may be noticed that, at the origin of coordinates, only two curves, from the different half-planes, pass. These two curves comprise the final segments of all optimal trajectories. We denote them by L_1 and L_1' (Fig. 3). On line L_1 control $u_1 = -1$ and on line L_1', control $u_1 = 1$. Analogous relationships lead us to the conclusion that ψ_2 changes sign on lines L_1 and L_1'. Generalizing what has been said, we conclude that the phase plane is divided into six regions (Fig. 3). Lines L_1 and L_1' divide the phase plane into two half-planes; in the left half-plane $u_1 = -1$ and, in the right one, $u_1 = 1$. Moreover, there is a strip in each half-plane, bounded by the lines Γ_1 and Γ_2 in the left half-plane and the lines Γ_1' and Γ_2' in the right one. If the initial point x(0) is in the third quadrant then the optimal trajectory rises upward with controls $u_1 = -1$ and $u_2 = 1$. Meeting line Γ_1, u_2 begins to vary in accordance with the law $u_2 = \alpha / 2x_2$. On leaving this strip, u_2 takes its minimum value, λ; when the trajectory meets line L_1', u_1 changes sign and u_2 jumps to its maximum value

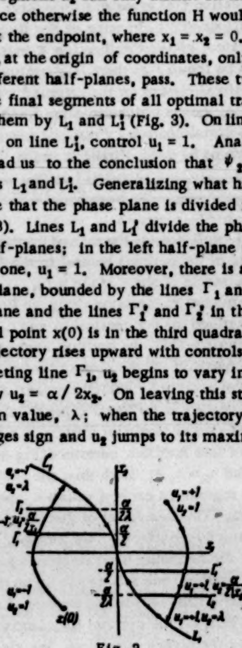

Fig. 3

after which the trajectory follows line L_1' to the origin of coordinates. The transient response and the laws of change of the controls with time are shown on Fig. 4.

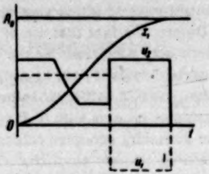

Fig. 4

We now consider the other case, when $\beta_2 = T_{em}/2 = \infty$, and β_1 is finite. In this case, we have the following system of differential equations

$$\frac{dx_1}{dt} = x_2, \quad \frac{dx_2}{dt} = \alpha x_3 u_2 - x_2 u_2^2,$$
$$\frac{dx_3}{dt} = -\beta_1 x_3 - \beta_1 u_1. \qquad (22)$$

The adjoint system of equations for the vector ψ will be

$$\frac{d\phi_1}{dt} = 0, \quad \frac{d\phi_2}{dt} = -\phi_1 + u_2^2\phi_2,$$
$$\frac{d\phi_3}{dt} = 0 - \alpha u_2\phi_2 + \beta_1\phi_3. \qquad (23)$$

The solution of this system is:

$$\phi_1(t) = \phi_{10} = \text{const},$$

$$\phi_2(t) = \left[-\phi_{10}\int_0^t e^{-\int_0^t u_2^2(s)\,ds}\,d\tau + \psi_{20}\right] e^{\int_0^t u_2^2(s)\,ds},$$

$$\psi_3(t) = \left[-\alpha\int_0^t u_2(\tau)\,\phi_2(\tau)\,e^{-\beta_1\tau}d\tau + \psi_{30}\right] e^{\beta_1 t}. \qquad (24)$$

We can conclude from expressions (24) that, by virtue of the constancy of $\psi_1(t)$ along the given trajectory, $\psi_2(t)$ cannot change its sign more than once. Since $u_2(t)$ is assumed to be always positive, then $\psi_3(t)$, in the general case, does not change sign more than twice. The Hamiltonian function is

$$H(x, \psi, u) = \qquad (25)$$
$$= \phi_1 x_2 + \phi_2(\alpha x_3 u_2 - x_2 u_2^2) + \phi_3(-\beta_1 x_3 - \beta_1 u_1).$$

For the Hamiltonian function to be maximal with respect to u_1, it is necessary that u_1 vary in accordance with the law

$$u_1 = -\operatorname{sign}\phi_3.$$

Thus, in general (in accordance with the remark made earlier), optimal control $u_1(t)$ consists of three intervals, in each of which u_1 assumes one of its boundary values. To determine the character of control $u_2(t)$, we rewrite the Hamiltonian function (25) in the following equivalent form:

$$H(x, \phi, u) = \phi_1 x_2 +$$
$$+ \phi_2\left[-x_2\left(u_2 - \frac{\alpha x_3}{2x_2}\right)^2 + \left(\frac{\alpha x_3}{2x_2}\right)^2 x_2\right] + \qquad (25')$$
$$+ \phi_3(-\beta_1 x_3 - \beta_1 u_1).$$

We consider separately the following cases.

1) $x_2 > 0$, $x_3 > 0$. When $\psi_2 < 0$, the Hamiltonian function H, according to (25'), attains a maximum for

$$u_2 = \begin{cases} 1, & \text{if } \dfrac{\alpha x_3}{2x_2} < \dfrac{1+\lambda}{2}, \\ \lambda, & \text{if } \dfrac{\alpha x_3}{2x_2} > \dfrac{1+\lambda}{2}. \end{cases}$$

When $\psi_2 > 0$, H is a maximum for

$$u_2 = \begin{cases} 1, & \text{if } \dfrac{\alpha x_3}{2x_2} \geqslant 1, \\ \dfrac{\alpha x_3}{2x_2}, & \text{if } \lambda \leqslant \dfrac{\alpha x_3}{2x_2} \leqslant 1, \\ \lambda, & \text{if } \dfrac{\alpha x_3}{2x_2} \leqslant \lambda. \end{cases}$$

2) $x_3 > 0$, $x_2 < 0$. In this case, the conditions for a maximum for H will be: $u_2 = \lambda$ for $\psi_2 < 0$ and $u_2 = 1$ for $\psi_2 > 0$.

3) $x_3 < 0$, $x_2 < 0$. The corresponding conditions are written as follows:

for $\psi_2 > 0$,

$$u_2 = \begin{cases} 1, & \text{if } \dfrac{\alpha x_3}{2x_2} < \dfrac{1+\lambda}{2}, \\ \lambda, & \text{if } \dfrac{\alpha x_3}{2x_2} > \dfrac{1+\lambda}{2}; \end{cases}$$

for $\psi_2 < 0$,

$$u_2 = \begin{cases} 1, & \text{if } \dfrac{\alpha x_3}{2x_2} \geqslant 1, \\ \dfrac{\alpha x_3}{2x_2}, & \text{if } \lambda \leqslant \dfrac{\alpha x_3}{2x_2} \leqslant 1, \\ \lambda, & \text{if } \dfrac{\alpha x_3}{2x_2} \leqslant \lambda; \end{cases}$$

4) $x_3 < 0$, $x_2 > 0$. In this region, H attains a maximum if

$$u_2 = \begin{cases} 1 & \text{for } \phi_2 < 0, \\ \lambda & \text{for } \phi_2 > 0. \end{cases}$$

On the basis of the discussion given, we can, in general, construct all the optimal trajectories in phase space. However, this necessitates a great deal of computational work. The structure of the switching surfaces for both controlling parameters is quite complicated.

The construction of these surfaces is an independent problem for investigation. Here, we speak only of certain features of the optimal transient responses in the system described by Eqs. (22).

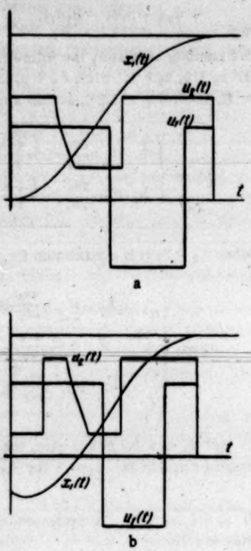

Fig. 5

Figure 5a gives the optimal transient response for zero initial conditions. Here, control $u_1(t)$, as it must, consists of three intervals. Control $u_2(t)$ has the same form as the corresponding control in the previous case. The difference amounts only to this: that the moment when u_2 switches from a minimum to a maximum does not coincide with the moment when u_1 is switched, but occurs later.

A completely different picture is obtained if the initial conditions are nonzero. As shown in Fig. 5b, for certain initial conditions, u_2 varies by a significantly more complicated law than in the case of the process with zero initial conditions.

CONCLUSIONS

The maximum principle of L. S. Pontryagin is a very powerful means for solving the problem of synthesizing control systems which give optimal speeds of response. Despite the fact that use of this principle leads only to necessary conditions for the optimality of controls, in certain cases it can, in conjunction with other information, provide sufficient information to permit the designing of systems with high speeds of response.

The generally accepted scheme for a control system containing a rotary amplifier with fixed motor excitation voltage is not the best one. It is more advantageous to introduce a variable excitation voltage whose law of variation can be exactly computed for a given system. By using the maximum principle, one can effect an exact synthesis of an optimal controlling device which makes the system best, in the sense of speed of response.

THE REDUCTION OF NONLINEAR CONTROL SYSTEM EQUATIONS TO THEIR SIMPLEST FORM

E. N. Rozenvasser

(Leningrad)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 1, pp. 15-19, January, 1960)
Original article submitted May 29, 1959

Formulas are given for linear transformations which take the equations of direct control systems to single *n*th-order differential equations. Use of this transformation allows one to shorten the computations required in carrying out certain calculations for control systems, for example, for determining the autooscillations in the case of piecewise-linear characteristics.

1. We shall consider the system of differential equations

$$x_k = \sum_{\alpha=1}^{n} b_{k\alpha} x_\alpha + h_k f(\sigma,\ t) \quad (k = 1,\ 2,\ \ldots,\ n),$$

$$\sigma = \sum_{s=1}^{n} j_s x_s, \tag{1}$$

where $b_{k\alpha}$, h_k, and j_s are constants, and $f(\sigma,\ t)$ is some nonlinear function.

The characteristic polynomial of the linear portion of system (1) will be written in the form

$$D(\lambda) = |\lambda\delta_{k\alpha} - b_{k\alpha}| = \lambda^n + f_1\lambda^{n-1} + \ldots + f_n \tag{2}$$

($\delta_{k\alpha}$ is a Kronecker delta).

We now introduce the determinants $H_s(\lambda)$ ($s = 1,\ 2,\ \ldots,\ n$) which are obtained by replacing the *s*th column of determinant (2) by the column $\{H\}$ whose components are the number h_k. If we expand the determinants in powers of λ, we shall have

$$H_s(\lambda) = \sum_{k=1}^{n} h_{sk}\lambda^{n-k}. \tag{3}$$

We introduce the additional notation

$$M(\lambda) = \sum_{s=1}^{n} j_s H_s(\lambda) = \sum_{l=1}^{n} m_l \lambda^{n-l}. \tag{4}$$

We consider, in addition to (1), the system of equations

$$D(p)\,y = f(\sigma,\ t),\quad \sigma = M(p)\,y, \tag{5}$$

where D and M are the polynomials of (2) and (4) and *p* is the symbol for differentiation.

Let

$$y' = \frac{dy}{dt},\quad y'' = \frac{d^2y}{dt^2},\ \ldots,\quad y^{(n-1)} = \frac{d^{n-1}y}{dt^{n-1}}$$

and the determinant composed of the numbers h_{sk} be nonzero. Then, we have the relationship

$$x_i = \sum_{s=1}^{n} h_{is}\, y^{(n-s)}. \tag{6}$$

We now consider the columns

$$\{U_1\} = \{H\}, \tag{7}$$

$$\{U_2\} = B\{U_1\},\ \ldots,\ \{U_n\} = B^{n-1}\{H\} = B\{U_{n-1}\},$$

where B is the matrix whose components are the numbers $b_{k\alpha}$.

We denote by Δ_n the determinants consisting, respectively, of the columns $\{U_1\},\ \{U_2\},\ \ldots,\ \{U_n\}$, and by Δ_n^s the algebraic complement of the element of the *s*th row and *n*th column of determinant Δ_n.

If we then solve system (6) for *y* and its derivatives, we get

$$y^{(n-k)} = \sum_{\alpha=1}^{n} m_{k\alpha} x_\alpha \tag{8}$$

where

$$m_{n\alpha} = \frac{\Delta_n^\alpha}{\Delta_n} \quad (\alpha = 1,\ 2,\ \ldots,\ n), \tag{9}$$

and the remaining quantities, m_{ps}, are defined by the recursion formulas

$$m_{ps} = \sum_{\alpha=1}^{n} m_{p+1,\alpha} b_{\alpha s}. \tag{10}$$

The derivations of formulas (6), (8), (9), and (10) are given in the Appendix.

2. For solving various control problems which relate to systems of the form of (1), it is convenient to make direct use of Eqs. (5) since, in every case, the computational work connected with the analysis of Eqs. (5) is simpler. As was noted earlier, Eqs. (5) can be written immediately if one knows the coefficients of the characteristic equation of linearized system (1) for $f(\sigma) = c\sigma$.

The subsequent transition from Eqs. (5) to the original system (1) is made by means of (6), and presents no difficulty.

In particular, let us consider the question of determining the autooscillations in system (1) in the case of a piecewise-linear characteristic. In system (1), let

$$f(\sigma, t) = f(\sigma) = a_i\sigma + b_i \quad \text{for} \quad \sigma_{i-1} < \sigma < \sigma_i, \tag{11}$$

where the σ_k are given. Then the corresponding system (5) will have the form:

$$\left[D(p) - a_i M(p)\right] y - b_i = 0$$

$$\text{for} \quad \sigma_{i-1} < M(p)\, y < \sigma_i. \qquad (12)$$

With this, the search for continuous periodic solutions of system (1) reduces to the search for periodic solutions of Eqs. (12) which are continuous up to the (n-1)th derivative inclusive.

If we give ourselves the type of periodic mode of operation and then find the general solutions of the corresponding linear Eqs. (12) on each segment of variation of σ, we can, by matching up the solutions, construct a system of transcendental equations for the determination of the autooscillation period and the time of motion on each portion of the nonlinear characteristic. The matching-up method does not differ from the methodology presented in [1] as applied to system (1). However, the use of (12) significantly shortens the computational work involved in matching up and setting up the equations for the periods since, as is known [2], setting up the general solution of Eqs. (12) and its derivatives on each of the segments is much simpler than setting up the general solution of the original system (1).

One can also seek the periodic solutions of Eqs. (12) directly in the form of trigonometric series by the method, for example, proposed by L. A. Gusev [3].

However, in the given case, there exists an essential simplification. In [3], following M. A. Aizerman and F. R. Gantmakher [4], the author uses the derived equation of the form

$$D(p)\,\sigma - M(p)\, f(\sigma) = 0, \qquad (13)$$

which was obtained from (1) by differentiation followed by elimination of unknowns. With this there are periodic solutions of Eq. (13) for definite conditions which relate the discontinuities of the derivatives of σ and $f(\sigma)$ at the moments of switching (saltus conditions). In [3], the saltus conditions were given in the form

$$\{\sigma\}_{q1} = U_q \{\sigma\}_{q2} - V_q, \qquad (14)$$

where $\{\sigma\}_{q1}$ is a column with values $\sigma - m_n b_q/(f_n - a_q m_n)$, $\sigma, \ldots, \sigma^{(n-1)}$ at time $t_q - 0$, $\{\sigma\}_{q2}$ is the same column at time $t_q + 0$, t_q is the time of the qth switching, U_q is a constant matrix, and V_q is a constant column.

By virtue of what has previously been said, the use of (13) as the derived equation allows one to replace the saltus conditions by the conditions of continuity of y, y', . . . , $y^{(n-1)}$ at the moments of switching. If, for this, we set up the conditions analogous to (14), we shall have

$$U_q = E, \quad V_q = \left| \begin{matrix} \dfrac{b_q}{f_n - q_q m_n} - \dfrac{b_{q+1}}{f_n - a_{q+1} m_n} \\ 0 \\ \cdot \\ \cdot \\ \cdot \\ 0 \end{matrix} \right| \qquad (15)$$

where E is the unit matrix.

For (15), Eqs. (27) of [3], which are used for the elimination of the arbitrary constants, are essentially simplified. Since the switchings occur for definite values of

$$\sigma_q = \sigma_{q\,\text{giv}} \qquad (16)$$

then, by eliminating the arbitrary constants, we arrive at equations for the periods which are analogous to Eqs. (30) of [3]:

$$\sigma_q(t_1, t_2, \ldots, t_h) = \sigma_{q\,\text{giv}} \qquad (q = 1, 2, \ldots, h). \qquad (17)$$

where $t_1, \ldots, t_h$ are the moments of switching.

If the times t_i are found, it is then easy to find y(t), y'(t), . . . , $y^{(n-1)}(t)$, after which, using (6), all the $x_i(t)$ are found. If Eq. (13) were used as the derived equation then, after finding the periodic solution $\sigma(t)$, the quantities $x_i(t)$ could only be found by integrating the corresponding system of linear inhomogeneous equations obtained from (1) by setting $\sigma = \sigma(t)$.

What has been presented here may also be used for finding the forced oscillations of system (1) for the case of piecewise-linear characteristics.

APPENDIX

Derivation of the Basic Formulas

For simplicity, we shall assume that the roots of equation $D(\lambda) = 0$: $\lambda = \lambda_\rho$ ($\rho = 1, 2, \ldots, n$) are simple, and also that, for each ρ, an m is found such that

$$H_m(\lambda_\rho) \neq 0.$$

Then, by introducing new variables z_ρ by the formulas

$$x_k = \sum_{\rho=1}^{n} \frac{H_k(\lambda_\rho)}{D'(\lambda_\rho)} z_\rho, \quad z_\rho = \frac{1}{H_m(\lambda_\rho)} \sum_{k=1}^{m} D_{km}(\lambda_\rho)\, x_k, \qquad (18)$$

where $D_{km}(\lambda)$ is the algebraic complement of the kth row and mth column of determinant (2), we take system (1) to the canonical form of A. I. Lur'e:

$$\dot{z}_\rho = \lambda_\rho z_\rho + f(\sigma), \quad \sigma = \sum_{\rho=1}^{m} \frac{M(\lambda_\rho)}{D'(\lambda_\rho)} z_\rho. \qquad (19)$$

On the other hand, system (5) also reduces to the form of (19) by means of the transformation:

$$z_\rho = \sum_{\alpha=1}^{n} B_{\alpha n}(\lambda_\rho)\, y^{(n-\alpha)}, \quad y^{(n-\alpha)} = \sum_{\rho=1}^{n} \frac{\lambda_\rho^{n-\alpha}}{D'(\lambda_\rho)} z_\rho, \tag{20}$$

where the $B_{\alpha n}(\lambda)$ are polynomials of the form

$$B_{1n} = 1, \quad B_{2n} = f_1 + \lambda,$$
$$B_{3n} = (f_1 + \lambda)\lambda + f_2, \ldots, B_{kn}\lambda = B_{k-1,\,n}\lambda + f_{k-1}. \tag{21}$$

By taking (18), (20), (21), and (3) into account, we can get

$$x_k = \sum_{l-1}^{n} p_{k\alpha} y^{(n-\alpha)}, \tag{22}$$

where the numbers $p_{k\alpha}$ are written in the form

$$p_{k\alpha} = \sum_{l=1}^{n} h_{kl}\pi_{l\alpha}, \tag{23}$$

where

$$\pi_{ls} = \sigma_{n-l+s-1} + f_1\sigma_{n-l+s-2} + \cdots + f_{s-1}\sigma_{n-l}$$
$$(1 \leqslant l \leqslant n,\ 1 \leqslant s \leqslant n), \tag{24}$$

and the quantities σ_k are defined by the relationships

$$\sigma_k = \sum_{\rho=1}^{n} \frac{\lambda_\rho^k}{D'(\lambda_\rho)}. \tag{25}$$

By taking into consideration the well-known equations for sums of the form of (25) [2]

$$\sigma_k = 0 \quad (k = 0, 1, \ldots, n-2),$$
$$\sigma_{n-1} = 1, \tag{26}$$

we obtain

$$\pi_{ls} = \begin{cases} 0 & \text{for} \quad l > s, \\ 1 & \text{for} \quad l = s. \end{cases} \tag{27}$$

Now, let $s \geq l + 1$. Then by virtue of (26) we have

$$f_{s-2}\sigma_{n-l-1} + \cdots + f_n\sigma_{s-l-1} = 0.$$

If we add this to (24), we find that

$$\pi_{ls} = \sigma_{n-l+s-1} + f_1\sigma_{n-l+s-2} + \cdots + f_n\sigma_{s-l-1}.$$

If we now take the identity

$$\frac{\lambda_\rho^{s-l-1}}{D'(\lambda_\rho)} D(\lambda_\rho) \equiv 0$$

and sum over all ρ, we get

$$\pi_{ls} = 0 \quad \text{for} \quad s > l. \tag{28}$$

We obtain (6) from (22), (23), (27), and (28). Formulas (9) can be obtained directly by solving system (6) for y, y', . . . , $y^{(n-1)}$ and then carrying out certain simplifications. Relationships (10) are obtained in the following way. From (18) and (20) we have that

$$m_{k\alpha} = \sum_{\alpha=1}^{n} \frac{\lambda_\rho^{n-k} D_{\alpha m}(\lambda_\rho)}{D'(\lambda_\rho) H_m(\lambda_\rho)}. \tag{29}$$

We set up the sum

$$\sum_{\alpha=1}^{n} b_{\alpha s} m_{k\alpha} = \sum_{\alpha=1}^{n}\sum_{\rho=1}^{n} \frac{\lambda_\rho^{n-k} b_{\alpha s} D_{\alpha m}(\lambda_\rho)}{D'(\lambda_\rho) H_m(\lambda_\rho)}.$$

By reversing the order of summation and by taking into account the equation [5]

$$\sum_{\alpha=1}^{n} b_{\alpha\beta} D_{\alpha\gamma}(\lambda_\rho) = \lambda_\rho D_{\beta\gamma}(\lambda_\rho),$$

we obtain (10).

THE RELATIONSHIP BETWEEN LINEAR SYSTEMS' TRANSIENT RESPONSES AND THEIR LAPLACE TRANSFORMS

N. S. Kochanov

(Leningrad)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 1, pp. 20-28, January, 1960)
Original article submitted April 23, 1959

Methods are considered for the determination of discrete values of a linear system's transient response from its given Laplace transform, and for finding the Laplace transform from equally spaced given values of the transient response. These methods do not require that the roots of algebraic equations be computed.

Posing of the Problem

In solving the problem of analyzing the transient responses in linear systems with lumped parameters, great difficulty arises because of the necessity of calculating the roots of algebraic equations in order to make the transition from the transform of a time-domain function to the time-domain function itself.

The use of the methods of calculating the transient responses from frequency characteristics in such problems involves a significant amount of computation and graphical construction.

There is thus great interest in numerical methods of calculating transient responses which would allow one, in many cases, to compute quite simply discrete values of the transient response without determining the roots of the characteristic equation, and without graphical constructions.

Among these methods are the approximate operator method of G. S. Pospelov [1] and the similar methods discussed in the foreign literature [2, 3].

The practical use of these methods is significantly limited by the fact that, to obtain sufficiently high accuracy of the computations, one must choose a small discrete step, which leads to a corresponding increase in the amount of computational work, since the computations are carried out with constant steps.

With this, to determine discrete values of transient responses, one must carry out the expansion of several fractions in series.

The distinguishing features of the method proposed in the present work are the use of recursion formulas for the computations, and the use of a method for doubling the discrete step.

In the solution of the problem of synthesizing linear systems with lumped constants, the first question that arises is the determination of the transform of a given function of time. With this, due to the condition of physical realizability of such systems, the transform sought must be a rational fraction.

Thus, the second task of the present paper is the finding of methods for the determination of the Laplace transforms of functions of time in the form of exponential polynomials which approximate the given time-domain characteristics.

Transforms of Transient Responses

We shall consider impulsive responses, or regular parts of transient responses, which provide Laplace transforms in the form of rational fractions

$$\overline{F}(p) = \frac{b_0 p^{n-1} + b_1 p^{n-2} + \cdots + b_{n-1}}{p^n + a_1 p^{n-1} + a_2 p^{n-2} + \cdots + a_n}. \qquad (1)$$

The expansion of these fractions in negative powers of p will have the form:

$$\overline{F}(p) = \frac{s_0}{p} + \frac{s_1}{p^2} + \frac{s_2}{p^3} + \cdots + \frac{s_k}{p^{k+1}} + \cdots \qquad (2)$$

The coefficients s_k, which are the initial values of the function F(t) and its derivatives, satisfy the recursion relationship

$$s_{n+i} + a_1 s_{n-1+i} + a_2 s_{n-2+i} + \cdots + a_n s_i = 0$$

$$(i = 0, 1, 2, \ldots). \qquad (3)$$

This relationship is obtained from the equation

$$p^n + a_1 p^{n-1} + a_2 p^{n-2} + \ldots + a_n = 0 \qquad (4)$$

by using the following systems of correspondences:

$$1 = p^0 \to s_0, \quad p \to s_1, \quad p^2 \to s_2, \ldots, p^i \to s_i, \ldots \qquad (5)$$

If the transient response is characterized by the system of discrete values $F_0, F_1, F_2, \ldots, F_{2n-1}, \ldots$, corresponding to equally spaced values of the argument t, then one can set up the series

$$\overline{F}(m) = \frac{F_0}{m} + \frac{F_1}{m^2} + \frac{F_2}{m^3} + \cdots + \frac{F_{2n-1}}{m^{2n}} + \cdots, \qquad (6)$$

where $m = e^{p\tau}$ and τ is the discrete step.

By converting this series to a continued fraction [4], one can find a fraction which converges to this series:

$$\bar{\Phi}(m) = \frac{B_0 m^{n-1} + B_1 m^{n-2} + \cdots + B_{n-1}}{m^n + A_1 m^{n-1} + A_2 m^{n-2} + \cdots + A_n}. \quad (7)$$

The expansion of this fraction by negative powers of m will coincide with series (6) up the term F_{2n-1}/m^{2n} inclusive, if 2n terms were used in converting the series to a continued fraction.

The following terms of this expansion will give the equally-spaced values of that nth-order exponential polynomial which, at the points $F_0, F_1, F_2, \ldots, F_{2n-1}$, assumes the given values.

If the equally spaced values $F_0, F_1, F_2, \ldots, F_{2n-1}$ are values of some nth-order exponential polynomial then by expanding fraction (7) in negative powers of m, one can compute the exact values of this exponential polynomial, $F_{2n}, F_{2n+1}, F_{2n+2}, F_{2n+3}, \ldots$

For this, the equally spaced values of the function under consideration can be computed by means of the recursion formula

$$F_{n+i} + A_1 F_{n-1+i} + A_2 F_{n-2+i} + \cdots + A_n F_i = 0$$

$$(i = 0, 1, 2, 3, \ldots), \quad (8)$$

which is obtained from the equation

$$m^n + A_1 m^{n-1} + A_2 m^{n-2} + \cdots + A_n = 0 \quad (9)$$

by using the following table of correspondences:

$$m^0 \to F_0, \quad m \to F_1,$$

$$m^2 \to F_2, \ldots, m^i \to F_i, \ldots \quad (10)$$

Thus, one can solve the problem of extrapolating an exponential polynomial given 2n equally-spaced values.

This fact allows one to develop a sufficiently simple method of calculating transient responses by means of recursion formulas.

Method of Constructing a Recursion Equation for Equally Spaced Values of a Time-Domain Function

Recursion equation (8), as was mentioned, can be obtained by means of Eq. (9). The coefficients of this equation, $A_1, A_2, \ldots, A_n$, are expressed, as is well known, in terms of its roots $e^{pk\tau}$:

$$A_1 = -(e^{p_1\tau} + e^{p_2\tau} + \cdots + e^{p_n\tau}),$$
$$A_2 = [e^{(p_1+p_2)\tau} + e^{(p_1+p_3)\tau} + \cdots + e^{(p_{n-1}+p_n)\tau}],$$
$$\cdots\cdots\cdots\cdots\cdots$$
$$A_n = (-1)^n e^{(p_1+p_2+\cdots+p_n)\tau}.$$

It follows from this that coefficient A_n of this equation can be exactly determined by coefficient a_1 of Eq. (4):

$$A_n = e^{-a_1\tau}.$$

However, the other coefficient cannot be determined in such fashion. For their computation, therefore, we use an approximate method.

If we express the relationship between parameters p and m in the form of an approximate formula

$$p \approx \frac{2}{\tau} \frac{m-1}{m+1},$$

then, after substituting this relationship in Eq. (4), we can obtain an Eq. (9) which is valid for sufficiently small τ.

To increase the size of the discrete step, we transform this equation. The coefficients of Eq. (9) are combinations of the roots $e^{pk\tau}$. By setting up the analogous combinations of the squares of these roots, $e^{2pk\tau}$, we obtain an equation with a double step.

The coefficients of the new, transformed equation are set up by the method, known in algebra, which was employed by N. I. Lobachevskii for solving algebraic equations of high degree:

$$\begin{aligned} A_1^{(1)} &= A_1^2 - 2A_2, \\ A_2^{(1)} &= A_2^2 - 2A_1A_3 + 2A_4, \\ &\cdots\cdots\cdots\cdots \\ A_{n-1}^{(1)} &= A_{n-1}^2 - 2A_{n-2}A_n, \\ A_n^{(1)} &= A_n^2. \end{aligned} \quad (11)$$

We thus obtain the equation for the double step

$$m^{2n} + A_1^{(1)} m^{2n-2} + A_2^{(1)} m^{2n-4} + \cdots + A_n^{(1)} = 0.$$

From this, the recursion formula follows

$$F_{2n+i} + A_1^{(1)} F_{2n-2+i} +$$

$$+ A_2^{(1)} F_{2n-4+i} + \cdots + A_n^{(1)} F_i = 0.$$

By using this method of doubling the step several times, we can increase the discrete step by factor of 4, 8, 16, etc., without decreasing the accuracy of the recursion formula.

With this, the given method can be applied both at the beginning and during the course of the computation of the transient characteristics, thus allowing, on the one hand, a sufficient accuracy of the recursion formula to be obtained and, on the other hand, a significant reduction in the amount of computational work to be realized.

The initial equally spaced values of the time-domain function sought, these being necessary for the use of recursion formulas, may be first of all computed by means of the series

$$F(t) = s_0 + s_1 t + s_2 \frac{t^2}{2!} + s_3 \frac{t^3}{3!} + \cdots,$$

which is obtained by expanding the given function in negative powers of p. With this, in order to simplify the computations, one can use equispaced function values for both positive and negative t, i.e., compute F(τ) and F(−τ), F(2τ), and F(−2τ), etc.

Example of the Computation of Transient Responses

We illustrate the method of computing transient responses by the example of an electrohydraulic servo system acted on by a unit step function.*

In this case, the Laplace transform of the function has the form:

$$\overline{F}(p) = \frac{0.0035\,p^2 + 0.37\,p + 9.5}{p\,[p^4 + 103\,p^3 + 3065\,p^2 + 149250\,p + 1081500]}$$

By separating the pole of the function for p = 0, we get

$$\overline{F}(p) = \frac{1}{1081500}\left\{\frac{9.5}{p} - \overline{F}_1(p)\right\},$$

where

$$\overline{F}_1(p) = \frac{9.5\,p^3 + 978.5\,p^2 + 25332.25\,p + 1017720}{p^4 + 103\,p^3 + 3065\,p^2 + 149250\,p + 1081500}.$$

The computation of the curve of the transient response will be carried out for the function $\overline{F}_1(p)$. If, in the system's characteristic equation

$$p^4 + 103\,p^3 + 3065\,p^2 + 149250\,p + 1081500 = 0$$

we make the substitution

$$p = \frac{2}{\tau}\,\frac{m-1}{m+1},$$

then, for the step τ = 0.005, we shall have

$$m^4 - 3.5263\,m^3 + 4.6615\,m^2 - 2.7283\,m + 0.5937 = 0.$$

By employing the method of doubling the step, we get

$$m^8 - 3.1118\,m^6 + 3.6754\,m^4 - 1.9086\,m^2 + 0.3525 = 0.$$

Thus, the recursion formula for the step τ = 0.01 will have the form:

$$F_{4+i} =$$

$$= 3.1118\,F_{3+i} - 3.6754\,F_{2+i} + 1.9086\,F_{1+i} - 0.3525\,F_i.$$

We determine the initial values of the function sought by means of the series

$$F_1(t) = 9.5 - 1892.5\,t^2 - 1712\,t^3 + 11221\,t^4.$$

We have $F_0 = 9.500$, $F_1 = 9.309$, $F_2 = 8.731$, and $F_3 = 7.760$. Further computations are carried out then by means of the recursion formulas for the step τ = 0.01 and also for 2τ = 0.02 and 4τ = 0.04:

$$F_{2(4+i)} = 2.3325\,F_{2(3+i)} - 2.3352\,F_{2(2+i)} + \\ + 1.0516\,F_{2(1+i)} - 0.1243\,F_{2i},$$

$$F_{4(4+i)} = 0.770\,F_{4(3+i)} - 0.796\,F_{4(2+i)} + \\ + 0.525\,F_{4(1+i)} - 0.0155\,F_{4i}.$$

The results of these computations are given in the table.

The values obtained are close to the values computed by other methods (cf. the graph on page 50 of the book by V. V. Solodovnikov et al., Frequency Methods of Constructing Transient Responses using Tables and Nomograms.) This accuracy can be increased if the initial discrete step is decreased.

This example shows the efficacy of the method of doubling the step since, for computing this same curve of the transient response with about the same accuracy using the other approximate methods cited at the beginning of this paper, a significantly greater number of points would have to be computed.

Method of Determining the Denominator of the Transform of an Approximating Function

We now pose the problem of determining the Laplace transform of an exponential polynomial used to approximate a given time-domain characteristic of a system.

The first step in the solution of this problem will be the determination of the denominator of the fraction expressing the transform being sought.

Let the given time-domain characteristic be approximated by an exponential polynomial for 2n equally spaced interpolation points. Then, function (7) can be found for the given equispaced values of the time-domain characteristic. Using this function, we can determine any number of equally spaced values of the exponential nth-order polynomial which assumes the given values at the selected interpolation points.

It is necessary for this that the function found be expanded in negative powers of m, or that recursion formula (8) be employed.

These equally spaced values can be used for the determination of the coefficients of the system's characteristic equation

$$p^n + a_1 p^{n-1} + a_2 p^{n-2} + \cdots + a_n = 0.$$

---

* This example was borrowed from the book by V. V. Solodovnikov, Yu. I. Topcheev, and G. V. Krutikova, Frequency Methods of Constructing Transient Responses using Tables and Nomograms [in Russian] (Gostekhizdat, 1955).

Table of Values of the Function F(t), Computed from the Formula

$$F(t) = \frac{1}{1081500}\,(9.5 - F_1(t))$$

t	0.00	0.01	0.02	0.03	0.04	0.05	0.06	0.08	0.10
$F(t)\cdot 10^6$	0.000	0.177	0.711	1.608	2.752	4.010	5.232	7.189	8.016
t	0.12	0.16	0.20	0.24	0.28	0.32	0.36	0.40	0.44
$F(t)\cdot 10^6$	7.733	6.236	6.918	8.858	8.998	7.956	8.419	8.978	9.086

If we use approximate formulas for the relationship between the parameters m and p which give convergent fractions for the logarithm, for example,

$$p \approx \frac{2}{\tau}\frac{m-1}{m+1},\quad p \approx \frac{3}{\tau}\frac{m^2-1}{m^2+4m+1},$$

$$p \approx \frac{4}{\tau}\frac{(m-1)(m^2+4m+1)}{(m+1)(m^2+10m+1)},$$

and substitute them in the sought system's characteristic equation, we then obtain, after some transformations,

$$m^n + A_1^* m^{n-1} + A_2^* m^{n-2} +$$

$$+ \cdots + A_{n-1}^* m + A_n^* = 0,$$

or

$$m^{2n} + D_1 m^{2n-1} + D_2 m^{2n-2} +$$

$$+ \cdots + D_{2n-1} m + D_{2n} = 0,$$

or

$$m^{3n} + G_1 m_{3n-1} + G_2 m^{3n-2} +$$

$$+ \cdots + G_{3n-1} m + G_{3n} = 0.$$

By using these equations and the table of correspondences given in (10), we can set up the recursion relationships connecting a definite number of equipspaced values of the exponential polynomial sought. Thus, we can obtain

$$F_{n+i} + A_1^* F_{n-1+i} + A_2^* F_{n-2+i} +$$

$$+ \cdots + A_{n-1}^* F_{1+i} + A_n^* F_i = 0,$$

or

$$F_{2n+i} + D_1 F_{2n-1+i} + D_2 F_{2n-2+i} +$$

$$+ \cdots + D_{2n-1} F_{1+i} + D_{2n} F_i = 0,$$

or

$$F_{3n+i} + G_1 F_{3n-1+i} + G_2 F_{3n-2+i} +$$

$$+ \cdots + F_{3n-1} F_{1+i} + G_{3n} F_i = 0.$$

By means of these recursion formulas, one can determine the unknowns $a_2, a_3, \ldots, a_n$ which enter into the coefficients $A_k^* \mid D_k, G_k \mid$. We note that coefficient a_1 equals

$$a_1 = -\frac{1}{\tau}\ln|A_n|.$$

For example, for the interpolation of a given time-domain characteristic, let there be used a second-order exponential polynomial which is defined by the four equispaced values F_0, F_1, F_2, and F_3. Then, the function $\overline{\Phi}(m)$ will have the form:

$$\overline{\Phi}(m) = \frac{B_0 m + B_1}{m^2 + A_1 m + A_2}.$$

By means of this function, we can determine F_4, F_5, etc. Then, for the determination of the coefficients of the second-order characteristic equation

$$p^2 + a_1 p + a_2 = 0$$

by using the approximate equality

$$p \approx \frac{3}{\tau}\frac{m^2-1}{m^2+4m+1}$$

we obtain the following equation:

$$\frac{9}{\tau^2}(F_{4+i} - 2F_{2+i} + F_i) +$$

$$+ a_1\frac{3}{\tau}(F_{4+i} + 4F_{3+i} - 4F_{1+i} - F_i) +$$

$$+ a_2(F_{4+i} + 8F_{3+i} + 18F_{2+i} + 8F_{1+i} + F_i) = 0,$$

where

$$a_2 = -\frac{1}{\tau}\ln|A_2|.$$

For characteristic equations of higher order, the coefficients are determined from a system of linear equations.

Method of Determining the Numerator of the Transform

The determination of the transform's numerator can be carried out by means of series whose coefficients are the initial values of the approximating function sought and its derivatives, or by the initial moments of this function.

We consider the series obtain by expanding the function $m\overline{\Phi}(m)$ in negative powers of m:

$$m\overline{\Phi}(m) =$$

$$= F_0 + \frac{F_1}{m} + \frac{F_2}{m^2} + \cdots + \frac{F_{2n-1}}{m^{2n-1}} + \frac{F_{2n}}{m^{2n}} + \cdots$$

The coefficients of this series are equispaced values of the exponential polynomial being sought.

If we expand the function $m^{-k} = e^{kp\tau}$ in a series and regroup terms, we get

$$\tau e^{p\tau}\overline{\Phi}(e^{p\tau}) =$$

$$= \left(F_0 + \sum_{i=1}^{\infty} F_i\right)\tau - p\sum_{i=1}^{\infty} i\tau^2 F_i + \frac{p^2}{2!}\sum_{i=1}^{\infty} i^2\tau^3 F_i - \cdots =$$

$$= \tau c_0 - pm_1 + \frac{p^2}{2!}m_2 - \frac{p^3}{3!}m_3 + \cdots$$

Here, m_1, m_2, and m_3 are the initial moments of the function.

It is easily seen that the sums entering into the given expansion are approximate expressions for the initial moments as defined by the trapezoidal quadrature formula.

Thus, we shall have

$$\overline{F}(p) \approx \tau\left(c_0 - \frac{F_0}{2}\right) - pm_1 + \frac{p^2}{2!}m_2 - \frac{p^3}{3!}m_3 + \cdots$$

An analogous representation can be obtained by first carrying out an expansion of the functions $e^{kp\tau}$ in the numerator and denominator of the fraction for $m\overline{\Phi}(m)$ and the expanding this fraction in positive powers of p, i.e.,

$$\tau e^{p\tau}\overline{\Phi}(e^{p\tau}) = \tau\frac{(B_0 + B_1 + \cdots + B_{n-1}) - p\tau[nB_0 + (n-1)B_1 + \cdots + B_{n-1}] + \cdots}{(1 + A_1 + \cdots + A_n) - p\tau[n + (n-1)A_1 + \cdots + A_{n-1}] + \cdots} =$$

$$= \tau c_0 - pm_1 + \frac{p^2}{2!}m_2 - \frac{p^3}{3!}m_3 + \cdots$$

It should be mentioned that the accuracy of the computations of the initial moments by such a method is higher, the higher the order of the moment.

While this assertion can be rigorously proven, it is better to illustrate it by a simple example.

Let it be required to determine the initial moments of the function e^{-t}. For this purpose, we expand the transform of the function in positive powers of p:

$$\frac{1}{p+1} = 1 - p + p^2 - p^3 + p^4 - \cdots$$

We now consider the interpolation of the given function by two points, t = 0 and t = 1. The function $\tau m\overline{\Phi}(m)$ will then have the form

$$\frac{m\tau}{m - 0.36788} = \frac{\tau e^{p\tau}}{e^{p\tau} - 0.36788}.$$

If we expand this function in positive powers of p we get

$$\tau e^{p\tau}\overline{\Phi}(e^{p\tau}) = 1.58198 - 0.92068p + 0.99615p^2 -$$

$$- 1.00108p^3 + 1.00012p^4 - \ldots \quad (\tau = 1).$$

By comparing the coefficients of the two expansions we easily see that the accuracy in the determination of the moments rapidly increases with increasing order of the moment, even for a significantly large discrete step.†

To determine the exact values of the lower-order moments, we can find an approximating fraction for the segment of the series whose coefficients are accurately defined, and expand this fraction in decreasing powers of p. By extending the expansion of this fraction, we can find the initial values of the function sought, plus those of its derivatives.

The method given permits the determination, with very high accuracy, of both the numerator and denominator of the first fraction expressing the transform of the approximating function sought.

To determine the fraction which approximates a segment of a series, one can also use the denominator of the fraction obtained by the method of the previous paragraph.

Thus, one can obtain the series

$$\overline{F}(p) = m_0 - m_1 p + m_2\frac{p^2}{2!} - m_3\frac{p^3}{3!} + \cdots$$

---

† The initial moments are proportional to the corresponding coefficients of the series.

The coefficients of the numerator of the Laplace transform are determined from the coefficients of this series:

$$b_{n-1} = a_n m_0,$$
$$b_{n-2} = -a_n m_1 + a_{n-1} m_0,$$
$$b_{n-3} = a_n \frac{m_2}{2!} - a_{n-1} m_1 + a_{n-2} m_0,$$
$$\cdots\cdots\cdots\cdots$$

Example. Let it be required to determine the Laplace transform for the exponential polynomial which is characterized by the values

$$F_0 = 0, \quad F_1 = 1, \quad F_2 = 1, \quad F_3 = 0.75 \quad \text{for} \quad \tau = 1.$$

Solution. For the given equispaced values, we construct the series

$$\overline{F}_1(m) = \frac{1}{m^2} + \frac{1}{m^3} + \frac{0.75}{m^4} + \cdots,$$

for which we determine the approximating second-order fraction:

$$\overline{\Phi}(m) = \frac{1}{m^2 - m + 0.25}.$$

By using the method presented earlier, we find the denominator of the transform, in the form

$$Q(p) = p^2 + 1.3863\,p + 0.4793.$$

To determine the numerator of the transform, we use the expansion

$$\frac{e^p}{0.25 - e^p + e^{2p}} =$$

$$= 4 - 12\,p + 26\,p^2 - 50\,p^3 + 90.167\,p^4 - 156.1\,p^5 + \cdots,$$

by means of which we find the zeroth-order initial moment: $m_0 = 4.18$.

The final solution of the problem is the expression

$$\overline{F}(p) = \frac{2.0034}{p^2 + 1.3863\,p + 0.4793}.$$

The exact transform of the initial function has the form:

$$\overline{F}(p) = \frac{2}{p^2 + 1.3863p + 0.4804} \rightarrow 2te^{-0{,}6931t}.$$

In conclusion, we note that this same problem could be solved by computing moments of sufficiently high order.

In particular, by using the moments of second, third, fourth, and fifth order, we get

$$\overline{F}(p) = \frac{2.0025}{p^2 + 1.3836\,p + 0.47907}.$$

CONCLUSION

1. The possibility was demonstrated of calculating transient responses by means of recursion formulas obtained on the basis of an approximate formula for the differentiation operator and the application of the method of doubling the discrete step.

The method of calculating transient responses presented here is highly accurate.

2. A method was presented of determining the Laplace transform corresponding to an exponential polynomial by interpolating the given time-domain characteristic for equally spaced points. This method can be used for finding the Laplace transforms of functions which are given graphically.

A GENERATOR OF RANDOM PROCESSES FROM THEIR GIVEN SPECTRAL DENSITY MATRICES

I. Matyash and Ya. Shilkhanek

(Pardubitse, Czechoslovakia)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 1, pp. 29-35, January, 1960)
Original article submitted July 20, 1959

A method is described for constructing a generator of n stationary random processes with arbitrary matrices of rational spectral densities, using a minimal number of uncorrelated white noise generators and stable linear filters. The transfer functions of these filters are determined by a very simple method from the given spectral densities. The method is illustrated by an example for the case when n = 3.

Analog computers are frequently used for the analysis and synthesis of automatic control and regulation systems which are acted upon by random functions of time. For this, the inputs to the computer must be random functions which correspond to the input random functions of the actual system.

In this paper we shall consider only stationary random functions (processes) whose proper and mutual spectral densities are rational-fractional functions of the variable $s = j\omega$. In practice it is necessary to replace the experimentally determined spectral densities by approximating rational functions. Methods of implementing such approximations are described in the literature (cf., for example, [1, 2]).

To study actual systems by means of analog computers (modeling devices), it is necessary to generate random processes with given spectral densities. The generation of one stationary random process with a given proper spectral density is described, for example, in [2]. In [3] a method is given for reproducing two processes with given proper and mutual spectral densities. However, with this method one can obtain two random processes with given spectral densities only in special cases

In the present paper we present a general method for generating any number n of stationary random processes with arbitrary proper and mutual spectral densities.

Generation of One Random Process

The generator's block schematic (cf. [2]) is shown in Fig. 1, where Q_1 is a white noise generator (a process with unit spectral density) and F_{11} is a filter with transfer function $Y_{11}(s)$.

Fig. 1.

The condition that the output signal $u_1(t)$ be a process with the given density ${}^1G_{11}(s)$ is written in the form

$$ {}^1G_{11}(s) = Y_{11}(s)\, Y_{11}(-s). \qquad (1)$$

Since ${}^1G_{11}(s)$ is a spectral density, there exists just one function $A_1(s)$ which does not have poles and zeros in the right half-plane and such that the following equation holds

$$A_1(s)\, A_1(-s) = {}^1G_{11}(s) \qquad (2)$$

(cf. [1, 2, 4]). By comparing this with (1), we obtain the well-known result (cf. [2])

$$Y_{11}(s) = A_1(s), \qquad (3)$$

wherein $Y_{11}(s)$ is the transfer function of a stable linear filter with minimal phase.

For the generation of several processes, it is sometimes necessary to construct a filter with nonminimal phase. If we connect in series with the filter whose transfer function is $A_1(s)$ a filter which varies only in phase, and whose transfer function has the form:

$$H_1(s) = \frac{f(s)}{f(-s)}, \qquad (4)$$

where f(s) is a polynomial then, obviously, the following relationship holds

$$|H_1(s)|^2 = H_1(s)\, H_1(-s) = 1, \qquad (5)$$

i.e., the spectral density of the output process is not changed.

Thus, the transfer function $Y_{11}(s)$ of filter F_{11} can be written in the general form:

$$Y_{11}(s) = A_1(s)\, H_1(s), \qquad (6)$$

where $H_1(s)$ is any function of the form of (4) such that the function $A_1(s)H_1(s)$ is the transfer function of a stable filter.

Generation of n Random Processes

Spectral densities of the random processes. We shall denote by ${}^1G_{ik}(s)$ (i, k = 1, 2, . . . , n) the given proper and mutual spectral densities of the random processes $u_1(t)$, $u_2(t)$, . . . , $u_n(t)$. The functions ${}^1G_{ik}(s)$ denote the mutual spectral density of the processes $u_i(t)$ and $u_k(t)$. The functions ${}^1G_{ik}(s)$ form the matrix of spectral densities $\| {}^1G_{ik}(s) \|$ (i, k = 1, 2, . . . , n) [5].

From the self-evident relationship

$$ {}^1G_{ki}(s) = {}^1G_{ik}(-s) \qquad (s = j\omega) \qquad (7) $$

we obtain

$$ {}^1G_{ki}(s) = {}^1G^{*}_{ik}(s), \qquad (8) $$

where the symbol $*$ denotes the complex conjugate quantity. Consequently, the spectral density matrix $\|{}^1G_{ik}(s)\|$ is a Hermitian matrix. It is completely defined by its $n(n+1)/2$ elements ${}^1G_{ik}(s)$ ($i = 1, 2, \ldots, n$; $k = 1, i+1, \ldots, n$).

The Appendix describes several properties of the spectral density matrix which are used in this paper.

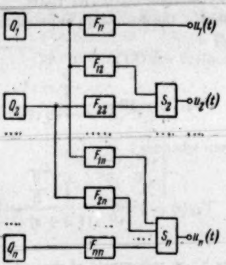

Fig. 2.

Block schematic of the generator. The block schematic of the generator of n random processes is shown in Fig. 2. It consists of n uncorrelated (for example, statistically independent) white noise generators $Q_1, Q_2, \ldots, Q_n$ (generators of uncorrelated processes with unit spectral densities), $n(n+1)/2$ stable linear filters F_{ik} ($i = 1, 2, \ldots, n$; $k = i, i+1, \ldots, n$) with transfer functions $Y_{ik}(s)$ and $n-1$ adders S_k ($k = 2, 3, \ldots, n$). Process $u_1(t)$ is found at the output of filter F_{11}, while process $u_k(t)$ ($k = 2, 3, \ldots, n$) is found at the output of adder S_k.

In order that the generator's output signals $u_1(t)$, $u_2(t), \ldots, u_n(t)$ be the processes with the given spectral density matrix $\|{}^1G_{ik}(s)\|$ ($i, k = 1, 2, \ldots n$), it is necessary (cf., for example, [6]) that the following conditions hold:

$$
\begin{aligned}
&{}^1G_{11}(s) = Y_{11}(s)\,Y_{11}(-s),\\
&{}^1G_{12}(s) = Y_{12}(s)\,Y_{11}(-s),\\
&{}^1G_{22}(s) = Y_{12}(s)\,Y_{12}(-s) + Y_{22}(s)\,Y_{22}(-s),\\
&\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots
\end{aligned}
$$

i.e., in general,

$$ {}^1G_{ik}(s) = \sum_{j=1}^{i} Y_{jk}(s)\,Y_{ji}(-s) $$

$$ \begin{pmatrix} i = 1, 2, \ldots, n \\ k = i, i+1, \ldots, n \end{pmatrix}. \qquad (9) $$

The problem thus reduces to determining the transfer functions $Y_{ik}(s)$ of the stable linear filters F_{ik} ($i = 1, 2, \ldots, n$; $k = i, i+1, \ldots, n$) such that system of equation (9) holds.

Determination of the transfer functions $Y_{ik}(s)$. From (9), by setting $i = 1$, we obtain

$$ {}^1G_{1k}(s) = Y_{1k}(s)\,Y_{11}(-s) \quad (k = 1, 2, \ldots, n). \qquad (10) $$

For $k = 1$, Eq. (10) is identical with (1). Consequently, in accordance with formula (6),

$$ Y_{11}(s) = A_1(s)\,H_1(s). \qquad (11) $$

By using (10), we find the functions $Y_{1k}(s)$ in the form

$$ Y_{1k}(s) = \frac{{}^1G_{1k}(s)}{A_1(-s)}\,H_1(s) \qquad (k = 1, 2, \ldots, n). \qquad (12) $$

The function $H_1(s)$, of the form given in (4), is such that all the $Y_{1k}(s)$ ($k = 1, 2, \ldots, n$) are transfer functions of stable filters. We obtain a function $H_1(s)$ of the least degree if, for the null points of $H_1(s)$ [the roots of the polynomial $f(s)$], we choose the set of poles in the right half-plane of the expressions ${}^1G_{1k}(s)/A_1(-s)$ (each pole being chosen with the maximum multiplicity in these expressions). This completely determines the function $H_1(s)$ [cf. (4)].

To compute the transfer functions $Y_{ik}(s)$ ($i > 1$), we define the auxiliary functions ${}^{r+1}G_{ik}(s)$ ($r = 1, 2, \ldots, n-1$) by the formula

$$ {}^{r+1}G_{ik}(s) = {}^1G_{ik}(s) - \sum_{j=1}^{r} Y_{jk}(s)\,Y_{ji}(-s) $$

$$ \begin{pmatrix} i = r+1, \ldots, n \\ k = i, \ldots, n \end{pmatrix}. \qquad (13) $$

These functions obviously satisfy the recursion relationship

$$ {}^{r+1}G_{ik}(s) = {}^rG_{ik}(s) - Y_{rk}(s)\,Y_{ri}(-s). \qquad (14) $$

After substituting (13) in (9) we obtain, for $r + 1 = i$,

$$ {}^iG_{ik}(s) = Y_{ik}(s)\,Y_{ii}(-s) $$

$$ (k = i, i+1, \ldots, n). \qquad (15) $$

For $k = i$ we obtain from this

$$ {}^iG_{ii}(s) = Y_{ii}(s)\,Y_{ii}(-s). \qquad (16) $$

If follows from (16) that the function ${}^1G_{ii}(s)$ ($i = 2, 3, \ldots, n$) must be real and nonnegative:

$$ {}^iG_{ii}(s) \geqslant 0 \qquad \begin{pmatrix} s = j\omega \\ i = 2, 3, \ldots, n \end{pmatrix}. \qquad (17) $$

It is proven in the Appendix that conditions (17) are met if the functions ${}^1G_{ik}(s)$ form a spectral density matrix.

Since formula (16) has the form of (1), we define the functions $Y_{ii}(s)$ in accordance with formula (6) by the method described earlier:

$$Y_{ii}(s) = A_i(s)\, H_i(s)\,, \tag{18}$$

where the functions $A_i(s)$ are defined by the equations

$$A_i(s)\, A_i(-s) = {}^iG_{ii}(s) \tag{19}$$

just as $A_1(s)$ of (2), and the $H_i(s)$ are as yet undetermined functions of the form of (4).

By substituting (18) in (15), we get

$$Y_{ik}(s) = \frac{{}^iG_{ik}(s)}{A_i(-s)} H_i(s)$$

$$\begin{pmatrix} i = 1, 2, \ldots, n \\ k = i, i+1, \ldots, n \end{pmatrix}. \tag{20}$$

The functions $H_i(s)$ are defined by the conditions that all the $Y_{ik}(s)$ ($k = i, i+1, \ldots, n$) be the transfer functions of stable filters [analogously to the function $H_1(s)$].

Formulas (20) define all the transfer functions $Y_{ik}(s)$ ($i = 1, 2, \ldots, n$; $k = i, i+1, \ldots, n$). In practice, one first computes transfer functions $Y_{1k}(s)$ from the given functions ${}^1G_{1k}(s)$ ($k = 1, 2, \ldots, n$), then determines the auxiliary functions ${}^2G_{ik}(s)$ from (14), then computes from these the transfer functions $Y_{2k}(s)$ ($k = 2, 3, \ldots, n$), etc. In general, the functions ${}^{r+1}G_{ik}(s)$ are determined step by step from the ${}^rG_{ik}(s)$ by formula (14). Transfer functions $Y_{r+1,k}(s)$ are computed from these by formulas (20).

Example. As an illustration, we use the example of the generator of three random processes whose spectral densities are given in the form

$${}^1G_{11}(s) = \frac{2 - s^2}{4 - s^2}\,, \qquad {}^1G_{12}(s) = \frac{s^2}{(3+s)(2-s)}\,,$$

$${}^1G_{13}(s) = \frac{2 - s^2}{(3+s)(2-s)}\,, \qquad {}^1G_{22}(s) = \frac{-2s^2 + 2s^4}{(2-s^2)(9-s^2)}\,,$$

$$G_{23}(s) = \frac{-2s + 2s^2}{9 - s^2}\,, \qquad {}^1G_{33}(s) = \frac{4 - 2s^2}{3 - s^2}\,.$$

It follows from (12) that

$$Y_{11}(s) = \frac{\sqrt{2} + s}{2 + s} H_1(s)\,,$$

$$Y_{12}(s) = \frac{s^2}{(3+s)(\sqrt{2} - s)} H_1(s)\,,$$

$$Y_{13}(s) = \frac{\sqrt{2} + s}{3 + s} H_1(s)\,.$$

From the stability conditions we obtain, based on what has been presented earlier,

$$H_1(s) = \frac{\sqrt{2} - s}{\sqrt{2} + s}\,.$$

By this, transfer functions $Y_{1k}(s)$ ($k = 1, 2, 3$) are completely determined.

From formula (14) we now compute the functions ${}^2G_{ik}(s)$:

$${}^2G_{22}(s) = \frac{-s^2}{9 - s^2}\,, \qquad {}^2G_{23}(s) = \frac{-2s + s^2}{9 - s^2}\,,$$

$${}^2G_{33}(s) = \frac{(2 - s^2)(15 - s^2)}{(3 - s^2)(9 - s^2)}\,.$$

From these, by (20), we obtain

$$Y_{22}(s) = \frac{s}{3 + s} H_2(s), \qquad Y_{23}(s) = \frac{2 - s}{3 + s} H_2(s).$$

Consequently, we can set $H_2(s) = 1$. This then determines functions $Y_{22}(s)$ and $Y_{23}(s)$.

Finally, the following expression for ${}^3G_{33}(s)$ follows from (14)

$${}^3G_{33}(s) = 10 \frac{\frac{9}{5} - s^2}{(3 - s^2)(9 - s^2)}\,.$$

From whence

$$Y_{33}(s) = \sqrt{10}\, \frac{\sqrt{\frac{9}{5}} + s}{(\sqrt{3} + s)(3 + s)}\,.$$

The block schematic of the generator of the three random processes desired is shown in Fig. 3.

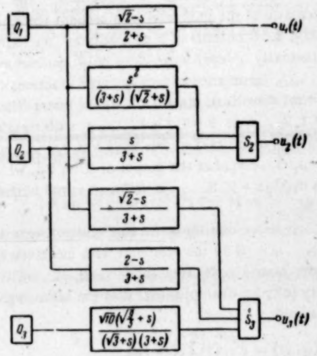

Fig. 3.

CONCLUSIONS

The method herein described for generating any number n of stationary random processes from a given matrix of rational spectral densities is a general method. It permits one to construct a generator of random processes from any matrix of rational spectral densities.

One easily convinces oneself that the generator contains the least number (n) of white noise generators Q_i and the least number ($n(n+1)/2$) of linear filters F_{ik}.

(In [3] there was described a generator of two processes which consisted of three white noise generators and three filters.)

The generator's functional schematic (Fig. 2) allows the transfer functions $Y_{ik}(s)$ of the filters F_{ik} to be computed in a very simple way from the given spectral densities [cf. formulas (20)].

APPENDIX

Certain Properties of Spectral Density Matrices

For brevity, we shall formulate these properties in the form of theorems. From these properties one can derive results which are important for the construction of the random process generators described in this paper.

Theorem 1. The functions ${}^{r+1}G_{ik}(s)$ ($i = r + 1, \ldots, n$; $k = 1, \ldots, n$) of Eq. (13) are defined by the relationships

$$
{}^{r+1}G_{ik}=\frac{\begin{vmatrix} {}^1G_{11}\ldots{}^1G_{1r}\,{}^1G_{1k} \\ \ldots\quad\ldots\quad\ldots \\ {}^1G_{r1}\ldots{}^1G_{rr}\,{}^1G_{rk} \\ {}^1G_{i1}\ldots{}^1G_{ir}\,{}^1G_{ik} \end{vmatrix}}{\Delta_r}, \tag{21}
$$

where

$$
\Delta_r=\begin{vmatrix} {}^1G_{11}\ldots{}^1G_{1r} \\ \ldots\quad\ldots\quad\ldots \\ {}^1G_{1r}\ldots{}^1G_{rr} \end{vmatrix}. \tag{22}
$$

Proof. From (14), we get that

$$
{}^{r+1}G_{ik}=\frac{\begin{vmatrix} {}^rG_{rr}\,{}^rG_{rk} \\ {}^rG_{ir}\,{}^rG_{ik} \end{vmatrix}}{{}^rG_{rr}}. \tag{23}
$$

The assertion of our theorem is proven by the method of complete induction. It follows from (23) that (21) is valid for $r = 1, 2, \ldots$ We assume that (21) is valid for all $r \leq m-1$. For $r = m$, we obtain from (23) that

$$
{}^{m+1}G_{ik}=\frac{\begin{vmatrix} {}^mG_{mm} & {}^mG_{mk} \\ {}^mG_{im} & {}^mG_{ik} \end{vmatrix}}{{}^mG_{mm}}. \tag{24}
$$

By assumption, we can assert the relationship

$$
{}^mG_{mm}=\frac{\Delta_m}{\Delta_{m-1}} \tag{25}
$$

from whence

$$
\frac{\Delta_m}{\Delta_{m-1}}\,{}^{m+1}G_{ik}=\begin{vmatrix} {}^mG_{mm} & {}^mG_{mk} \\ {}^mG_{im} & {}^mG_{ik} \end{vmatrix}. \tag{26}
$$

From Sylvester's determinant identity we get

$$
\begin{vmatrix} {}^mG_{mm}\,{}^mG_{mk} \\ {}^mG_{im}\,{}^mG_{ik} \end{vmatrix}=\frac{1}{\Delta_{m-1}}\cdot\begin{vmatrix} {}^1G_{11} & \ldots & {}^1G_{1m} & {}^1G_{1k} \\ \ldots & & \ldots & \ldots \\ {}^1G_{m1} & \ldots & {}^1G_{mm} & {}^1G_{mk} \\ {}^1G_{i1} & \ldots & {}^1G_{im} & {}^1G_{ik} \end{vmatrix}. \tag{27}
$$

By comparing (26) and (27) we immediately obtain the equation

$$
{}^{m+1}G_{ik}\,\Delta_m=\begin{vmatrix} {}^1G_{11} & \ldots & {}^1G_{1m} & {}^1G_{1k} \\ \ldots & & \ldots & \ldots \\ {}^1G_{m1} & \ldots & {}^1G_{mm} & {}^1G_{mk} \\ {}^1G_{i1} & \ldots & {}^1G_{im} & {}^1G_{ik} \end{vmatrix} \tag{28}
$$

which proves the theorem.

Corollary of Theorem 1. By virtue of (21), we have the equation

$$
{}^rG_{rr}=\frac{\Delta_r}{\Delta_{r-1}} \qquad (r=2, 3, \ldots, n). \tag{29}
$$

Consequently, conditions (17) can be written in the form

$$
\frac{\Delta_r}{\Delta_{r-1}}\geqslant 0 \qquad (r=2,3,\ldots,n). \tag{30}
$$

Theorem 2. A necessary and sufficient condition for the matrix $\| {}^1G_{ik} \|$ ($i, k = 1, \ldots, n$) to be a spectral density matrix is that it be a nonnegative Hermitian matrix.

For the proof, cf. [5] and [7].

Theorem 3. A necessary and sufficient condition that a Hermitian matrix be nonnegative is that all its principal minors be nonnegative.

For the proof, cf., for example, [8].

Theorem 4. If $\| {}^1G_{ik} \|$ ($i, k = 1, 2, \ldots, n$) is a spectral density matrix then, for any $r = 2, 3, \ldots, n$, the matrix $\| {}^rG_{ik} \|$ ($i, k = r, r + 1, \ldots, n$) [cf. (21)] is also a spectral density matrix.

Proof. The validity of the following inequality is a consequence of theorem 3:

$$
\Delta_r \geqslant 0 \qquad (r=1,2,\ldots,n). \tag{31}
$$

From Sylvester's determinant identity, one easily proves that all the principal minors of matrix $\| {}^rG_{ik} \|$ are nonnegative. We then obtain the assertion of theorem 4 by using theorems 2 and 3.*

Corollary of Theorem 4. If all the matrices $\| {}^rG_{ik} \|$ ($r = 2, 3, \ldots, n$) are spectral density matrices, then inequalities (17) and (30) hold. It suffices for this, by theorem 4, that matrix $\| {}^1G_{lk} \|$ be a spectral density matrix. It follows from this that, using the method described in this paper, one can construct a generator of random stationary processes with any arbitrary matrix of rational spectral densities.

---

* The validity of theorem 4 follows directly from (13), since it is easy to determine the random processes for which the spectral density matrix is the matrix $\| {}^rG_{ik} \|$ ($i, k = r, \ldots, n$).

ON THE STABILITY OF SERVO-CONTROLLED SYSTEMS WITH RANDOM STIMULI

P. S. Landa

(Moscow)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 1, pp. 36-41, January, 1960)
Original article submitted April 13, 1959

Excitation conditions are found for servo systems containing nonlinear backlash-type elements. The probability of excitation of such a system when noise is present is computed as a function of time.

Due to feedback paths, both designed and parasitic, and also to the various types of nonlinear elements, automatic control systems which are stable for small oscillations can be excited by large disturbances. Such systems with rigid excitation have, for even relatively small fluctuating stimuli, a finite probability of being excited to autooscillation during a given time interval. Therefore, the solution of the problem of computing this probability is of significant interest for the rational choice of the parameters of such systems.

The problem posed may be solved comparatively simply in the case when the object of control is an oscillatory system with one degree of freedom, and the controlling organ contains some nonlinear element, for example, backlash, dry friction, etc.

In this paper we use, as an example, the system whose block schematic is shown in Fig. 1. The dotted line denotes the additional feedback path between the controlled object's motion and the control organ in this system. The character of this feedback is defined by the coefficient β which, in general, can be complex. For simplicity we shall consider β to be real, but the method is easily generalized to the case when β takes on complex values.

We shall assume that the controlling stimulus g(t) varies very slowly in comparison with the system's natural frequency of oscillation. It may then be neglected in writing the system's equations. With this, the system under consideration, as is clear from Fig. 1, is described by the following equations:

$$\ddot{x} + 2\delta\dot{x} + \omega^2 x = kz_1 - \omega^2\zeta(t),$$
$$\dot{z} = b\varepsilon, \quad \varepsilon = \beta x - z, \; z_1 = f(z), \qquad (1)$$

where $\zeta(t) = -\omega^2\zeta_1(t)/k$ is a stationary random function with zero mean and f(z) is the backlash characteristic (Fig. 2).

We also assume that

$$b \gg \delta, \qquad (2)$$

i.e., the servo motor's time constant is small in comparison with the natural time of the controlled object.

If a = 0 (no backlash), the system becomes linear and the following conditions for oscillatory instability can easily be written for it:

$$\beta < 0, \quad k > \frac{2\delta\omega(1+\alpha^2)}{|\beta|\alpha} = k_0, \qquad (3)$$

where $\alpha = \omega/b$ (with this, the excitation is soft).

If a ≠ 0, the system becomes stable for small oscillations about the equilibrium position. However, for definite values of k, even if conditions (3) do not hold, rigid excitation of oscillations is possible in the system.

In this case, we shall find the excitation conditions and the system's steady-state oscillations in the absence of noise, and also the probability of system excitation as a function of time and of the magnitude of the noise.

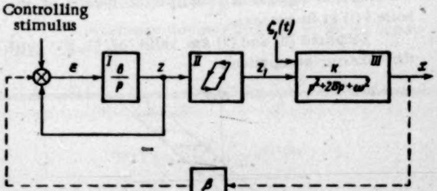

Fig. 1. Block schematic of a servo system. I is a servo motor of the hydraulic amplifier type, II is a nonlinear element of the backlash type, and III is the controlled object.

For this, we use the method presented in [1, 2], and we write the contracted equations for the amplitude and phase of the oscillations, wherein we define the latter in the following way:

$$x = A\cos(\omega t + \varphi), \quad \dot{x} = -A\omega\sin(\omega t + \varphi). \qquad (4)$$

By virtue of assumption (2), we can express the coordinate z in terms of A and φ:

$$z = \frac{\beta}{\sqrt{1+\alpha^2}} A\cos(\omega t + \varphi + \psi), \qquad (5)$$

where

$$\phi = \operatorname{arc\,tg}(-\alpha).$$

By substituting (4) in (5) and expanding the function f(z) = F(t) in a Fourier series in t, we obtain equations in the coordinates (variables) A and φ:

$$\dot{A} = -\delta A - \frac{k\beta C}{2\omega\sqrt{1+\alpha^2}} A \sin\chi + \xi, \qquad (6)$$

$$\dot{\varphi} = -\frac{k\beta C}{2\omega\sqrt{1+\alpha^2}} \cos\chi + \frac{\xi'}{A}; \qquad (7)$$

Here, we have introduced the following notation:

$$C = \begin{cases} 0 & \text{for } \dfrac{\beta A}{\sqrt{1+\alpha^2}} \leqslant a, \\ \dfrac{1}{\pi}\sqrt{(u^2-1)^2+v^2} & \text{for } \dfrac{\beta A}{\sqrt{1+\alpha^2}} \geqslant a, \end{cases}$$

$$\operatorname{tg}\chi = \alpha\pi \frac{F_\alpha(u)}{v+\alpha(u^2-1)}, \quad u = 1 - 2\frac{a\sqrt{1+\alpha^2}}{|\beta| A},$$

$$v = \frac{3\pi}{2} - \arcsin u + u\sqrt{1-u^2},$$

$$F_\alpha(u) = \begin{cases} 0 & \text{for } \dfrac{\beta A}{\sqrt{1+\alpha^2}} \leqslant a, \\ \dfrac{1}{\alpha\pi}(\alpha v + 1 - u^2) & \text{for } \dfrac{\beta A}{\sqrt{1+\alpha^2}} \geqslant a, \end{cases}$$

ξ and ξ' are δ-correlated random functions with zero means and correlation function $K(\tau) = 2\lambda^{-1}\delta(\tau)$, where $\lambda^{-1} = \omega^2\kappa(\omega)/4$; $\kappa(\omega)$ is half the spectral density of the noise $\zeta(t)$ at frequency ω.

Equations (6) and (7) are valid (cf. [1, 2]) with the following assumptions.

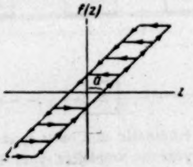

Fig. 2.

1. The oscillations in the system are almost harmonic, i.e., A and φ slowly vary during the period. This requirement corresponds to the condtions:

$$\frac{\delta}{\omega} < 1; \qquad \frac{k|\beta|}{\omega^2(1+\alpha^2)} < 1,$$

$$\begin{cases} \sqrt{\overline{\zeta^2}} < A_0 & \text{for } \tau_{\text{cor}} \geqslant \dfrac{2\pi}{\omega}, \\ \sqrt{\omega\kappa(\omega)} < A_0 & \text{for } \tau_{\text{cor}} < \dfrac{2\pi}{\omega}, \end{cases} \qquad (8)$$

where A_0 is the amplitude of the unstable limiting cycle and τ_{cor} is the correlation time of the noise $\zeta(t)$.

2. The correlation time of the noise is small in comparison with the system's relaxation time, i.e.,

$$\tau_{\text{cor}} < \frac{1}{\delta} \text{ and } \tau_{\text{cor}} < \frac{\omega(1+\alpha^2)}{k|\beta|}.$$

Since the right side of Eq. (7) does not depend on φ, this expression can be considered as the correction to the system's frequency of oscillations:

$$\Delta\omega = -\frac{k\beta C}{2\omega\sqrt{1+\alpha^2}}\cos\chi + \frac{\xi'}{A}.$$

The presence of the random stimulus in the right side leads only to fluctuations of the frequency about the mean value

$$\omega_0 = \omega + \Delta\omega_{\text{me}},$$

where

$$\Delta\omega_{\text{me}} = -\frac{k\beta C}{2\omega\sqrt{1+\alpha^2}}\cos\chi.$$

By virtue of conditions (8), $\Delta\omega_{\text{me}} \ll \omega$.

To answer the question of system stability, it suffices to investigate only Eq. (6), since it does not depend on φ.

With no noise present, the magnitudes of the limiting cycles are determined from the equations

$$\frac{k\beta}{2\omega\sqrt{1+\alpha^2}} C \sin\chi = -\delta$$

or

$$F_\alpha(u) = -\frac{2\omega\delta(1+\alpha^2)}{k\beta\alpha}. \qquad (9)$$

The graph of the function $F_\alpha(u)$ as a function of u for various values of α is given on Fig. 3. The function $F_\alpha(u)$ has an extremum at the point $u_0 = \alpha/\sqrt{(1+\alpha^2)}$, equal to $F_\alpha(u_0) > 1$. Consequently, as is clear from the graph, limiting cycles are possible with the conditions

$$\beta < 0, \quad k > \frac{2\omega\delta(1+\alpha^2)}{|\beta|\alpha F_\alpha(u_0)} = \frac{k_0}{F_\alpha(u_0)}.$$

The points of intersection of the line defined by the right member of Eq. (9) with the curve $F_\alpha(u)$ give the amplitudes of the unstable and stable limiting cycles, where the left point corresponds, as is easily shown, to the unstable cycle.

If $k > k_0$, which corresponds to the condition for excitation of oscillations in the absence of noise, then there is no steady-state stable mode for the system. If, however, $k_0/F_\alpha(u_0) < k < k_0$ then, with backlash in the system, it is possible to have autooscillations with stationary amplitude whose excitation occurs rigidly. Using the method suggested by R. L. Stratonovich (cf. [1, 2]) for the approximate solution of the Fokker-Planck equation, we compute the probability of system excitation when it is stimulated by a random force.

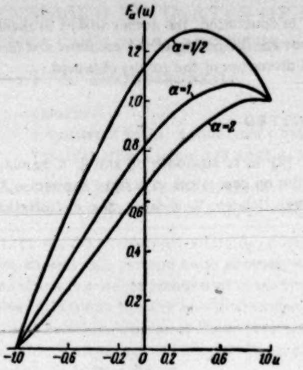

Fig. 3.

It is necessary for this to impose additional conditions on the magnitude of the random stimulus:

$$\frac{1}{\sqrt{\lambda\delta}} < A_0, \quad \frac{1}{\sqrt{\lambda K}} < A_0, \tag{10}$$

where

$$K = -\left.\frac{\partial^2 U(A)}{\partial A^2}\right|_{A=A_0},$$

$$U(A) = \delta\frac{A^2}{2} - \frac{2k\alpha a^2}{\omega|\beta|}\int\frac{F_\alpha(u)}{(1-u)^2}\,du.$$

We now write the corresponding Fokker-Planck equation for the amplitude's distribution density w(A,t):

$$\frac{\partial w}{\partial t} = -\frac{\partial G}{\partial A}, \tag{11}$$

where

$$G = -\left[\delta + \frac{k\beta\alpha F_\alpha(u)}{2\omega(1+\alpha^2)}\right]Aw + \frac{1}{\lambda A}w - \frac{1}{\lambda}\frac{\partial w}{\partial A}.$$

As follows from [2], the probability of system excitation at time $\tau \leq t$ equals $q(t) = 1 - e^{-\gamma/2t}$, where

$$\gamma = G_0|_{A=A_0},$$

$$G_0 = -\left[\delta + \frac{k\beta_\alpha F_\alpha(u)}{2\omega(1+\alpha^2)}\right]Aw_0 + \frac{1}{\lambda A}w_0 - \frac{1}{\lambda}\frac{dw_0}{dA},$$

and, as $w_0(A)$, one can take as an approximation the steady-state solution of the Fokker-Planck equation with zero boundary conditions:

$$\frac{dG_0}{dA} = 0,$$

$$w_0(A_0) = 0, \quad \int_0^{A^0} w_0(A)\,dA = 1. \tag{12}$$

By virtue of the zero boundary condition, we obtain the simple expression for γ:

$$\gamma = -\frac{1}{\lambda}\left.\frac{dw_0}{dA}\right|_{A=A_0}.$$

Since, due to conditions (10), we consider the noise to be quite small, we can assume that the effect of the zero boundary condition on the course of the distribution density $w_0(A)$ is limited to a narrow region close to the boundaries characterized by the inequality $\Delta A < \sqrt{1/\lambda K}$. It is natural to assume that, outside of this region, $w_0(A)$ coincides with the steady-state solution of Eqs. (12), w(A), which satisfies the condition that it vanishes at infinity.

As one easily convinces oneself by direct substitution in (12),

$$w(A) = CAe^{-\lambda U(A)}.$$

The normalizing constant C can be computed approximately by using conditions (10):

$$C^{-1} = \int_0^{A_0} Ae^{-\lambda U(A)}\,dA \approx \frac{1}{\lambda\delta}.$$

Based on what has been said earlier, we can set

$$w_0(A) = w(A)\,w^*(A), \tag{13}$$

where $w^*(A)$ is a correction factor, equal to zero for $A = A_0$ and equal to unity for $A_0 - A > 1/\sqrt{\lambda K}$.

By substituting (13) in (12), we obtain the equation for $w^*(A)$:

$$\frac{d}{dA}\left(w\frac{dw^*}{dA}\right) = 0 \tag{14}$$

with the conditions

$$w^*(A_0) = 0, \quad w^*(A) = 1 \text{ for } A_0 - A > \frac{1}{\sqrt{\lambda K}}. \tag{15}$$

We also note that

$$\left.\frac{dw_0}{dA}\right|_{A=A_0} = w(A_0)\left.\frac{dw^*}{dA}\right|_{A=A_0} = -\lambda\gamma.$$

We can now write the first integral of Eq. (14):

$$w(A)\frac{dw^*}{dA} = -\lambda\gamma.$$

To determine the magnitude of γ, we use conditions (15):

$$w^*(A)\Big|_{A_0-A>\sqrt{\frac{1}{\lambda K}}} = C^{-1}\lambda\gamma\int_{A_0}^{A}\frac{1}{A}e^{\lambda U(A)}\,dA \approx$$

$$\approx \gamma\frac{1}{\delta A_0}\sqrt{\frac{\pi}{2\lambda K}}\,e^{\lambda U(A_0)} = 1.$$

From whence

$$\gamma = \delta A_0\sqrt{\frac{2\lambda K}{\pi}}\,e^{-\lambda U(A_0)},$$

where

$$K = \frac{a\alpha k}{A_0\omega\sqrt{1+\alpha^2}}\left.\frac{dF_\alpha(u)}{du}\right|_{A=A_0}.$$

Thus, the probability of system excitation during any given interval of time is completely determined. Knowing it, we can easily compute the average time during which the system is excited. It equals $t_{av} = 2/\gamma$.

SUMMARY

1. The presence of backlash can lead to undesirable system excitation.
2. The excitation is rigid.

3. Even for low noise, one can cite a time interval during which the system is excited with probability arbitrarily close to unity.

In conclusion, the author wishes to thank Prof. S.P. Strelkov for the posing of the problem and for the very useful discussion of the results obtained.

ON UNBIASED ESTIMATES OF SIGNALS WHICH DEPEND NONLINEARLY ON UNKNOWN PARAMETERS

I. A. Boguslavskii

(Moscow)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 1, pp. 42-47, January, 1960)
Original article submitted April 2, 1959

A method is presented which, in many cases, allows one to use linear theory for obtaining, in the presence of noise, an unbiased estimate of a signal which depends nonlinearly on unknown parameters.

In [1-4], the problem of obtaining, in the presence of noise, an optimal, in some sense or other, estimate of a signal which is a linear function of unknown parameters was solved. In many cases of practical importance, the signal is a nonlinear function of these parameters. The general solution of the corresponding nonlinear problem was obtained by V. S. Pugachev.*

However, there is a definite practical interest in artificial ways of effectively solving the problem in certain cases by using the well-known linear methods of statistical dynamics. One such method is presented below. The method allows one, for example, to implement sufficiently simply an unbiased filtering of a random process whose signal satisfies a nonlinear differential equation of a definite type with unknown initial conditions. The method can be used for smoothing, without dynamic errors, the coordinates and velocity of Sputniks and cosmic rockets during their unpowered flight phases, etc.

Description of the Method

A random process Z(t) is observed, its form being

$$Z(t) = \Phi(c_1, c_2, \ldots, c_n, t) + m(t),$$

where Φ is the signal, the c_k are random parameters, and m(t) is the noise.

Let it be possible to give a transformation I which takes Φ to a function of the form $\sum_{k=1}^{n} c_k W_k(t)$ with the $W_k(t)$ known a priori, and a transformation II which, when applied to the result of an application of transformation I, leads back to the function Φ. In addition, we shall assume that the random process $Z_1(t)$ which results from the application of transformation I to Z(t), may be presented approximately in the form

$$Z_1(t) = \sum_{k=1}^{n} c_k W_k(t) + m_1(t),$$

where $m_1(t)$ is a random noise process whose correlation function can be expressed in terms of the probability characteristics of the noise m(t).

Then, a scheme for obtaining an unbiased estimate of the signal can be constructed in the following manner.

1. We apply transformation I to Z(t).
2. We apply $Z_1(t)$ to the input of an optimal unbiased filtering link, constructed in accordance with the well-known linear methods on the basis of the data on the functions $W_k(t)$ and the correlation function of the noise $m_1(t)$; after the selected memory time T of the link, we obtain at its output the function $\sum_{k=1}^{n} c_k W_k(t)$ with a decreased random error.
3. We apply transformation II to the output of this link.

The realization of the sequence of operations just described allows one to construct, with time lag T, the function $\Phi(c_1, c_2, \ldots, c_n, t)$ without dynamic errors and with decreased random errors only if transformation II insignificantly "increases" the noise at the output of the optimal linear link.

Let it be known that the signal Φ satisfies a nonlinear differential equation of the form

$$a_0(t)\frac{d^n\Phi}{dt^n} + a_1(t)\frac{d^{n-1}\Phi}{dt^{n-1}} + \cdots + a_n(t)\Phi = F[t, \Phi] \tag{1}$$

with unknown initial conditions

$$c_1 = \Phi(0), \quad c_2 = \Phi^{(1)}(0), \ldots, c_n = \Phi^{(n-1)}(0).$$

Because of the presence of the function F(t, Φ) in the right member of (1), the signal in the case under consideration is a nonlinear function of the unknown parameters $c_1, c_2, \ldots, c_n$. It follows from (1) that

$$\Phi(c_1, c_2, \ldots, c_n, t) = \sum_{k=1}^{n} c_k W_k(t) + \int_0^t W(t, \tau) F[\tau, \Phi]\, d\tau, \tag{2}$$

where $W_k(t)$ is the solution of the homogeneous equation

$$a_0(t)\frac{d^n W_k}{dt^n} + a_1(t)\frac{d^{n-1} W_k}{dt^{n-1}} + \cdots + a_n(t) W_k = 0$$

with initial conditions

$$W_k^{(m)}(0) = \begin{cases} 0 & \text{for} \quad m \neq k, \\ 1 & \text{for} \quad m = k, \end{cases}$$

and W(t, τ) is the impulsive response of the corresponding linear dynamic link.

---

* In a paper given February 16 and March 2, 1959, at the seminar on probabilistic methods in automatic control theory of the Institute of Automation and Remote Control of the Academy of Sciences of the USSR.

It is clear from (2) that transformation I should be defined by the relationship

$$Z_1(t) = Z(t) - \int_0^t W(t,\tau)\,F[\tau, Z(\tau)]\,d\tau, \qquad (3)$$

and transformation II by the relationship

$$Z_2(t) = Z^*(t) + \int_0^t W(t,\tau)\,F[\tau, Z(\tau)]\,d\tau, \qquad (4)$$

where $Z^*(t)$ denotes the result of optimal unbiased filtering of the process $Z_1(t)$. After time T, given by the solution of the optimization problem, $Z_2(t)$ will differ from $\Phi(c_1, c_2, \ldots, c_n, t)$ only by a random error.

As a rule, one can approximately set $m_1(t) \approx m(t)$ only if the link with impulsive response $W(t, \tau)$ possesses essential filtering properties, and $F[t, \Phi]$ is of the same order as Φ. Analogously to what has been presented, one can obtain an unbiased estimate of the result of applying any given linear operator S to the function Φ.

In this case

$$Z_2(t) = Z^*(t) + S\left\{\int_0^t W(t,\tau)\,F[\tau, Z(\tau)]\,d\tau\right\},$$

where $Z^*(t)$ is the optimal unbiased estimate, after time lag T, of the function $S\left\{\sum_{k=1}^{n} c_k W_k(t)\right\}$.

We note that, for a given function $\Phi(c_1, c_2, \ldots, c_n, t)$, the corresponding nonlinear differential equation can be found by eliminating the parameters c_k from the following system of n + 1 algebraic equations:

$$\begin{aligned} \Phi &= \Phi(c_1, c_2, \ldots, c_n, t), \\ \frac{d\Phi}{dt} &= \Phi_t'(c_1, c_2, \ldots, c_n, t), \\ \frac{d^n\Phi}{dt^n} &= \Phi_t^{(n)}(c_1, c_2, \ldots, c_n, t). \end{aligned}$$

However, a direct application of the transformations of (3) and (4) can only be used for obtaining an unbiased estimate in the case when the nonlinear portion of the differential equation obtained depends only on Φ and t.

By using the Jacobian of the functions $\Phi, \Phi_t', \ldots$ with respect to $c_1, c_2, \ldots$, one can obtain an analytic expression for the condition cited.

For n = 1, this condition is always met. Thus, if for example,

$$\Phi = \frac{c}{c+t},$$

then

$$\frac{d\Phi}{dt} = -\frac{c}{(c+t)^2} \quad \text{and} \quad t\frac{d\Phi}{dt} + \Phi = \Phi^2.$$

If, to the method presented, one adds the optimally determined derivatives of the function $Z_1(t)$, one can then, in conjunction with the method of successive approximation, obtain an unbiased estimate even when the nonlinear portion is a function of the derivatives of the function Φ.

Obtaining an unbiased estimate by the scheme presented above does not require that a nonlinear differential equation be solved. Therefore, in the example to be considered below, the use of the scheme allows a concrete engineering problem to be solved in an uncomplicated way.

Determination of the Smoothed Values of the Elements of a Sputnik's Trajectory

We now construct a methodology for determining, without dynamic errors, the smoothed values of the position and velocity of a Sputnik. For brevity we shall consider the problem in a plane; taking nonplanar motion into account for the smoothing engenders no difficulties.

Let x and y be the coordinates of the Sputnik with respect to a rectangular coordinate system passing initially through the center of the earth but not rotating with it. If one neglects the atmospheric braking of the Sputnik and the effect of the nonsphericity of the earth, then x and y satisfy the nonlinear differential equations

$$\ddot{x} = -gR^2 \frac{x}{(x^2+y^2)^{\frac{3}{2}}}, \qquad (5)$$

$$\ddot{y} = -gR^2 \frac{y}{(x^2+y^2)^{\frac{3}{2}}}, \qquad (6)$$

where R is the radius of the earth; g = 9.81 meters/sec^2.

Therefore, x(t), for example, is described by the formula

$$x(t) = x(0) + \dot{x}(0)\,t - \int_0^t \frac{gR^2(t-\tau)\,x(\tau)}{[x^2(\tau)+y^2(\tau)]^{\frac{3}{2}}}\,d\tau \qquad (7)$$

or by the formula

$$x(t) = x(0)\cos\omega t + \frac{\dot{x}(0)}{\omega}\sin\omega t -$$
$$-\frac{1}{\omega}\int_0^t \sin\omega(t-\tau)\,x(\tau)\left\{\frac{1}{[x^2(\tau)+y^2(\tau)]^{\frac{3}{2}}} - \frac{1}{R^3}\right\}d\tau, \qquad (8)$$

where $\omega = \sqrt{g/R}$.

In formula (8) the portion of the signal which depends linearly on the nonlinear parameters x(0) and $\dot{x}(0)$ is separated more completely than in formula (7). However, the effectiveness of the filtering turns out to be practically the same, whether (7) is used or (8). We may therefore use formula (7) which provides a simpler form of the linear operator which implements optimal unbiased filtering of the result of transformation I. Let the following random process be observed

$$Z_x(t) = x(t) + m_x(t),$$

where $m_x(t)$ is the random error in measuring the coordinate $x(t)$ by terrestrial radar (radio) and optical means.

It follows from (7) that transformation I is defined by the relationship

$$Z_{x1}(t) = Z_x(t) + \int_0^t \frac{gR^2(t-\tau)Z_x(\tau)}{[Z_x^2(\tau) + Z_y^2(\tau)]^{\frac{3}{2}}}\,d\tau, \quad (9)$$

and transformation II by the relationship

$$Z_{x2}(t) = Z_x^*(t) - \int_0^t \frac{gR^2(t-\tau)Z_x(\tau)}{[Z_x^2(\tau) + Z_y^2(\tau)]^{\frac{3}{2}}}\,d\tau. \quad (10)$$

The nub of the problem under consideration is that, in the given case, the function $W(t, \tau)$ does not possess the filtering properties [with the use of (7) or (8), $W(t, \tau)$ equals, respectively, $t-\tau$ or $\sin\omega(t-\tau)/\omega$]. Therefore, the dispersion of the noise $m_{x1}(t)$ contained in $Z_{x1}(t)$ increases without bound in the course of time.

However, if T is limited by some value completely admissible for practical purposes (cf. the Appendix), then $m_{x1}(t)$ coincides in practice with the noise $m_x(t)$. Therefore, with the known correlation function of the noise $m_x(t)$, it is easy to construct a scheme which takes $Z_{x1}(t)$ to $Z_x^*(t)$, which is the optimal unbiased filtering of the random process whose signal is a linear function of time.

In the case of the limitation on T already mentioned, transformation II does not in practice decrease the efficiency of this filtering.

In an analogous way, one carries out the unbiased filtering of the random errors arising in the measurement of coordinate y. If it is necessary to find $V_x(t)$ and $V_y(t)$, the projections of the Sputnik's velocity vector, then transformation I, as before, is described by relationship (9), and transformation II takes the form

$$V_x(t) = V_x^*(t) - \int_0^t \frac{gR^2 Z_x(\tau)}{[Z_x^2(\tau) + Z_y^2(\tau)]^{\frac{3}{2}}}\,d\tau,$$

where $V_x^*(t)$ is the result of unbiased optimal differentiation of random process $Z_{x1}(t)$.

If the lack of sphericity of the earth is taken into account, the smoothing scheme remains unchanged only if the constant g in the formula is replaced by a function of x and y, defined by well-known relationships of potential theory. To take into account the braking of the Sputnik by the atmosphere, one must add, to the right members of Eqs.(5) and (6) and, certainly, to the integrands in (9) and (10), terms which depend, not only on x and y, but also on V_x and V_y. The forms of these terms are known if we know the density of the atmosphere as a function of x and y, and the drag coefficient as a function of V. With this, the smoothing method is somewhat complicated, it being required to use successive approximations, and may be laid out in the following way. First, using the method given above, wherein the braking force is not taken into account, we find V_x and V_y with some dynamic error. The values of V_x and V_y found are used to construct terms in which this force is taken into account, these terms being added to the integrands in (9) and (10), after which the process is repeated, resulting in new, more accurate values of V_x and V_y. By carrying out this process several times, we obtain V_x and V_y practically without dynamic errors, and with random errors defined, for limited T, on the basis of the random errors of the optimal differentiation. We may note that frequently one need not use successive approximations but may, instead of V_x and V_y, use the results of numerical differentiation with specially chosen increments of the observed quantities Z_x and Z_y.

The method can also be used, without change, for obtaining smoothed values of the coordinates and the projections of the velocity of cosmic rockets (space probes) describing complicated paths under the influence of the gravitational fields of earth and several other heavenly bodies. In this case, the right members of Eqs. (5) and (6) contain terms which depend on x, y and on the current value of t, these terms taking into account the variations in the coordinates of these bodies with respect to the earth during the course of the smoothing process.

APPENDIX

We denote by $\Delta(t)$ the random component contained in the integral terms of formulas (9) and (10) due to the presence of the random errors $m_x(t)$ and $m_y(t)$ and, by $\sigma_\Delta^2(t)$, we denote its dispersion.

We assume that, in practice, the magnitude of $x^2 + y^2$ is several orders of magnitude greater than the quantity $2(xm_x + ym_y) + m_x^2 + m_y^2$. Thus,

$$\Delta(t) \approx \int_0^t \frac{gR^2(t-\tau)m_x(\tau)}{[x^2(\tau) + y^2(\tau)]^{\frac{3}{2}}}\,d\tau$$

and

$$\sigma_\Delta^2(t) \leqslant \frac{g^2}{R^2}\int_0^t\int_0^t (t-\tau_1)(t-\tau_2)\,\varphi_x(\tau_1, \tau_2)\,d\tau_1\,d\tau_2, \quad (11)$$

where $\varphi_x(t_1, t_2)$ is the correlation function of random error $m_x(t)$.

We assume that

$$\varphi_x(t_1, t_2) = \sigma_0^2 e^{-\gamma|t_1 - t_2|}.$$

It follows from (11) that, in this case

$$\sigma_\Delta(t) \leqslant \sigma_0 \frac{g}{R}\sqrt{\frac{2}{3\gamma}t^3 - \frac{1}{\gamma^2}t^2 - \frac{2}{\gamma^3}te^{-\gamma t} + \frac{2}{\gamma^4}(1 - e^{-\gamma t})}. \quad (12)$$

For definiteness, we set $\gamma = 1\ \text{sec}^{-1}$, and we shall assume that, in constructing the scheme for the optimal unbiased filtering which takes $Z_{x1}(t)$ to $Z_x(t)$, and for computing σ_x^2, the dispersion of the noise at the output of this scheme, we can ignore $\Delta(t)$ ($m_x(t) \approx m_{x1}(t)$), if

$$\sigma_\Delta(t) < 0{,}1\ \sigma_0. \qquad (13)$$

It follows from (12) that (13) holds for $t < 1900$ sec. In this case, the optimal circuit's impulsive response is easily found, and

$$\sigma_x^2 = \sigma_0^2 \frac{24 + 24\gamma T + 8\gamma^2 T^2}{24 + 24\gamma T + 8\gamma^2 T^2 + \gamma^3 T^3}, \qquad (14)$$

where T is the memory of the optimal circuit and σ_x^2 is the dispersion of the noise contained in $Z_x^*(t)$.

It follows from (12) and (14) that the addition of an integral term in correspondence with formula (10) to the output of the optimal circuit does not, in practice, increase the random error, if $t = T < 500$ sec. Therefore, the memory of the optimal circuit should be defined by the conditions

$$T = t \quad \text{for} \quad t < 500 \text{ sec},$$
$$T = 500 \text{ sec} \quad \text{for} \quad t \geqslant 500 \text{ sec}.$$

In this case, formula (14) can be used to define the dispersion of the random error in the smoothed coordinates of the Sputnik.

Starting with time t = 500 sec, the lower limit of the integrals in the right members of formulas (9) and (10) should be replaced by t-500.

It is shown analogously that this same choice of T allows one to neglect $\Delta(t)$ in the determination of V_x also. Then, the impulsive response of the optimal differentiating circuit is easily found, and σ_V^2, the dispersion of the random error in the determination of the projections of the Sputnik's velocity, is described by the relationship

$$\sigma_V^2 = \sigma_0^2 24\gamma^2 \frac{2 + \gamma T}{24\gamma T + 24\gamma^2 T^2 + 8\gamma^3 T^3 + \gamma^4 T^4}. \qquad (15)$$

If, for example, we choose $\sigma_0 = 1$ km, we get from (14) and (15) that, after 200 sec of receiving information from the Sputnik, one can find its coordinates and the projections of its velocity without dynamic error, and with random errors characterized by the quantities $\sigma_x = 200$ m and $\sigma_V = 1.7$ m/sec.

SYNTHESIZING CONTROL SYSTEMS WITH MONOTONICALLY DECREASING GAINS BY THE ROOT-LOCUS METHOD

Ya. I. Rubinovich

(Moscow)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 1, pp. 48-55, January, 1959)
Original article submitted May 11, 1959

We consider a periodically connected control system which contains a link whose gain decreases monotonically with time. We introduce the concept for the quasi-majorant closed control system for which, using the root-locus method, we choose a correcting circuit.

Posing of the Problem

We assume that the control process lasts for time T, after which the control system returns to its initial state, and the process is again repeated when the controlled object is subjected to the same, or to an analogous, perturbing movement.

In the general case, the open-loop control circuit consists of two series-connected links: link I with transfer function

$$G(s)=\frac{\prod\limits_{i=1}^{m}(s+z_i)}{\prod\limits_{i=1}^{n}(s+p_i)}, \tag{1}$$

where n ≥ m, and the p_i lie in the left half of the s plane, and link II, whose variable gain decreases monotonically with time in accordance with the law

$$K_1(t)=\frac{K_0}{(t+a)^r}. \tag{2}$$

The quantity r lies within the limits $1 \le r \le 4$, and depends on the telecontrol method being used.

To simplify the analysis, we replace link II by link II*, whose gain varies in accordance with the law

$$K_1^*(t)=Ae^{-\frac{t}{\tau}}. \tag{3}$$

The coefficients A and τ are so chosen than $K_1(0) = K_1^*(0)$ and $K_1(T) = K_1^*(T)$. Then

$$A=\frac{K_0}{a^r}, \qquad \tau=\frac{T}{\ln\left(1+\frac{T}{a}\right)^r}$$

and

$$K_1^*(t)=\frac{K_0}{a^r}\exp\left[-\frac{t}{T}r\ln\left(1+\frac{T}{a}\right)\right]. \tag{4}$$

It follows, from the properties of exponential functions, that

$$K_1^*(t) > K_1(T) \text{ for } 0 < t < T.$$

The system thus obtained, consisting of links I and II*, will be quasi-majorant* with respect to the initial system with link II.

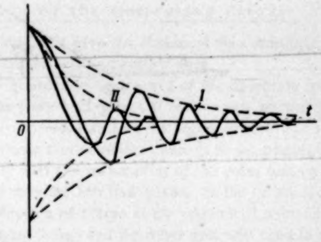

Fig. 1

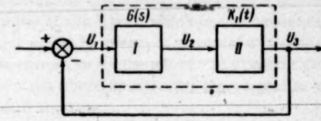

Fig. 2

Since function G(s) has no poles in the right half-plane, the closed-loop system with link II* (Fig. 2) will also be quasi-majorant with respect to the closed-loop system with link II.

If a signal $U_1(t)$ is applied to the input of link I of the open-loop system then, at the output of link II*, one obtains the signal $U_3(t)$, whose Laplace transform has the form:

$$U_3(s)=AG\left(s+\frac{1}{\tau}\right)U_1\left(s+\frac{1}{\tau}\right). \tag{5}$$

Thus, the exponentially decreasing gain is equivalent, in the open-loop system, to a shift to the left by the amount $1/\tau$ of all the zeros and poles of the transfer function and of the disturbing stimulus. It is obvious that, if the zeros and poles of the disturbing stimulus are

---

* A system will be called quasi-majorant with respect to another system if the envelope of the first system's transient response completely contains the transient response curve of the second (given) system. For example, the system which gives the transient response corresponding to curve I on Fig. 1 is quasi-majorant with respect to the system giving curve II for its transient response.

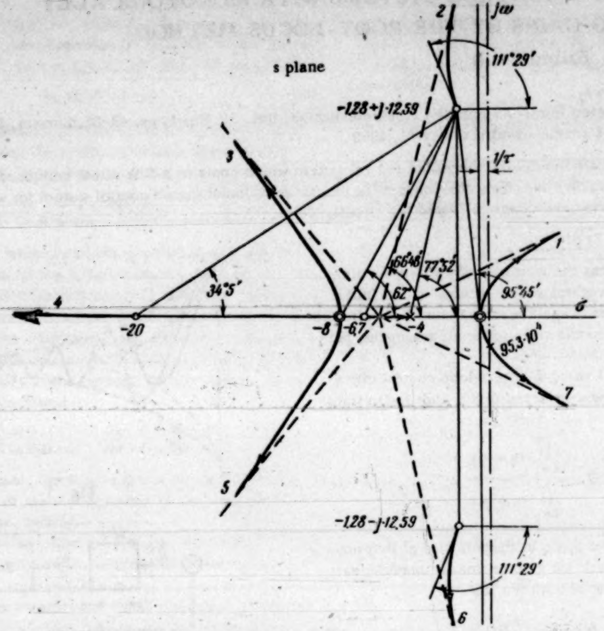

Fig. 3. O is a simple pole, ʘ is a double pole, and × is a simple zero.

shifted to the right by the same quantity, $1/\tau$, then the curve of $U_3^*(t)$ which one obtains in this case will be quasi-majorant with respect to curve $U_3(t)$ corresponding to Eq. (5). The system with open-loop transfer function $AG(s + 1/\tau)$ will, after closing the loop by a feedback path, be quasi-majorant with respect to the initial system (Fig. 2). Therefore, one can make certain estimates of stability and transient response quality for the initial system by investigating the quasi-majorant system obtained.

We use the following concrete example for showing the method of synthesizing such control systems.

Let link I's transfer function have the following form:

$$G(s) = \frac{(s+z_1)}{s^2(s+p_1)(s+p_2)^2(s+p_3)(s^2+2\zeta\omega_n s+\omega_n^2)}, \tag{6}$$

where $z_1 = 4$, $p_1 = 6.7$, $p_2 = 8$, $p_3 = 20$, $\zeta = 0.101$ and $\omega_n = 12.65$/sec.

The gain of link II varies in accordance with the following law:

$$K_1(t) = \frac{K_0}{t+a}, \tag{7}$$

where $K_0 = 2 \cdot 10^5$ and $a = 0.2$ sec. Operation time is $T = 10$ sec.

It is necessary to so choose a series-connected correcting circuit that, after closing the loop with a feedback path, one obtains a relative damping coefficient† for the system of not less than 0.2 for any pair of complex poles.

Root Motion Analysis of the Closed-Loop System

We draw the positions of the zeros and poles of function G(s) on the complex $s = (\sigma + j\omega)$ plane (Fig. 3). The arrows on the curves show the direction of motion of the poles as K_{syst} increases.

If the system is closed by a negative feedback path (Fig. 2) then, as the system gain K_{syst} increases from zero to infinity, the roots of the closed-loop system's characteristic equation (the poles of the closed-loop system) will move from the poles of the open-loop system to its zeros.

We now construct the trajectories of the roots as they move. The rules for constructing such trajectories have been published in the literature [1-5], so that we shall use them here without proof. As is well known, the number of individual trajectory branches tending to infinity equals the difference

---

† By the relative damping coefficient we understand the damping coefficient which corresponds to the presence of just one pair of complex poles.

q = (number of finite poles) –
– (number of finite zeros).

In our example, there will be seven such branches. For a sufficiently large gain K, these trajectory arms tend to asymptotes which start at one point on the real axis and form, with that axis, angles equal to ± [180°/ q + + i • 360°/ q], where i = 0, 1, 2, 3, . . . , etc.

We find the coordinate of the point of intersection of the asymptotes by the formula

$$s_1 = \frac{\Sigma(\text{poles}) - \Sigma(\text{zeros})}{q} =$$

$$= \frac{(-6.7 - 2.8 - 20 - 2\cdot 1.28) - (-4)}{7} = -5.89$$

and we draw the asymptotes at the angles (Fig. 3)

$$\theta_1 = \pm\frac{180^\circ}{7} = \pm 25^\circ 42',$$

$$\theta_3 = \pm\left(25^\circ 42' + \frac{360^\circ}{7}\cdot 2\right) = \pm 128^\circ 30',$$

$$\theta_2 = \pm\left(25^\circ 42' + \frac{360^\circ}{7}\right) = \pm 77^\circ 6',$$

$$\theta_4 = \pm\left(25^\circ 42' + \frac{360^\circ}{7}\cdot 3\right) = \pm 180^\circ.$$

All portions of the real axis lying to the left of an odd-numbered root (zero or pole), where the roots are counted starting from the far right, are parts of trajectories. We thus find that the pole at point s = −6.7 moves along the real axis to the zero at point s = −4, and the pole at point s = −20 tends to infinity along the real axis towards the left.

We now determine the slope of the trajectory starting from the pole s = −1.28 + 12.59j. To do this, we join this pole with the remaining roots and poles. The slope angle sought, θ, is found from the relationship

Σarg(vectors from zeros) – Σarg(vectors from poles) – θ° = 180° ± n · 360°.

In our case,

$$77^\circ 52' - [90^\circ + 2\cdot 95^\circ 45' + 66^\circ 48' +$$

$$+ 2\cdot 62^\circ + 34^\circ 5'] - \theta^\circ = 180^\circ + n\cdot 360^\circ,$$

$$\theta^\circ = -428^\circ 31' - 180^\circ \pm n\cdot 360^\circ = -248^\circ 31'$$

$$\text{or} \quad -111^\circ 29'.$$

We can now easily construct approximate trajectories of the roots' motion, as was done on Fig. 3. If all the curves are shifted to the left by the amount

$$\frac{1}{\tau} = \frac{\ln\left(1 + \frac{T}{a}\right)}{T} = \frac{\ln 51}{10} = 0.393$$

or, equivalently, the imaginary axis is shifted to the right by this amount, we obtain the root locus of the quasi-majorant system (Fig. 3).

A system with a constant gain will be unstable for any value of that gain, since the double pole at the origin will immediately enter into the right half-plane.

The quasi-majorant system becomes unstable for $K_{syst} \geq 95.3 \cdot 10^4$, as one may verify by determining the value of the gain for which the pole moving along arm I intersects the shifted imaginary axis. For this, we take the product of the lengths of the vectors from the poles to the point of intersection and divide this by the product of the lengths of the vectors from the zeros to this same point.

Choice of the Correcting Circuit

We first give the choice of the correcting circuit for a system with a constant gain.

In order to keep arm I of the trajectory from entering the right half-plane, it is necessary to introduce a zero on the real axis on the segment from 0 to s = − 6.7. The closer this additional zero is to the origin, the more sharply will the trajectories of the poles turn up from the origin into the left half-plane. In the limiting case, the introduction of a zero at the origin will neutralize one of the poles there, and the other pole will tend to the zero at the point s = − 4 along the real axis. The introduction of a zero at the origin means the introduction of a pure derivative of the signal, which can be accomplished in practice either by means of a special differentiating amplifier circuit, or by the use of tachometer generators in the cases where the circuit's input signal is in the form of a shaft rotation.

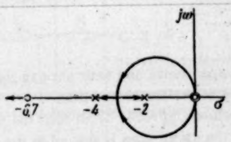

Fig . 4

For the realization of a zero on the real axis by a passive RC circuit, it is desirable that the zero not be too close to the origin. We shall introduce a zero at the point $s = -z_1^{*} = -2$. Then, an approximate sketch of the motion of the root in the neighborhood of the origin takes the form shown in Fig. 4.

For realizing this zero by means of a series-connected passive RC network, it is necessary that the transfer function of the correcting circuit have the form:

$$G_2(s) = \frac{(s + z_1^{*})}{(s + p_1^{*})} \frac{p_1}{z_1^{*}}.$$

It is desirable to choose the pole p_1^{*} sufficiently far from the origin so that the component of system behavior attributable to it will be rapidly damped. However, it is undesirable to remove it too far, since the

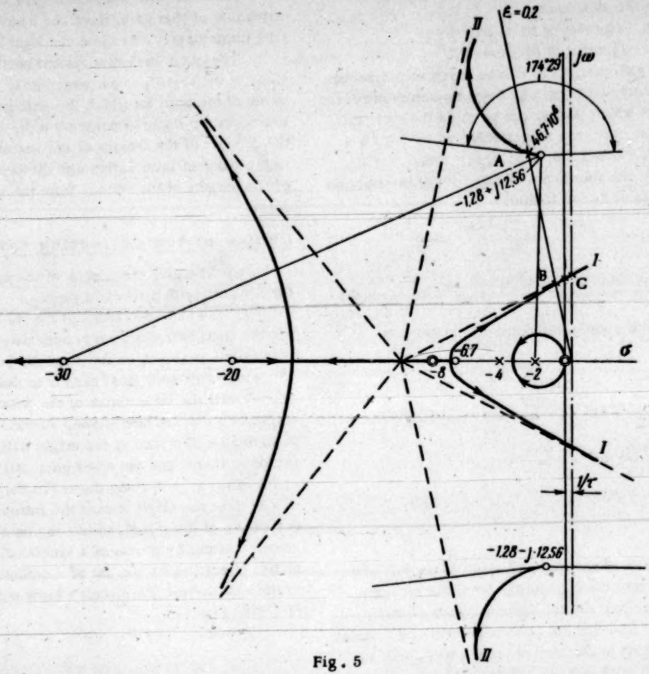

Fig. 5

requisite capacitance and resistance in the network would be difficult to realize in practice.

We choose $p_1^* = 30$. With this, the point of intersection of the asymptotes is shifted to the left by the amount $(p_1^* - z_1^*)/7 = (30-2)/7 = 4$.

The slopes of the asymptotes do not change. By again joining the pole and zero introduced with the point $s = -1.28 + 12.59j$, we find the additional rotation of the trajectory starting from the pole:

$\Delta\theta^\circ = \arg(\text{vector from } z_1^*) - \arg(\text{vector from } p_1^*) =$
$= 86^\circ 45' - 23^\circ 45' = 63^\circ$.

The root locus takes the form shown on Fig. 5. We now determine for what gain the poles of the closed-loop quasi-majorant system will lie on the intersections of the line of constant damping coefficient, $\xi = 0.2$, with trajectories I and II.

For point A we get

$$K_{\text{syst}} = \frac{30.6 \cdot 22 \cdot 14^2 \cdot 13.6 \cdot 13.1^2 \cdot 25 \cdot 4 \cdot 1}{13 \cdot 12.9} = 46.7 \cdot 10^6;$$

for point B

$$K_{\text{syst}} = \frac{29.8 \cdot 20 \cdot 8.72^2 \cdot 7.6 \cdot 4.7^2 \cdot 8.1 \cdot 9.2}{5.8 \cdot 4.8} = 20.5 \cdot 10^6.$$

At the boundary of stability of the quasi-majorant system (point C)

$$K_{\text{syst}} = \frac{30.8 \cdot 21 \cdot 9.8^2 \cdot 8.7 \cdot 5^2 \cdot 17.7 \cdot 7.8}{6.8 \cdot 5.6} = 49 \cdot 10^2.$$

For the quasi-majorant system, the required gain is

$$K_{\text{syst}} = \frac{p_1^*}{z_1^*} \frac{K_0}{a} = \frac{30}{2} \frac{2 \cdot 10^5}{0.2} = 15 \cdot 10^6.$$

Thus, the introduction of the correcting circuit provides system stability, but does not give the necessary damping coefficient.

We note that the introduction of zeros and poles on the real axis does not, in general, have much effect on the displacement of the complex poles when the gain is small, since they will be translated in a small neighborhood of the point $s = -1.28 \pm 12.59j$. Consequently, the sole means of obtaining the necessary damping coefficient is to eliminate these poles, which can be done by a correcting circuit with zeros at the points cited.

We thus obtain the following desirable transfer function for the correcting circuit:

$$G_2(s) = \frac{(s+2)\,(s^2 + 2\xi\omega_n s + \omega_n^2)\,15 p_2^* p_3^*}{(s+30)\,(s+p_2^*)\,(s+p_3^*)\,\omega_n^2}.$$

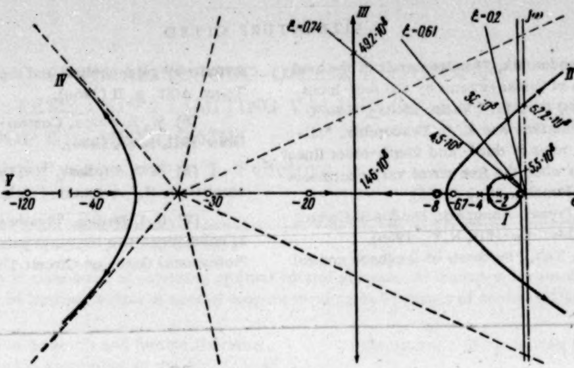

Fig. 6.

The poles at the points $-p_2^*$ and $-p_3^*$ are introduced in order to obtain a passive network realizable by capacitances and resistances. As a rule, these should be chosen further to the left than the original zeros and poles, in order that the components in the transient response introduced by them be rapidly damped. In addition, the introduction of these poles moves the point of intersection of the asymptotes to the left, which increases the system's stability.

We choose $p_2^* = 40$ and $p_3^* = 120$. Then, the open-loop circuit thus obtained will have the following transfer function:

$$G_{\text{syst}}(s) =$$

$$= \frac{K_{\text{syst}}\ (s+2)(s+4)}{s^2 (s+6.7)(s+8)^2 (s+20)(s+30)(s+40)(s+120)}.$$

The magnitude of K_{syst} for the quasi-majorant system (with the correcting circuit) will equal

$$K_{\text{syst}} = \frac{15 p_2^* p_3^*}{\omega_n^2} \frac{K_0}{a} = \frac{15 \cdot 40 \cdot 120}{12.65^2} \cdot \frac{2 \cdot 10^5}{0.2} = 4.5 \cdot 10^8.$$

The root locus of the closed-loop system is shown on Fig. 6. The values of the gains are given directly on the curves. The relative damping coefficient of any pair of complex poles is greater than 0.2. With this, the pair of poles on arm III of the trajectory provides a component of the transient response which is rapidly damped and has small oscillation. The poles on arm I provide a component which is small in magnitude (due to the proximity of the zeros at points -2 and -4) and which is slowly damped.

The roots on arms IV and V give very rapidly damped terms and do not have any practical effect on the system's transient response or frequency characteristic. Thus, the system obtained completely satisfies the requirements posed.

When the poles $-1.28 \pm 12.59j$ are not exactly compensated, there arises a slowly damped, rapidly oscillating, component of insignificant amplitude whose magnitude equals the residues at these poles, i.e., is proportional to the magnitude of the dipole obtained in this case [3, 5].

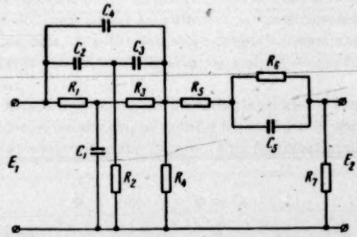

Fig. 7. R_1 = 11.6 kohm, R_2 = 1.1 kohm, R_3 = 23 kohm, R_4 = 11.3 kohm, R_5 = 22.5 kohm, R_6 = 832 kohm, R_7 = 17.7 kohm, C_1 = 2.5 μf, C_2 = 22 μf, C_3 = 1.1 μf, C_4 = 0.0725 μf, C_5 = 0.6 μf.

The correcting function is implemented by the network shown in Fig. 7. The synthesis of this network from the given function $G_2(s)$ was carried out by Dasher's method [7]. To connect the network in the circuit, it is necessary to equalize the gains of the network and of the function $G_2(s)$ since, for dc, $G_2(0) = 1$ and the network gives $E_2/E_1 = 0.005$. Consequently, it is necessary to connect in the circuit an amplifier with gain equal to

$$K_a = \frac{1}{0.005} = 200.$$

CONSTRUCTING OPTIMAL SECOND-ORDER AUTOMATIC CONTROL SYSTEMS USING LIMITING VALUES OF CONTROL LOOP ELEMENT GAINS

S. V. Emel'yanov and A. I. Fedotova

(Moscow)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 1, pp. 56-63, January, 1960)
Original article submitted June 20, 1959

The possibility is considered of obtaining optimal control processes in second-order automatic control systems with the use of limiting values of control loop element gains by means of nonlinear "key"-type correcting devices.

Recently, both in domestic and foreign literature, ever greater attention has been given to the questions of improving the quality of automatic control systems by means of the introduction of nonlinear transformers (function generators) which realize desirable control laws [1-10].

A significant number of works are devoted to the synthesis and realization of nonlinear control laws which provide for the flow of optimal transient responses in automatic control systems when there are limitations imposed on one or several of the systems' coordinates [11-18]. However, the question of constructing optimal automatic control systems using limiting values of control loop element gains has occupied comparatively little space.

The purpose of the present paper is to determine the control law (and also its realization) with which one can obtain optimal transient responses in second-order linear automatic control systems using limiting values of the systems' transmission coefficient.

For the systems under consideration here, we shall understand by optimal transient responses those transient responses which, for unit jump disturbances, have no overshoot, wherein the time during which the value of the controlled coordinate is less than some previously given constant value is minimal.

1. Construction of Optimal Transient Responses of Second-Order Automatic Control Systems Using Limiting Values of Transmission Coefficients

We consider a linear second-order automatic control system (Fig. 1) whose transmission coefficient is bounded.

The equations of the system's links can be written in the following form:

the equation of the object being controlled

$$T_a \dot{x} + \rho x = -\mu + f(t); \tag{1}$$

the equation of the executive mechanism

$$T_s \dot{\mu} = \xi; \tag{2}$$

the equation of the forcing device

$$x - g(t) = \varphi; \tag{3}$$

the equation of the summing device

$$\xi = K\varphi + T\dot{\varphi}.$$

Here, $\underline{x}$ is the relative deviation of the controlled coordinate, φ is the relative change of the error signal, μ is the relative deviation of the controlling organ, $1/\rho$ is the object's static transmission coefficient, T_a/ρ is the time constant of the object of control, T_s is the integration constant of the executive mechanism, K is the gain of the error signal amplifier, T is the differentiator's time constant, ξ is the summing device's output quantity, f(t) is the external disturbance and g(t) is the forcing stimulus.

After elimination of the variables $\underline{x}$ and μ from Eqs. (1)-(3), we obtain, by setting f(t) = g(t) = 0, the differential equation of the system's free (natural) oscillations.

$$\ddot{\varphi} + 2h\dot{\varphi} + \omega_0^2\varphi = 0.$$

Here,

$$2h = \frac{\rho}{T_a} + \frac{T}{T_a T_s}, \quad \omega_0^2 = \frac{K}{T_a T_s}. \tag{4}$$

In the automatic control system under consideration, let the coefficients T_a, T_s, and ρ be some constant numbers which depend on the design peculiarities of the object and the controller, and let the gains K and T be variable within the limits

$$-K_0 \leqslant K \leqslant K_0, \quad -T_0 \leqslant T \leqslant T_0,$$

where K_0 and T_0 are the limiting values of the actual system's gains.

It is required to determine the sequence of changes of the gains K and T during the flow of the transient response which is necessary for obtaining an optimal transient response in the system for stepwise changes in the magnitude of the disturbing stimulus f(t) or of the forcing function (stimulus) g(t). In other words, it is required to determine the nonlinear control law and its realization

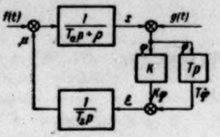

Fig. 1

for obtaining an optimal transient response in the automatic control system under investigation.

It is convenient to carry out the synthesis of a nonlinear control law for the class of systems under consideration by means of the phase plane method. Then, the problem posed is the construction of the automatic control system's phase plane which images the sequence of variations of the coefficients (structure) of the system during the transient response for various initial conditions.

The various combinations of signs of the coefficients K and T give four different system structures:

1) $K > 0, \quad T > 0$;
2) $K > 0, \quad T < 0$;
3) $K < 0, \quad T > 0$;
4) $K < 0, \quad T < 0$.

For the first case, the equation describing the free oscillations will have the form:

$$\ddot{\varphi} + 2h\dot{\varphi} + \omega_0^2\varphi = 0. \tag{5}$$

After the elimination of time from Eq. (5), we obtain the image of the transient response on the φ, $\dot{\varphi}$ plane.

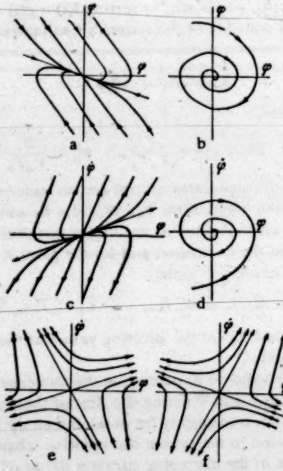

Fig. 2.

For $\omega_0^2 > h^2$, the equation of the phase trajectories will be the equation of the family of helices spiraling into the origin [6] (Fig. 2b):

$$(\dot{\varphi} + h\varphi)^2 + (\omega_0^2 - h^2)\varphi^2 = \\ = c \exp \frac{2h}{\sqrt{\omega_0^2 - h^2}} \quad \operatorname{arc\,tg} \frac{\dot{\varphi} + h\varphi}{\sqrt{\omega_0^2 - h^2}\,\varphi} \tag{6}$$

where $\underline{c}$ is a constant.

For $\omega_0^2 < h^2$, the equation of the phase trajectories will be the equation of a family of deformed parabolas tangent to the line $\dot{\varphi} = -q_1\varphi$ at the origin [11] (Fig. 2a):

$$\dot{\varphi} + q_1\varphi = c_1(\dot{\varphi} + q_2\varphi)^{\frac{q_1}{q_2}}. \tag{7}$$

Here,

$$q_1 = -h + \sqrt{h^2 - \omega_0^2},$$
$$q_2 = -h - \sqrt{h^2 - \omega_0^2},$$

and c_1 is a constant.

For the second case (if $T > \rho T_s$), the equation of the system's free oscillations will be

$$\ddot{\varphi} - 2h\dot{\varphi} + \omega_0^2\varphi = 0. \tag{8}$$

For $\omega_0^2 > h^2$, the phase trajectories are spirals starting from the origin (Fig. 2d) and, for $\omega_0^2 < h^2$, we obtain a family of parabola-like curves on the phase plane but, as it moves along any of the integral curves, the representative (image) point will move ever further from the equilibrium position (Fig. 2c).

In the third case, the equation of the free oscillations has the form:

$$\ddot{\varphi} + 2h\dot{\varphi} - \omega_0^2\varphi = 0. \tag{9}$$

The equation of the phase trajectories will be the equation of a family of deformed hyperbolas (Fig. 2e) [11]:

$$c_2(\dot{\varphi} - \varphi q_2')^{q_2'}(\varphi + \varphi q_.')^{q_1'} = 1. \tag{10}$$

Here, c_2 is a constant,

$$q_1' = -h + \sqrt{h^2 + \omega_0^2}, \quad q_2' = -h - \sqrt{h^2 + \omega_0^2}.$$

The equations of the asymptotes to the hyperbolas have the form:

$$\dot{\varphi} = -q_1'\varphi, \quad \dot{\varphi} = -q_2'\varphi. \tag{11}$$

And, for the fourth case, the equation of the system's free oscillations is written in the form

$$\ddot{\varphi} - 2h\dot{\varphi} - \omega_0^2\varphi = 0. \tag{12}$$

The equation of the phase trajectories will also be the equation of a family of deformed hyperbolas analogous to (10). These intervals will have other slopes for the asymptotes (Fig. 2f). For this family of curves, the asymptote equations are

$$\dot{\varphi} = -q_1^{*}\varphi, \quad \dot{\varphi} = -q_2^{*}\varphi. \tag{13}$$

Here,

$$q_1^{*} = h + \sqrt{h^2 + \omega_0^2}, \quad q_2^{*} = h - \sqrt{h^2 + \omega_0^2}.$$

We now determine the sequence of changes of the system's structure for which the image point will so move to the origin that the transient response will be optimal with respect to the controlled coordinate.

In the automatic control system under consideration, let there be applied a disturbing stimulus f(t) of the unit step type, which is equivalent to the presence of some nonzero initial conditions, specifically, $\dot{\varphi} = \varphi_0$, $\varphi = 0$. It is easily seen from a consideration of the phase trajectories (Fig. 2) that, for the image point to proceed to the equilibrium position with minimal deviation of the error φ during the duration of the transient response, with these initial conditions it must move in the region $\varphi\dot{\varphi} > 0$ along phase trajectories corresponding to an automatic control system with positive values of the coefficients K and T (Fig. 2a,b). With any other combination of signs for K and T, the image point would either move away from the equilibrium position (Fig. 2c,e,f) or have a large maximum deviation of the error φ during the transient response (Fig. 2d).

After the error signal reaches its maximum value ($\varphi = \varphi_{\max}$, $\dot{\varphi} = 0$) this discrepancy should be liquidated as soon as possible. In order that this requirement be met, the phase plane for $\varphi\dot{\varphi} < 0$ must be so constructed that, for given initial conditions, the area under the integral curve will be maximal, since it is well known that, in this portion of the phase plane, the duration of the control is inversely proportional to the area under the integral curve.

In order for the response to occur without overshoot, one of the components of the integral curve to be synthesized must pass through the origin in this region of the phase plane and, in order for the area under the integral curve to be maximal, it is necessary that the slope of this phase trajectory be as large as possible.

It is clear, from a consideration of the phase sketches (Fig. 2), that there are trajectories passing through the origin in the required portion of the phase plane for three different combinations of signs of K and T (Fig. 2a,e,f). It is easily remarked that the greatest slope of the null phase trajectory corresponds to the structure of the system with a positive value of the differentiator's time constant T and a negative gain K of the error signal (Fig. 2e).

As follows from Eqs. (9) and (11), the equation of such a phase trajectory has the form: $\dot{\varphi} = -q_2^{*}\varphi$. Here, $q_2^{*} = -h - \sqrt{h^2 + \omega_0^2}$.

The second component of the integral curve should be so chosen that the image point will travel from position $\varphi = \varphi_{\max}$, $\dot{\varphi} = 0$ along the null phase trajectory chosen by us with the largest possible value of the coordinate $\dot{\varphi}$. This also makes it possible to obtain the greatest area under the integral curve. From this point of view, those phase trajectories are most suitable which correspond to the unstable structural scheme with a positive value of K and a negative value of T (Fig. 2c and d).

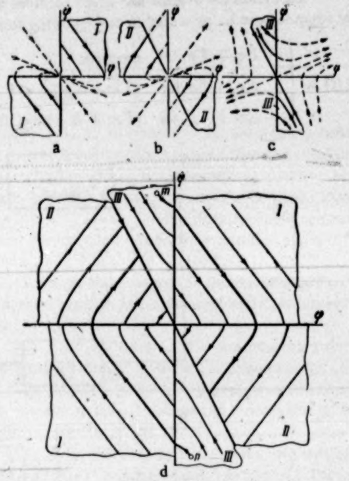

Fig. 3.

The process of constructing the phase "portrait" for obtaining an optimal transient response in the system is shown in Fig. 3a,b,c, and d.

Thus, the phase portrait of the optimal control system can be presented in the form of a three-sheeted phase surface (Fig. 3d).* The first sheet corresponds to the phase plane satisfying the condition $\varphi\dot{\varphi} \geq 0$ (Fig. 3a) and Eq. (5) for the free oscillations. The second sheet corresponds to the portion of the phase plane which satisfies the condition $(T_j\dot{\varphi} + K_j\varphi)\varphi < 0$ (Fig. 3b).

The constant coefficients T_j and K_j are so chosen that the boundary of the sheet, corresponding to the equation

$$T_j\dot{\varphi} + K_j\varphi = 0,$$

coincides with the phase trajectory described by the equation $\dot{\varphi} = -q_2^{*}\varphi$, where $q_2^{*} = -h - \sqrt{h^2 + \omega_0^2}$ (Fig. 2e), and passing through the origin.

The third sheet corresponds to the phase plane satisfying the condition $(T_j\dot{\varphi} + K_j\varphi)\varphi \leq 0$ (Fig. 3c). The boundary of the sheet, corresponding to the equation $T_j\dot{\varphi} + K_j\varphi = 0$ is common to the second and third sheets.

---

* The method of multisheeted phase surfaces, as applied to automatic control systems, has been worked out in [18-20].

Thus, it is clear from an analysis of the phase planes constructed, that the optimal control system changes its structure three times during the transient response when the system operates in the stabilization mode, and twice when the system operates in the tracking mode. In both cases, the disturbing action is taken to be in the form of unit jumps.

The nonlinear control law which provides this shift of structure can be presented in the following form:

$$\xi(t)=\begin{cases} K\varphi+T\dot{\varphi} & \text{for}\quad \varphi\dot{\varphi}\geqslant 0,\\ K\varphi-T\dot{\varphi} & \text{for}\quad (T_j\dot{\varphi}+K_j\varphi)\,\dot{\varphi}<0,\\ -K\varphi+T\dot{\varphi} & \text{for}\quad (T_j\dot{\varphi}+K_j\varphi)\,\varphi\leqslant 0.\end{cases}\qquad (14)$$

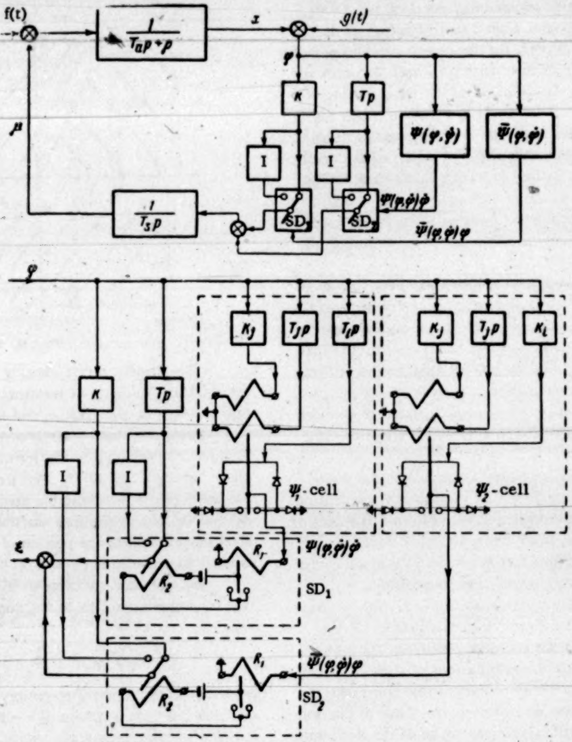

Fig. 4.

2. Realization of the Optimal Control Law

For the automatic control system to have the phase portrait shown in Fig. 3, it must contain a nonlinear correcting device which realizes the optimal control law given by (14). It follows from expression (14) that the nonlinear link must contain a switching device which varies the signs of the error signal and its derivative during the transient response as a function of their signs and relationships.

For the realization of this control law, we us a nonlinear "key"-type correcting device consisting of two monotypic Ψ-cells [4] (Fig. 4).

The first Ψ_1-cell passes the signal $\dot{\varphi}$ only under the condition $(T_j\dot{\varphi}+K_j\varphi)\dot{\varphi}\leq 0$, and the second Ψ_2-cell passes signal φ under the condition that $(T_j\dot{\varphi}+K_j\varphi)\varphi\leq 0$. The static characteristics of these nonlinear devices are shown in Fig.5.†

The signal from the output of these Ψ-cells acts on switching devices SD_1 and SD_2, consisting of the relay

---

† The nonlinear coefficients $\Psi(\varphi,\dot{\varphi})$ and $\bar{\Psi}(\varphi,\dot{\varphi})$ in the hatched portions of the $\varphi\dot{\varphi}$ plane equal the constant coefficients T_1 and K_1, respectively. In the nonhatched portions they equal zero.

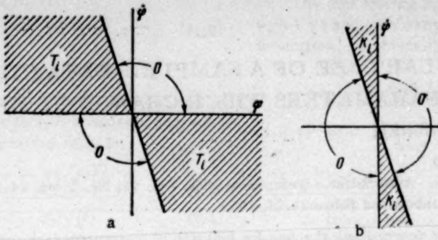

Fig. 5.

set R_1 and R_2. These devices provide the necessary changes in the signs of the error and its derivative by means of the inverter I.

The coefficients K_j and T_j of the correcting device are chosen on the basis of the relationship

$$\frac{K_j}{T_j} = h + \sqrt{h^2 + \omega_0^2}.$$

The connection between these coefficients and the system's parameters is defined by the following equation

$$\frac{K_j}{T_j} = \frac{T_s p + T}{2T_a T_s} + \sqrt{\frac{(T_s p + T)^2 + 4KT_a T_s}{4T_a^2 T_s^2}}. \quad (15)$$

Generally speaking, coefficients T_i and K_i can be chosen arbitrarily as functions of the dead zones of relays R_1 and R_2.

ON ONE PARTICULAR CASE OF A SAMPLED-DATA SYSTEM WITH VARIABLE PARAMETERS WHICH CHANGE BY JUMPS

V. I. Teverovskii

(Dnepropetrovsk)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 1, pp. 64-71, January, 1960)
Original article submitted February 26, 1959

A method is given for determining the transfer function of a sampled-data system with periodically varying parameters in the particular case when the system is comprised of a series connection of a first-order link with variable parameters and links with constant parameters.

Among systems with variable parameters, a special place is occupied by systems whose parameters vary periodically at the pulse repetition frequency, remaining constant during the pulses and in the intervals between pulses, and changing by jumps at the boundaries of these time segments. Works by F. M. Kilin, E. A. Rozenman, and others have been devoted to these systems. A method for designing such systems in the general case was given in [1]. This method leads to cumbersome computations. In [2] Ya. Z. Tsypkin presented a simple method for investigating first-order systems.

The attempt is made in the present work to design sampled-data systems with periodically varying parameters for the very important particular case when only one root of the characteristic equation changes. As will be shown, this means physically that the system consists of a series connection of a first-order link with variable parameters and a system with constant parameters.

1. The First-Order Link*

We consider a link described by the equation

$$(q-q_0)\,x(\bar{t}) = -kq_0 f(\bar{t}). \qquad (1.1)$$

Here and in the sequel we shall use the dimensionless variables $\bar{t} = t/T$, $q = pT$ $(p = d/dt)$, where T is the repetition period of the input pulses.

The parameters q_0 and $\underline{k}$ are variable, and are subject to the following relationships:

$$\left.\begin{aligned} q_0 &= q_1 \\ k &= k_1 \end{aligned}\right\} \text{ for } n \leqslant t \leqslant n+\gamma,$$

$$\left.\begin{aligned} q_0 &= q_1' \\ k &= k_1' \end{aligned}\right\} \text{ for } n+\gamma < \bar{t} < n+1.$$

Here, $n = 0, 1, 2, \ldots$, $\gamma = \tau/T$, τ is the duration of the input pulses,

$$f(\bar{t}) = f[n] \quad \text{for} \quad n \leqslant \bar{t} \leqslant n+\gamma$$

and

$$f(\bar{t}) = 0 \quad \text{for} \quad n+\gamma < \bar{t} < n+1.$$

By solving Eq. (1.1) for the interval $(n, n+\gamma)$ with initial condition x[n] and for the interval $(n+\gamma, n+1)$ with initial condition $x[n+\gamma]$, and by also taking into account that no jump in the initial conditions occurs at the boundary of the intervals cited, we obtain the difference equation

$$x[n+1] = \\ = k_1 f[n]\left(1-e^{q_1\gamma}\right)e^{q_1'(1-\gamma)} + x[n]\,e^{q_1\gamma + q_1'(1-\gamma)}. \qquad (1.2)$$

If we take the discrete Laplace transform of Eq.(1.2 taking into account the lead theorem and the condition x(0) = 0 [3], we obtain

$$X^*(q) = k_1\frac{\left(1-e^{q_1\gamma}\right)e^{q_1'(1-\gamma)}}{e^q - e^{q_{1\,\mathrm{av}}}}\,F^*(q), \qquad (1.3)$$

where $X^*(q)$ and $F^*(q)$ are the discrete Laplace transform of the step functions x[n] and f[n], respectively, and

$$q_{1\,\mathrm{av}} = q_1\gamma + q_1'(1-\gamma).$$

Consequently, the transfer function of the first-orde sampled-data system with variable parameters has the form:

$$W^*(q) = k_1\frac{\left(1-e^{q_1\gamma}\right)e^{q_1'(1-\gamma)}}{e^q - e^{q_{1\,\mathrm{av}}}}. \qquad (1.4)$$

We now determine the impulsive response of system (1.4) at an arbitrary moment of time.

Letting $\bar{t} - n = \varepsilon$, we get

$$w[n,\varepsilon] = k_1\left(e^{-q_1\gamma} - 1\right)e^{q_{1\,\mathrm{av}}n}e^{q_1\varepsilon} \qquad (0 \leqslant \varepsilon \leqslant \gamma,\ \ n > 0), \qquad (1.5)$$

$$w[n,\varepsilon] = k_1\left(1-e^{q_1\gamma}\right)e^{q_{1\,\mathrm{av}}n}e^{q_1'(\varepsilon-\gamma)} \qquad (\gamma < \varepsilon < 1, n > 0), \qquad (1.6)$$

$$w[0,\varepsilon] = k_1\left(1-e^{q_1\varepsilon}\right) \qquad (0 \leqslant \varepsilon \leqslant \gamma). \qquad (1.7)$$

---

* The investigation of such links was provided in [2].

$$w[0, \varepsilon] = k_1 (1 - e^{q_1\gamma}) e^{q_1'(\varepsilon-\gamma)}$$

$$(\gamma < \varepsilon < 1). \qquad (1.8)$$

2. The Second-Order System

We now consider the second-order system consisting of a series connection of the link with variable parameters and a link with constant parameters (Fig. 1):

$$(q - q_{10}) x_1(\bar{t}) = - k q_{10} f(\bar{t}),$$

$$(q - q_2) x(\bar{t}) = - q_2 x_1(\bar{t}). \qquad (2.1)$$

Here, q_2 = const, $q_{10} = q_1$, and $k = k_1$ when $n \leq \bar{t} \leq n + \gamma$, $q_{10} = q_1'$ and $K = k_1'$ when $n + \gamma < \bar{t} < n + 1$.

Fig. 1.

We now determine the impulsive response of the system described by Eqs. (2.1).

In this case, the input to link 2 with constant parameters is signal $x_1(\bar{t})$, the impulsive response of link 1 with variable parameters [cf. Eqs. (1.5)-(1.8)]:

$$(q - q_2) w_2[n, \varepsilon] = - q_2 w_1[n, \varepsilon]. \qquad (2.2)$$

The solution is carried out for the time interval (n, n + 1).

The result of solving Eq. (2.2) with initial condition $w_2[n]$ is

$$w_2[n + \gamma] = k_1 (e^{-q_1\gamma} - 1) \frac{q_2}{q_1 - q_2} (e^{q_2\gamma} - e^{q_1\gamma}) \times$$

$$\times e^{q_1 a v^n} + w_2[n] e^{q_2\gamma}.$$

By now solving Eq. (2.2) with initial condition $w_2(n + \gamma)$ and then carrying out some elementary transformations, we obtain the following difference equation:

$$w_2 \, n + 1] = w_2[n] e^{q_2} -$$

$$- k_1 (e^{-q_1\gamma} - 1) \frac{q_2}{q_1 - q_2} (e^{q_2(1-\gamma)+q_1\gamma} - e^{q_2}) e^{q_1 a v^n} -$$

$$- k_1 (1 - e^{q_1\gamma}) (e^{q_1'(1-\gamma)} - e^{q_2(1-\gamma)}) \frac{q_2}{q_1' - q_2} e^{q_1 a v^n}. \qquad (2.3)$$

As is well known, one gives the name operator, or transfer function, of a sampled-data system to a series of the form

$$W^*(q) = \sum_{n=1}^{\infty} w[n] e^{-qn} \quad \text{for} \quad w(0) = 0, \qquad (2.4)$$

where w[n] is the impulsive response of the corresponding continuous system.

It may be easily shown that

$$\sum_{n=1}^{\infty} w[n+1] e^{-qn} = e^q \sum_{n=1}^{\infty} w[n] e^{-qn} - w[1]. \qquad (2.5)$$

Indeed, by making the substitution n = k - 1, we get

$$\sum_{n=1}^{\infty} w[n+1] e^{-qn} = e^q \sum_{k=2}^{\infty} w[k] e^{-qk}.$$

By adding and subtracting w[1] in the right member, we obtain (2.5).

If we multiply both sides of Eq. (2.3) by e^{-qn} and then sum them over n from 1 to infinity, taking into account (2.5) and the equality [3], we get

$$\sum_{n=1}^{\infty} e^{\alpha n} e^{-qn} = \frac{e^{\alpha}}{e^q - e^{\alpha}},$$

$$W_2^*(q) = k_1 \frac{\left[(1 - e^{-q_1\gamma})(e^{q_2(1-\gamma)+q_1\gamma} - e^{q_2}) \frac{q_2}{q_1 - q_2} + (e^{q_1\gamma} - 1) \frac{q_2}{q_1' - q_2} (e^{q_1'(1-\gamma)} - e^{q_2(1-\gamma)})\right] e^{q_1 a v}}{(e^q - e^{q_2})(e^q - e^{q_1 a v})} + \frac{w_2[1]}{e^q - e^{q_2}}; \qquad (2.6)$$

$w_2[1]$ is determined analogously to $w_2[n + 1]$ on the basis of expressions (1.7) and (1.8), account being taken of the fact that $w_2(0) = 0$.

As the result, we obtain

$$w_2[1] = k_1 \frac{q_2 (q_1 - q_2) e^{q_1 a v} - q_1 (q_1' - q_2) e^{q_2} + q_2 (q_1' - q_1) e^{q_1\gamma + q_2(1-\gamma)}}{(q_1 - q_2)(q_1' - q_2)} + \frac{(q_2 - q_1)(q_2 e^{q_1'(1-\gamma)} - q_1' e^{q_2(1-\gamma)})}{(q_1 - q_2)(q_1' - q_2)}. \qquad (2.7)$$

By taking (2.7) into account, we obtain the final expression for $W_2^*(q)$:

$$W_2^*(q) = k_1 \frac{b_1 e^q + b_0}{(e^q - e^{q_2})(e^q - e^{q_1 a v})}, \qquad (2.8)$$

where

$$b_0 = e^{q_2 + q_1 a v} + \frac{q_2 e^{q_2 + q_1'(1-\gamma)} - q_1 e^{q_1 a v + q_2(1-\gamma)}}{q_1 - q_2}; \qquad (2.9)$$

$$b_1 = \frac{w_2[1]}{k_1}. \qquad (2.10)$$

If the system is astatic and its linear portion has a transfer function of the form

$$W_a(q) = \frac{-kq_{10}}{(q-q_{10})\,q}, \qquad (2\ 11)$$

it is then easily seen that the corresponding discrete transfer function can be obtained by passing to the limit:

$$W^*_a(q) = \lim_{q_2 \to 0}\left[-\frac{1}{q_2}W^*_2(q)\right]. \qquad (2.12)$$

By carrying out some elementary transformations, we get

$$W^*_a(q) = k_1\frac{[(\dot{q}'_1-q_1)(1-e^{q_1\gamma}) + q_1(e^{\dot{q}'_1(1-\gamma)} - e^{q_1\mathrm{av}}) + \gamma q_1 q'_1]\,e^q}{q_1 q'_1 (e^q - e^{q_1\mathrm{av}})(e^q-1)} + \frac{q'_1(e^{q_1\mathrm{av}} - e^{\dot{q}'_1(1-\gamma)} - \gamma q_1 e^{q_1\mathrm{av}})}{q_1 q'_1 (e^q - e^{q_1\mathrm{av}})(e^q-1)}. \qquad (2.13)$$

In the very important particular case when $\gamma \ll 1$, the expression for $W^*(q)$ is significantly simplifed. By taking into account that $e^{q_i\gamma} \approx 1 + q_i\gamma$ (if $|q_i\gamma| \ll 1$), we get

$$W^*_2(q) = k_1\frac{\gamma q_1 q_2 (e^{q_1} - e^{q_2})e^q}{(q'_1-q_2)(e^q - e^{q_1\mathrm{av}})(e^q - e^{q_2})}. \qquad (2.14)$$

3. A System of Arbitrary Order with One Variable Root of the Characteristic Equation

Let there be given a system of arbitrary order r. One of the roots of the system's characteristic equation is variable, all the roots being assumed to be simple. It may then be shown that the system takes the form of a series connection of a variable link 1 and a constant portion 2 which is described by an equation of order (r-1).

Fig. 2.

The transfer function of link 1 (Fig. 2) is

$$W_1(q) = -k_1\frac{q_{10}}{q-q_{10}}, \qquad (3.1)$$

where q_{10} is the variable root, assuming the values of q_1 and q_1^*.

The transfer function of the constant portion 2 is

$$W_{r-1}(q) = \frac{P(q)}{Q(q)}, \qquad (3.2)$$

where P(q) and Q(q) and polynomials in q, the order of P(q) being less than the order of Q(q).

Then,

$$W_{r-1}(q) = \frac{P(q)}{Q(q)} = \sum_{k=1}^{r-1}\frac{P(q_k)}{Q'(q_k)}\frac{1}{q-q_k} = \sum_{k=1}^{r-1}\frac{c_k}{q-q_k}, \qquad (3.3)$$

where q_k are the roots of the equation $Q(q) = 0$, $Q'(q_k) = dQ(q)/dq\,|_{q=q_k}$.

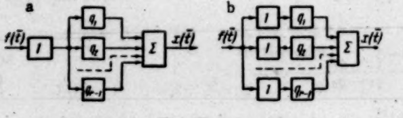

Fig. 3.

On the basis of (3.3), the block diagram of the system may be given as shown on Fig. 3 a.†

On Fig. 3 a, $q_1, q_2, \ldots, q_{r-1}$ denote the links whose transfer functions are the terms of sum (3.3); Σ is a summing device.

Obviously, the processes in the system are not changed if the block schematic is varied so as to take the form shown in Fig. 3 b. But, it is clear from Fig.3 b, that an rth-order system with variable parameters can be given in the form of a parallel connection of r-1 second-order systems and, consequently, the discrete transfer function of such a system has the form:

$$W^*(q) = \sum_{k=1}^{r-1} c_k W^*_k(q), \qquad (3.4)$$

where

$$W^*_k(q) = -\frac{1}{q_k}\frac{b_{1k}e^q + b_{0k}}{(e^q - e^{q_1\mathrm{av}})(e^q - e^{q_k})},$$

$$b_{1k} = \frac{q_1(q_k - q'_1)e^{q_k} + q_k(q'_1 - q_1)e^{q_k(1-\gamma)+q_1\gamma}}{(q_1-q_k)(q'_1-q_k)} + \frac{q_k(q_1-q_k)e^{q_1\mathrm{av}} + (q_1-q_k)(q'_1 e^{q_k(1-\gamma)} - q_k e^{\dot{q}'_1(1-\gamma)})}{(q_1-q_k)(q'_1-q_k)}$$

$$b_{0k} = e^{q_1\mathrm{av}+q_k} + \frac{q_k e^{q_k+\dot{q}'_1(1-\gamma)} - q_1 e^{q_1\mathrm{av}+q_k(1-\gamma)}}{q_1-q_k}. \qquad (3.5)$$

If $q_k = 0$, then expression (2.13) can be used for computing $W^*_k(q)$.

If $\gamma \ll 1$, then $W^*_k(q)$ can be computed by formula (2.14) by replacing q_2 by q_k in its right member and dividing by $(-q_k)$.

---

† A similar representation of the schematic is given in [1].

Up till now, we have assumed that the first link is a simple inertial one. If, however, the transfer function of this link has the form:

$$W_1(q) = k_1 \frac{q + \alpha}{q + \beta}, \tag{3.6}$$

where k_1, α, and β are variable parameters, then the link may be presented in the form of a parallel connection of an inertial link and an ideal amplifier with variable parameters:

$$W_1(q) = k_1 - k_1 \frac{\beta - \alpha}{q + \beta}. \tag{3.7}$$

Since the input to the variable system is $f(\bar{t})$ at times $n + \gamma < \bar{t} < n + 1$, varying the amplifier parameters does not affect the process, and the discrete transfer function of the second-order system whose first link has a transfer function of the form (3.7) is obtained in the form of a difference of the discrete first-order transfer function corresponding to the second link, but multiplied by k_1, and the discrete transfer function of the second-order system whose first link has a transfer function of the form $k_1(\beta - \alpha)/(q + \beta)$.

Thus, for a sampled-data system with periodically varying parameters, it is sufficiently simple to determine the discrete transfer function which has constant parameters (in the case when only one root of the characteristic equation varies). It is particularly simple to obtain the expression when the pulses are of short duration ($\gamma \ll 1$).

In conclusion, we consider an example of the application of the method presented above.

4. Transient Response in a Radar Range Finder

The range finder's operation is based on the comparison of the position of the pulse reflected from the target with the position of a pair of special selector pulses – semistrobe S and the translation of S after the translation in time of the echo pulse EP.

Fig. 4.

The block schematic of the range-finder is given in Fig. 4.

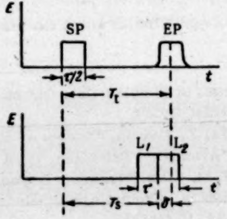

Fig. 5.

The scheme shown does not, of course, represent the contemporary state of radar technology, but is very convenient as an example of the application of the method presented here.

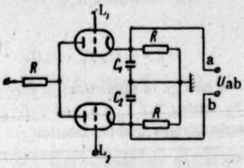

Fig. 6.

The nomenclature used on Fig. 4 is as follows: ED is the error discriminator, A is an amplifier, EM is the executive mechanism, T_t is the temporal position of the middle of the echo pulse from the target with respect to the sonde pulse SP, and T_s is the position of the semistrobe boundary (Fig. 5). The ED processes the voltage proportional to the quantity $\delta = T_t - T_s$. We now consider one discriminator circuit (Fig. 6).

Tubes L_1 and L_2 are normally cut off, and are opened by the semistrobes. If the center of the EP coincides with the boundary of a semistrobe, the charges taken by capacitors C_1 and C_2 during a period are equal, and $U_{ab} = 0$.

If the EP is displaced relative to the semistrobes, the charges taken by C_1 and C_2 are unequal, and $U_{ab} \neq 0$.

It is easily seen that the error discriminator parameters are different when the semistrobes are present from what they are when the semistrobes are absent.

Strictly speaking, the system under consideration is a system with pulse-width modulation (PWM). But with low porosity $\gamma = \tau/2T_r$ (τ is the total length of the semistrobes and T_r is the repetition period of the sonding pulses) and if the condition $\tau/2 \ll T_c$ holds (T_c is the time constant of the charging of capacitors $C_1 = C_2 = C$), one can replace the system with PWM by a system with pulse-amplitude modulation with a constant pulse duration equal to $\tau/2$. Moreover, the time for switching the discriminator parameters is defined by the duration of the semistrobes $\tau/2 = \text{const}$.

From what has been said above, we obtain the following equations for the discriminator.

$$(T_c p + 1) U_{ab} = k_1 \frac{R}{R + R_1} \delta \quad \text{for} \quad nT_r \leqslant t \leqslant nT_r + \frac{\tau}{2} \tag{4.1}$$

and

$$(T_p p + 1) U_{ab} = 0 \quad \text{for} \quad nT_r + \frac{\tau}{2} < t < (n + 1) T_r \tag{4.2}$$

Here, $k_1 = 4E/\tau$, E is the amplitude of the echo pulse at the discriminator's input,

$$T_c = \frac{CRR_1}{R + R_1} \approx CR_1, \quad T_p = RC.$$

The amplifier and the executive mechanism are links with constant parameters. Their equations are, respectively,

$$U_2 = k_2 U_{\text{ab}}, \tag{4.3}$$

$$(T_M p + 1)\, p T_s = k_3 U_2. \tag{4.4}$$

We now go to dimensionless parameters.

By letting $T_r / T_p = a_1$ and $T_c / T_p = \alpha$, we obtain the discriminator's transfer function:

$$W_1(q) = k_1 \frac{(1-\alpha')\,\frac{a_1}{\alpha'}}{q + \frac{a_1}{\alpha'}}, \tag{4.5}$$

where $\alpha' = \alpha$ for $n \le \bar{t} \le n + \gamma$ and $\alpha' = 1$ for $n = \gamma < \bar{t} < n + 1$.

The transfer function of the amplifier and the EM takes the form

$$W_2(q) = \frac{k_2 k_3 T_r \; a_2}{(q + a_2)\, q} = k_2 k_3 T_r \left(\frac{1}{q} - \frac{1}{q + a_2}\right). \tag{4.6}$$

By taking into account that $\gamma \ll 1$ and using formula (2.14), we obtain the transfer function of the open-loop sampled-data system in the form

$$W^*(q) = k_1 k_2 k_3 T_r\,(1-\alpha)\,\frac{\gamma}{\alpha}\left[\frac{(1-e^{-a_2})\,e^q}{(e^q - e^{-a_{1\,\text{av}}})(e^q - 1)} - \frac{a_1 (e^{-a_1} - e^{-a_2})\,e^q}{(a_2 - a_1)(e^q - e^{-a_2})(e^q - e^{-a_{1\,\text{av}}})}\right].$$

where

$$a_{1\,\text{av}} = \frac{a_1}{\alpha}\gamma + a_1(1-\gamma) \approx a_1\left(1 + \frac{\gamma}{\alpha}\right).$$

After some elementary transformations, we finally obtain

$$W^*(q) = k\,\frac{\left(1 - \frac{a_1 e^{-a_2} - a_2 e^{-a_1}}{a_1 - a_2}\right) e^{2q} + \left(e^{-(a_1 + a_2)} - \frac{a_1 e^{-a_2} - a_2 e^{-a_1}}{a_1 - a_2}\right) e^q}{(e^q - e^{-a_{1\,\text{av}}})(e^q - e^{-a_2})(e^q - 1)}. \tag{4.7}$$

If the transfer function of the open-loop sampled-data system has the form:

$$W^*(q) = k\,\frac{B_2 e^{2q} + B_1 e^q}{A_3 e^{3q} - A_2 e^{2q} + A_1 e^q - A_0},$$

then, starting from the analogy of the Nyquist criterion, one can show that the following inequality must hold in order that the closed-loop system be stable:

$$k < \left|\frac{A_0^2 + A_1 A_3 - A_0 A_2 - A_3^2}{A_0 B_2 + A_3 B_1}\right|. \tag{4.8}$$

For the given case, inequality (4.8) takes the form

$$k < \frac{(1 - e^{-(a_2 + a_{1\,\text{av}})})(e^{-a_2} + e^{-a_{1\,\text{av}}} - e^{-(a_2 + a_{1\,\text{av}})})}{e^{-(a_2 + a_{1\,\text{av}})}\left(1 - \frac{a_1 e^{-a_2} - a_2 e^{-a_1}}{a_1 - a_2}\right) + e^{-(a_1 + a_2)} - \frac{a_1 e^{-a_2} - a_2 e^{-a_1}}{a_1 - a_2}}. \tag{4.9}$$

If $a_2 \ll 1$ and $a_1 \ll 1$, which corresponds to $T_p \gg T_r$ and $T_M \gg T_r$, then inequality (4.9) simplifies to

$$k < \frac{(1 - e^{-a_{1\,\text{av}}})(1 - e^{-a_{1\,\text{av}}} + a_2 e^{-a_{1\,\text{av}}})}{a_1}. \tag{4.10}$$

If the condition $a_{1\,\text{av}} \ll 1$ also holds, then condition (4.9) takes the form:

$$k < \frac{a_2 a_{1\,\text{av}} + a_{1\,\text{av}}^2}{a_1}. \tag{4.11}$$

In conclusion, the author wishes to express his gratitude to Ya. Z. Tsypkin for his aid in the preparation of this paper.

ON METHODS OF SIMULATING RATIONAL-FRACTION FUNCTIONS WITHOUT THE USE OF DIFFERENTIATING ELEMENTS

B. Ya. Kogan

(Moscow)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 1, pp. 72-81, January, 1960)
Original article submitted June 2, 1959

Methods of simulating rational-fraction transfer functions without the use of differentiating elements when the original differential equations contain constant and variable coefficients are compared. It is asserted that the minimum number of operational amplifiers required is n + 3, where n is the order of the differential equation. For simplicity of the circuit and for the minimum amount of preliminary calculation, the method of combining derivatives is preferable for constant coefficients, whereas the method of going over to the equivalent system of first-order equations is preferable when the coefficients are variable.

In the investigation of automatic control and regulation systems by means of electronic analog computers, the necessity frequently arises of reproducing rational-fraction transfer functions of the form

$$W(s) = \frac{b_m s^m + b_{m-1} s^{m-1} + \cdots + b_1 s + b_0}{s^n + a_{n-1} s^{n-1} + \cdots + a_1 s + a_0}, \quad (1)$$

where

$$m \leqslant n,$$

and $b_m, b_{m-1}, \ldots, b_1, b_0$ and $a_{n-1}, a_{n-2}, \ldots, a_1, a_0$ are given constant coefficients.

Transfer functions of this type are obtained, for example, from the approximate representation of lags by a Padé series, the synthesis of correcting circuits, and a number of problems in the statistical dynamics of automatic control systems.

The use of differentiators in the setups for these transfer functions is proscribed because of the sharp amplification of the noise which is always found in the output signals of operational amplifiers, the representation of the right members as given functions of time being possible only in a very limited number of cases when the law of change of the input signal is known beforehand.

Various methods of reproducing these transfer functions using only integrating and adding elements are known from the literature [1-4]. These methods can be reduced to four basic ones:

1) direct integration;

2) decomposition of the transfer function into simpler ones (method of structure transformation);

3) decomposition into first-order equations;

4) combination of derivatives.

In the literature, these methods were not compared among themselves, and some of them were mentioned only superficially. It is also of interest to establish the possibility of extending them to the case when the coefficients of the differential equation giving rise to (1) are given functions of time.

1. Method of Direct Integration

It is convenient to consider this method in terms of the simple example of the equation

$$_3y''' + a_2y'' + a_1y' + a_0y =$$
$$= b_0x + b_1x' + b_2x'' + b_3x'''$$

with given constant coefficient a_0, a_1, a_2, and a_3, and b_0, b_1, b_2, and b_3, initial conditions $y(0)$, $y'(0)$, and $y''(0)$, and a disturbance x whose dependence on time is not given beforehand.

We solve the initial equation for the difference of the highest derivatives:

$$a_3y''' - b_3x''' =$$
$$= -(a_2y'' - b_2x'') - (a_1y' - b_1x') - (a_0y - b_0x).$$

By introducing the symbolic integration operator $\int dt = 1/p$, $\int\int dt\, dt = 1/p^2$, etc., we obtain

$$a_3y - b_3x = -\frac{1}{p}(a_2y - b_2x) -$$
$$- \frac{1}{p^2}(a_1y - b_1x) - \frac{1}{p^3}(a_0y - b_0x). \quad (2)$$

In order to retain the initial values of the coefficients a_0, a_1, a_2, a_3, b_0, b_1, b_2, and b_3 in the setup of the problem, we add the term $-(a_2-1)y$ to the right and left sides of expression (2). The result is

$$y = -\frac{1}{p}(a_2y - b_2x) - \frac{1}{p^2}(a_1y - b_1x) -$$
$$- \frac{1}{p^3}(a_0y - b_0x) + b_3x - (a_3 - 1)y. \quad (3)$$

Expression (3) allows the structural scheme (block schematic) of the setup to be given directly. Indeed, if we denote by the new variable z_1 the sum of all the terms in (3) which contain the symbol for integration, we obtain the equation

$$y = z_1 + b_3x - (a_3 - 1)\,y. \tag{4}$$

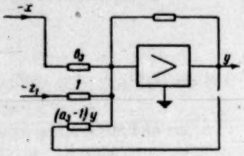

Fig. 1.

The quantity y, in correspondence with (4), can be formed by means of an adder, as shown on Fig. 1. It should be mentioned that such a method for isolating y gives a stable setup only in case $a_3 > 1$. If $a_3 < 1$, it is necessary to divide all the coefficients by a_3 as a preliminary step. With this, there is no longer the necessity of introducing the term $(a_3-1)y$ and, in the problem setup, there appear the new values of the coefficients:

$$\frac{a_2}{a_3},\quad \frac{a_1}{a_3},\quad \frac{a_0}{a_3};\quad \frac{b_0}{a_3},\quad \frac{b_1}{a_3},\quad \frac{b_2}{a_3},\quad \frac{b_3}{a_3}.$$

For the further construction of the scheme, we determine the value of the product pz_1:

$$pz_1 = -(a_2y - b_2x) - \frac{1}{p}(a_1y - b_1x) - \frac{1}{p^2}(a_0y - b_0x).$$

By introducing the notation

$$z_2 = -\frac{1}{p}(a_1y - b_1x) - \frac{1}{p^2}(a_0y - b_0x),$$

we get

$$pz_1 = -(a_2y - b_2x) + z_2. \tag{5}$$

Consequently, it is necessary to add an integrator to the schematic of Fig. 1. By continuing similarly, we arrive at the expression

$$pz_2 = -(a_1y - b_1x) + z_3, \tag{6}$$

where

$$pz_3 = -(a_0y - b_0x),\quad z_3 = -\frac{1}{p}(a_0y - b_0x).$$

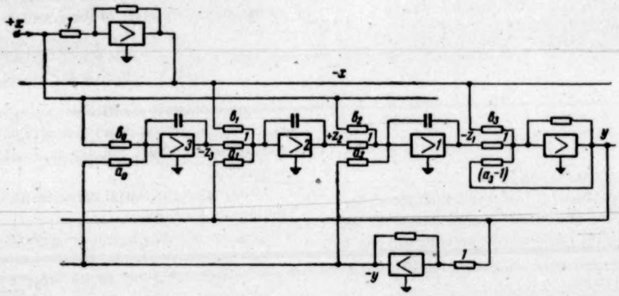

Fig. 2.

Equations (4), (5), and (6) lead directly to the setup shown on Fig. 2. For m = n, the total number of blocks required here is n + 3. For m < n, one can obviously dispense with the output adder, so that the number of blocks will be n + 2.

The initial conditions for integrators 1, 2, and 3 can be computed by giving the relationships for z_1, z_2, and z_3 in the form

$$z_1(0) = a_3y(0) - b_3x(0),$$

$$z_2(0) = a_3y'(0) - b_3x'(0) + a_2y(0) - b_2x(0),$$

$$z_3(0) = a_3y''(0) - b_3x''(0) + a_2y'(0) - b_2x'(0) + a_1y(0) - b_1x(0).$$

The regularities apparent in the relationships given allow one to write directly the relationships for the initial conditions for the kth integrator:

$$z_k(0) = z_{n-j} = \sum_{1}^{n-j}\left[a_{(i+j)}y^{(i-1)}(0) - b_{(i+j)}x^{(i-1)}(0)\right], \tag{7}$$

where j = n − k, i = 1, 2, 3, . . .

The basic advantage of the method just considered is that the setup is implemented from the original coefficients, and the computation of the initial conditions is carried out with comparative simplicity.

2. Decomposition of the Transfer Function into Simpler Ones

The basis of this method is that any transfer function W(s) can be considered as the transfer function of some single-loop system with negative feedback, in which the forward path has transfer function $W_1(s)$ and the feedback path has transfer function $W_2(s)$. The conditions imposed on the functions W_1 and W_2 are that the numerator of the first may not contain terms with s, and the numerator of the second may be a polynomial in s which is of degree one less than the polynomial in the numerator of W(s).

Indeed, let

$$W(s) = \frac{R(s)}{P(s)} = \frac{W_1(s)}{1 + W_1(s)\,W_2(s)}. \tag{8}$$

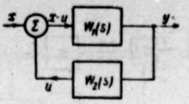

Fig. 3.

The block schematic of the connection of $W_1(s)$ and $W_2(s)$ is given in Fig. 3.

Let

$$W_1(s) = \frac{y(s)}{x(s) - u(s)} = \frac{1}{Q_1(s)},$$

$$W_2(s) = \frac{u(s)}{y(s)} = \frac{Q_2(s)}{Q_3(s)}. \tag{9}$$

We now find the conditions which must be satisfied by $Q_1(s)$, $Q_2(s)$, and $Q_3(s)$ so that Eq. (8) may be valid:

$$\frac{R(s)}{P(s)} = \frac{Q_2(s)}{Q_1(s)\,Q_2(s) + Q_3(s)}, \tag{10}$$

whence

$$R(s) = Q_2(s), \quad P(s) = Q_1(s)\,Q_2(s) + Q_3(s). \tag{11}$$

It follows from conditions (11) that the degree of polynomial $Q_1(s)$ must be equal to the difference of the degrees of polynomials $P(s)$ and $R(s)$, and from (9) and (10) that the degree of polynomial $Q_3(s)$ must be one less than the degree of polynomial $R(s)$. By using these special characteristics, we can write the general form of the polynomials $Q_1(s)$ and $Q_3(s)$:

$$Q_1(s) = \sum_{i=0}^{n-m} l_i s^i, \quad Q_3(s) = \sum_{i=0}^{m-1} m_i s^i, \tag{12}$$

where l_i and m_i are constants to be determined.

For example, let $R(s) = b_0 + b_1 s + b_2 s^2 + b_3 s^3$ and $P(s) = a_0 + a_1 s + a_2 s^2 + s^3$. Then, in accordance with (12), we obtain

$$Q_1(s) = l_0, \quad Q_2(s) = b_0 + b_1 s + b_2 s^2 + b_3 s^3,$$

$$Q_3(s) = m_0 + m_1 s + m_2 s^2.$$

To determine the values of l_0, m_0, m_1, and m_2, we substitute the values found for Q_1, Q_2, and Q_3 in (11). The result is

$$a_0 + a_1 s + a_2 s^2 + s^3 = l_0 b_3 s^3 + (l_0 b_2 + m_2) s^2 +$$

$$+ (l_0 b_1 + m_1) s + l_0 b_0 + m_0,$$

whence the coefficients sought will be

$$l_0 = \frac{1}{b_3}, \quad m_0 = a_0 - \frac{b_0}{b_3},$$

$$m_1 = a_1 - \frac{b_1}{b_3}, \quad m_2 = a_2 - \frac{b_2}{b_3}.$$

Thus,

$$W_1(s) = \frac{1}{l_0}, \quad W_2(s) = \frac{m_0 + m_1 s + m_2 s^2}{b_0 + b_1 s + b_2 s^2 + b_3 s^3}.$$

In its turn, $W_2(s)$ can be presented as

$$W_2(s) = \frac{W_{11}(s)}{1 + W_{11}(s)\,W_{22}(s)},$$

where

$$W_{11}(s) = \frac{1}{n_0 + n_1 s}, \quad W_{22}(s) = \frac{c_0 + c_1 s}{m_0 + m_1 s + m_2 s^2}.$$

To determine the unknown coefficients we use, based on (11), the relationship

$$b_0 + b_1 s + b_2 s^2 + b_3 s^3 =$$

$$= (n_0 + n_1 s)(m_0 + m_1 s + m_2 s^2) + (c_0 + c_1 s).$$

By equating coefficients, we get

$$c_0 = b_0 - \left(b_2 - b_3 \frac{m_1}{m_2}\right) \frac{m_1}{m_2},$$

$$c_1 = b_1 - \left[b_3 \frac{m_0}{m_2} + \frac{m_1}{m_2}\left(b_2 - b_3 \frac{m_1}{m_2}\right)\right],$$

$$n_0 = \frac{b_2 - b_3 \dfrac{m_1}{m_2}}{m_2}, \quad n_1 = \frac{b_3}{m_2}.$$

We now decompose $W_{22}(s)$ into the simpler components:

$$W_{22}(s) = \frac{W_{111}(s)}{1 + W_{111}(s)\,W_{222}(s)},$$

$$W_{111}(s) = \frac{1}{q_0 + q_1 s}, \quad W_{222}(s) = \frac{r_0}{c_0 + c_1 s}.$$

We determine the coefficients r and q from the relationship

$$m_0 + m_1 s + m_2 s^2 = (q_0 + q_1 s)(c_0 + c_1 s) + r_0,$$

whence

$$q_1 = \frac{m_2}{c_1}, \quad q_0 = \left(m_1 - \frac{c_0}{c_1} m_2\right) \frac{1}{c_1},$$

$$r_0 = m_0 - \left(m_1 - m_2 \frac{c_0}{c_1}\right) \frac{c_0}{c_1}.$$

Thus, the problem leads to the setup of the following system of equations:

$$\begin{aligned} y &= \frac{1}{l_0}(x - u), \\ (n_0 + n_1 s)\,u &= y - u_1, \\ (q_0 + q_1 s)\,u_1 &= u - u_2, \\ (c_0 + c_1 s)\,u_2 &= r_0 u_1. \end{aligned} \tag{13}$$

The block schematic and the setup which correspond to this system of equations are given in Figs. 4 and 5. The initial conditions for the new variables u, u_1, and u_2 can be found from the given initial conditions by means of system (13). As follows from Fig. 5, this method gives a setup requiring a large number of integrators in comparison with the method of direct integration. In addition, a comparatively large amount of time must be expended on the computation of the coefficients of the transformed equations.

3. Decomposition of the Initial Inhomogeneous nth-Order Equation into a System of n Inhomogeneous First-Order Equations

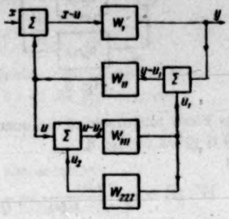

Fig. 4.

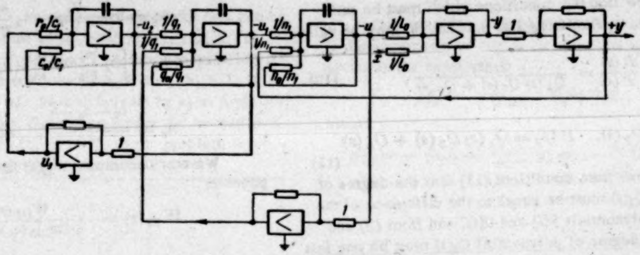

Fig. 5.

While this decomposition is not unique, the best results are given by the method described in [3], according to which the linear differential equation with constant coefficients

$$\frac{d^n y}{dt^n} + a_{n-1}\frac{d^{n-1}y}{dt^{n-1}} + \ldots + a_1\frac{dy}{dt} + a_0 y =$$
$$= b_0 x + b_1\frac{dx}{dt} + \ldots + b_{n-1}\frac{d^{n-1}x}{dt^{n-1}} + b_n\frac{d^n x}{dt^n} \quad (14)$$

can be presented in the form of a system of linear first-degree differential equations:

$$\begin{aligned} y &= y_1 + \alpha_n x, \\ \frac{dy_1}{dt} &= y_2 + \alpha_{n-1}x, \\ &\ldots\ldots\ldots \\ \frac{dy_{n-1}}{dt} &= y_n + \alpha_1 x, \\ \frac{dy_n}{dt} &= -a_{n-1}y_n - a_{n-2}y_{n-1} - \\ &- \ldots - a_1 y_2 - a_0 y_1 + \alpha_0 x. \end{aligned} \quad (15)$$

Indeed, by eliminating $y_1, y_2, \ldots, y_n$ from the last equation of system (15), we arrive at an equation of the form

$$\frac{d^n y}{dt^n} + a_{n-1}\frac{d^{n-1}y}{dt^{n-1}} + \ldots + a_1\frac{dy}{dt} + a_0 y = \alpha_n\frac{d^n x}{dt^n} +$$
$$+ (\alpha_{n-1} + \alpha_n a_{n-1})\frac{d^{n-1}x}{dt^{n-1}} +$$
$$+ \ldots + (\alpha_1 + a_{n-1}\alpha_2 + \ldots + a_1\alpha_n)\frac{dx}{dt} +$$
$$+ (\alpha_0 + \alpha_1 a_{n-1} + \ldots + \alpha_{n-1}a_1 + \alpha_n a_0)\,x. \quad (16)$$

In order that Eqs. (15) and (16) be identical, it is necessary that the values of the new coefficients α_i satisfy the following equations:

$$\begin{aligned} b_0 &= \alpha_0 + \alpha_1 a_{n-1} + \alpha_2 a_{n-2} + \ldots + \alpha_{n-1}a_1 + \alpha_n a_0, \\ b_1 &= \alpha_1 + \alpha_2 a_{n-1} + \ldots + a_{n-1}a_2 + \alpha_n a_1, \\ b_2 &= \alpha_2 + \ldots + \alpha_{n-1}a_3 + \alpha_n a_2, \\ &\ldots\ldots\ldots\ldots\ldots\ldots \\ b_{n-1} &= \alpha_{n-1} + \alpha_n a_{n-1}, \\ b_n &= \alpha_n. \end{aligned} \quad (16a)$$

The block schematic for the system of equations (15) is constructed in the form shown on Fig. 6a. The total number of blocks required is n + 3. The coefficients α_0, $\alpha_1, \ldots, \alpha_n$ are easily computed on the basis of (16a) by successively substituting the values of α_1, starting with $\alpha_n = b_n$. The initial conditions for the new variables y_1, $y_2, \ldots, y_n$ are determined by means of system of equations (15) from the given $y(0)$, $y^{(1)}(0), \ldots y^{n-1}(0)$

and $\quad x(0),\ x^{(1)}(0),\ x_0^{(2)}(0), \ldots, x^{(n-1)}(0).$

As an example, we consider the reproduction of the transfer function

$$W(s) = \frac{s^2 - \frac{6}{\tau}s + \frac{12}{\tau^2}}{s^2 + \frac{6}{\tau}s + \frac{12}{\tau^2}},$$

approximating the transfer function of a lag link, $e^{-s\tau}$, by a Padé series for $\mu = \nu = 2$ [6]. Here, $n = 2$, $a_0 = 12/\tau^2$, $a_1 = 6/\tau$, $a_2 = 1$, $b_0 = 1/\tau^2$, $b_1 = -6/\tau$, and $b_2 = 1$.

On the basis of (15), the equivalent system of equations is written in the form

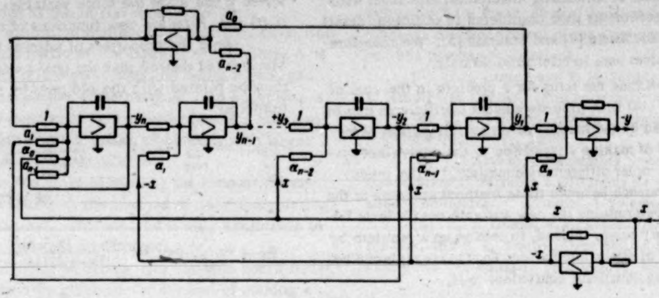

Fig. 6a.

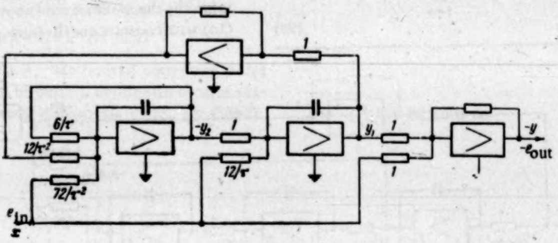

Fig. 6b.

$$\frac{dy_2}{dt} = -a_1 y_2 - a_0 y_1 + \alpha_0 x,$$

$$\frac{dy_1}{dt} = y_2 + \alpha_1 x, \quad y = y_1 + \alpha_2 x,$$

where y corresponds to the output signal e_{out} and x to the input signal e_{in}. Based on what has gone before, the coefficients α_0, α_1 and α_2 will be

$$\alpha_2 = b_2 = 1, \quad \alpha_1 = b_1 - a_1 = -\frac{12}{\tau}, \quad \alpha_0 = \frac{72}{\tau^2}.$$

The setup is shown on Fig. 6 b.

4. The Method of Combining Derivatives

We separate initial Eq. (14) into two by introducing the new variable

$$u = \frac{x}{p^n + a_{n-1}p^{n-1} + \ldots + a_1 p + a_0}. \tag{17}$$

As the result, we get

$$y = b_n \frac{d^n u}{dt^n} + b_{n-1}\frac{d^{n-1}u}{dt^{n-1}} + \ldots + b_1 \frac{du}{dt} + b_0 u. \tag{18}$$

Expression (17) can be rewritten in differential form:

$$\frac{d^n u}{dt^n} + a_{n-1}\frac{d^{n-1}u}{dt^{n-1}} + \ldots + a_1\frac{du}{dt} + a_0 u = x. \tag{19}$$

To establish the setup on the computer, it is initially necessary to "set up" Eq. (19) by the method of reducing the order of the derivatives and thereafter forming the desired variable y in the form of a sum of derivatives with respect to u with the proper coefficients. The values of the derivatives $d^i u/dt^i$ are obtained directly from the corresponding outputs of the integrators for the solution of Eq. (19). Some simplification of the setup is achieved if $d^n u/dt^n$ is eliminated from Eq. (18) by substituting its value from Eq. (19). The result is the set of equations

$$\frac{d^n u}{dt^n} + a_{n-1}\frac{d^{n-1}u}{dt^{n-1}} + \ldots + a_1\frac{du}{dt} + a_0 u = x,$$

$$y = (-b_n a_{n-1} + b_{n-1})\frac{d^{n-1}u}{dt^{n-1}} + \ldots + (-b_n a_1 + b_1)\frac{du}{dt} + (-b_n a_0 + b_0)u + b_n x.$$

For m = n = 3, the block schematic of the setup for these equations is shown in Fig. 7. In the general case, n + 3 operational blocks are needed in the setup. It is not necessary to carry out laborious computations to determine the coefficients for the setup.

5. Methods of Simulating Differential Equations with Variable Coefficients

Methods of simulating differential equations with variable coefficients were considered in sufficient detail by Laning and Battin [3] and Matyash [5]. We therefore limit ourselves here to brief remarks only.

Establishing the setup for a problem in the case of solving Eq. (14) with time-dependent coefficients can be implemented by the method of direct integration or by the method of making a transition to the equivalent system of first-order differential equations.* The fundamental difference between these methods amounts to the method of determining the new variable coefficients for the equations' setup. Indeed, in setting up a problem by the method of direct integration, Eq. (14) is replaced by the following equations, equivalent to it,

$$\sum_{j=0}^{n}(-1)^{j}(\alpha_{j}\ y)^{(j)} = -\sum_{j=0}^{m}(-1)^{j}(\beta_{i}x)^{(j)}, \tag{20}$$

where y and x are the same variables as in (14), but $\alpha_j(t)$ and $\beta_j(t)$ are new functions of time.

Using the properties of adjoint linear operators, Matyash [5] showed that the new variable coefficients must be related with the old ones by the following relationships:

$$\beta_{m-k} = \sum_{i=0}^{k}(-1)^{(m-i)}\frac{(m-i)!}{(m-k)!\,(k-i)!}b_{m-i}^{(k-i)}$$

$$(k = 0, 1, 2, \ldots, m).$$

$$\alpha_{n-k} = \sum_{i=0}^{k}(-1)^{n-i}\frac{(n-i)!}{(n-k)!\,(k-i)!}a_{n-i}^{(k-i)}$$

$$(k = 0, 1, 2, \ldots, n).$$

The block schematic for the setup of Eq. (20) is obtained by the methods used above for differential equation (14) with constant coefficients, with the sole difference that, at the proper places, dividers of the variable coefficients are connected for the establishment of $\beta_{m-k}(t)$ and $\alpha_{n-k}(t)$.

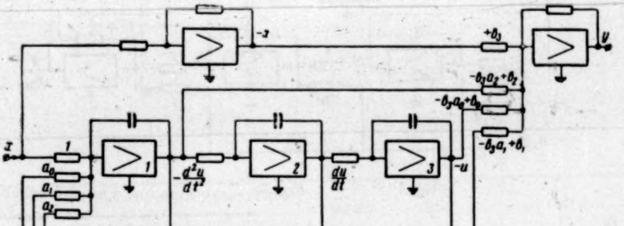

Fig. 7.

The transition to an equivalent system of first-order differential equations is made exactly the same as in the case of constant coefficients, but here the new coefficients, $\alpha_n(t), \alpha_{n-1}(t), \ldots, \alpha_0(t)$, must be considered as some functions of time. The determination of these functions of time in terms of the original variable coefficients can be performed on the basis [3] of the recursion formulas

$$\alpha_0(t) = b_0(t),$$

$$\alpha_i(t) = b_i(t) - \sum_{k=0}^{i-1}\sum_{r=0}^{i-k} C_{n+r-i}^{n-i}a_{i-k+r}(t)\frac{d^r\alpha_k(t)}{dt^r}.$$

It follows from a comparision of the two methods considered that the transition to an equivalent system of first-order differential equations requires less computational work, since the original variable coefficients $a_j(t)$ enter into the setup in untransformed form. In solving a problem by the method of direct integration, one has to recompute all the variable coefficients entering into the equation actually set up.

SUMMARY

The comparison of the methods considered for simulating rational-fraction transfer functions allows the following conclusions to be drawn.

1. Reproduction of rational-fraction transfer functions and the differential equations which give rise to them by means of electronic analog computers without differentiating elements can be implemented by several methods. For nonzero initial conditions, one must also

---

* The methods of decomposing transfer functions into simpler ones and of combining derivatives are invalid here, since they lead to an interchange of differential operators which, with variable coefficients, is inadmissible.

know the values of the independent variable and its first (n-1) derivatives at the initial moment of time.

2. The minimum number of operational amplifiers in the block schematic of the setup is n + 3, where n is the order of the differential equation being set up, and does not depend on the setup method. An exception is the method of decomposing a transfer function into simpler ones, which leads to block schematics with larger numbers of operational amplifiers.

3. From the point of view of the amount of preliminary work required, the method of combining derivatives is the simplest. This method is only applicable to problems with constant coefficients.

4. For solving problems with variable coefficients, preference should be given to the method of making a transition to an equivalent system of first-order differential equations as requiring the least amount of additional computational work.

ON CONSTRUCTING BRIDGE CIRCUITS BY THE SHORT-CIRCUIT METHOD

A. Ya. Tolchan

(Moscow)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 1, pp. 82-92, January, 1960)
Original article submitted April 18, 1959

Net structure is proposed as the general representation of bridge circuits. On the basis of an analysis of complete nets, sufficient grounds for the possibility of constructing bridge circuits by the short-circuit method are deduced.

The problem of constructing, from an existent circuit's structural formula F(a,b,. . . , w), the bridge circuit equivalent to it is a very urgent one, since a significant gain in number of circuit elements might thereby be obtained in many cases. One of the methods of carrying out such constructions is well known under the name of the short-circuit method [1].

Practical application of this method is limited by the circumstance that, in the majority of cases, the parts of the circuit necessary for the construction are missing from the original structural formula F(a, b, . . . , w) [1].

In connection with this, the necessity arises of investigating the conditions under which use of this method is possible, as well as the methods of transforming the original structural formula to a form more convenient to use.

To investigate bridge circuits in the general case, it is convenient to present them in the form of a "complete net" as shown on Fig. 1. A complete net is a rectangular net with one element connected in each side of each mesh (elemental grid rectangle), where there are equal numbers of meshes in each file (row) in any given direction. All the nodes of its two opposite sides are connected to the input and output nodes.

The sides of the meshes are conventionally called longitudinal and lateral, depending on whether they are parallel or perpendicular to the input and output terminal buses. This nomenclature is also extended to the individual elements, depending on the side of the mesh they are connected in.

Longitudinal series of elements are called rows while lateral ones are called columns. Initial elements are denoted by I and final ones by F. The denotation of the remaining elements is in accordance with Fig. 1, and the numeration of rows and columns is from left to right and from top to bottom (not counting the rows of the initial and final elements).

The nodes of the net are denoted by $\alpha_{i,n}$, where i is the number of the longitudal elements' row and n the number of the lateral elements' column at the intersection of which the node is to be found.

Each planar bridge circuit can be converted (transformed) to a complete net. For this, all elements connected between two series-parallel nodes are replaced by one element; full rows and columns of longitudinal and lateral elements are then made up by adding elements equal to zero in places where gaps initially appeared, and elements equal to unity at places where conducting lines initially appeared. This transformation is not single-valued but among the variants of the resulting complete nets there is always a variant such that there are no zeros in the first or last rows of longitudinal elements. To obtain this variant, it suffices to begin the transformation by filling in these rows with elements occurring in the original planar scheme. Several examples of such a transformation are given in Fig. 2.

Conversely, from a net with a sufficient number of columns and rows of longitudinal and lateral elements, one may obtain any planar scheme, if part of the elements reduce to zero or to unity, and certain elements, where necessary, are replaced by series-parallel connections of a number of elements.

For nonplanar circuits, analogously, the general form of a bridge structure is a complete space lattice. Each of its facets (or of its cross sections parallel to any facet) is a complete planar net such as those considered above. Each cell of the lattice is a cube in each edge of which one element is connected. All the nodes of two opposite facets of the lattice are joined to the input and output nodes. Its conversion to a nonplanar circuit and vice versa are carried out by methods analogous to those described for plane nets.

All further exposition will deal exclusively with planar circuits and plane nets. The question of extending the conclusions derived from a consideration of plane nets to nonplanar circuits and to space lattices requires special consideration.

Relationships which exist in a complete net are valid in all cases when the individual elements equal zero or unity, i.e., are valid for any bridge circuit. Indeed, zero and unity are particular values which a circuit element may assume.

For the analysis of a complete net, we use a special "table of correspondences." Let t be a row of longitudinal elements and s be a column of lateral elements in a net.

Each column in a table is headed by one of the initial elements I_n, and each row by a final element F_p. In the cell of the table at the intersection of column I_n and row F_p, we write the full structural formula of the circuit joining nodes α_{in} and α_{tp}, denoted by us as Π_{np}. As a preliminary step, this circuit must be presented (for example, by a successive expansion by initial and final elements) in the form of a sum of circuits, each consisting of series connections of elements only. In the sequel, we shall call each such component circuit entering into Π_{np} an elementary circuit, and denote it by π_{np}.

Any bridge circuit presents itself, in the most general form, as some middle portion $f(a_{ij}, b_{mn})$ connected to input and output nodes via initial and final elements (Fig. 3 a). It is essential here that there be no isolated parallel circuits in the middle portion which are connected to the input and output nodes. This circumstance is used in the short-circuit method, where one initially seeks a middle portion of the circuit which is connected to the output node via all the final elements and is connected to the input node via one of the initial elements. After this, one seeks the points for connecting the remaining initial elements to the middle portion [1].

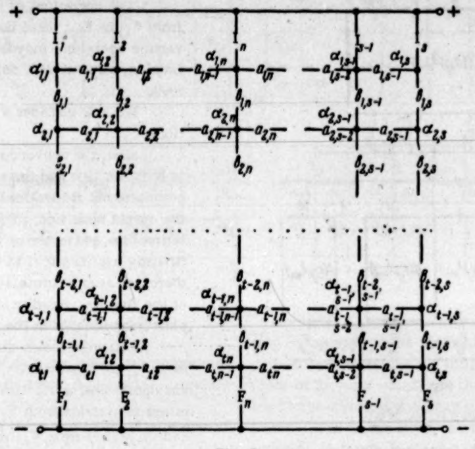

Fig. 1.

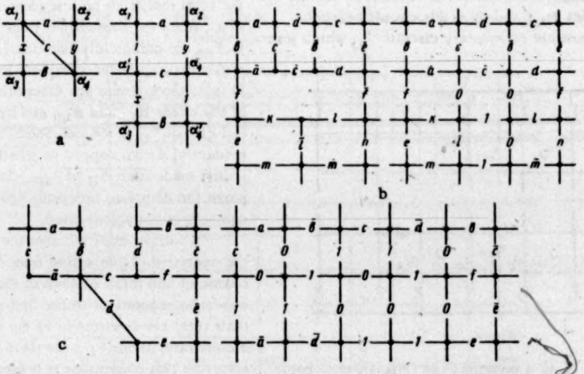

Fig. 2.

In the most general case, the decomposition of a bridge circuit by initial and final elements must give a set of parallel circuits, each of which is a middle portion, $f(a_{ij}, b_{mn})$ joined to the input node via one initial element and to the output node via one final element (Fig. 3 b).

This suggests that, among the elementary circuits into which any two of the full parallel circuits mentioned above may be decomposed, there must be elements similar in content, and differing only in the placement of the points at which the initial and final elements are connected to the middle portions and the elements themselves.

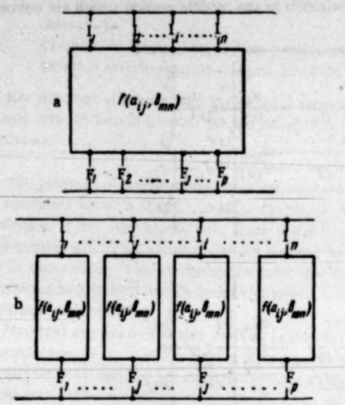

Fig. 3.

Analysis of a Complete Net

Let there be given some complete net, namely, a two-terminal network with s columns of lateral elements and t rows of longitudinal elements. Let Π_{ij} be the circuit joining nodes $\alpha_{1,i}$ and $\alpha_{t,j}$, this circuit being the sum of all the possible elementary circuits π_{ij} which join these nodes.

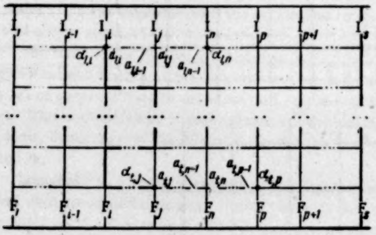

Fig. 4.

Theorem. If, in a complete net (Fig. 4), one choose any pair of nodes, $\alpha_{1,i}$ and $\alpha_{t,j}$, some other pair of nodes, $\alpha_{1,n}$ and $\alpha_{t,p}$, and then, in some elementary circuit π_{ij} of Π_{ij}, one replaces the elements in it which come from the set of longitudinal elements connected in the first row between nodes $\alpha_{1,i}$ and $\alpha_{1,n}$ and in the tth row between nodes $\alpha_{t,j}$ and $\alpha_{t,p}$ by all the elements of this set lacking in it, then the newly obtained elementary circuit will be some circuit π_{np} of Π_{np}.

On Fig. 4, only those nodes and elements mentioned in the theorem are noted. One of the possible circuits π_{ij} is shown in heavy lines.

In the sequel, we shall call such an operation the "operation of converting from π_{ij} to π_{np}" for two pairs of nodes from the first and tth rows. If this operation is carried out for all circuits π_{ij} of Π_{ij}, this is then the "operation of converting from Π_{ij} to Π_{np}".

The operations of converting from π_{ij} to π_{nj} and from π_{ij} to π_{ip}, these being particular cases of the conversion operation, may be considered as conversion operations in, respectively, only the first and only in the tth rows.

We now consider a number of preliminary propositions.

First, the conversion operation occurs analogously in both the first and the tth rows, since the structure of a complete net is identical on both the input node side and the output node side. This means that all conditions, relationships, and results of the conversion operation in the first row are identical to those in the tth row. We shall therefore always formulate propositions henceforth in terms of the first row, bearing in mind that they are also completely applicable to the tth row.

It may be shown that the operation of converting from π_{ij} to π_{np} actually breaks down into two independent operations, which can be carried out in either order: either conversion from π_{ij} to π_{nj}, i.e., in the first row, and thereafter from π_{nj} to π_{np}, i.e., in the tth row or, conversely, initially from π_{ij} to π_{ip}, i.e., in the tth row and then from π_{ip} to π_{np}, i.e., in the first row. Indeed, the final results for both sequences of operations are identical, since the conversions from π_{ij} to π_{nj} and from π_{ip} to π_{np} are completely identical, from the point of view of the makeup of the group of elements to be converted. In fact, these groups are determined only by the positions of the nodes $\alpha_{1,i}$ and $\alpha_{1,n}$ and by the behavior of the initial circuit π_{ij} in the neighborhood of the first row which, evidently, do not depend on whether or not the conversion is first made from π_{ij} to π_{ip}. One can clearly use this to prove the complete independence of the order of the two component operations cited.

It follows from this that the character and result of the operation of converting from π_{ij} to π_{np} depend on the character and result of each of the individual component conversion operations in the first and tth rows which, in their turn, are determined by the behavior of the original elementary circuit π_{ij} near the first and the tth rows separately. This means that it is meaningful to differentiate the forms of the elementary circuits in the net by the character of their behavior close to the first (tth) row.

From this point of view, two cases are theoretically possible, while we shall formulate with respect to the first row only.

1. The original elementary circuit π_{ij} is so situated in the net that, once having started out from one node of the first row of longitudinal elements, it never again passes through any node of this row which is comprised in the set of nodes situated between $\alpha_{1,i}$ and $\alpha_{1,n}$, including

$\alpha_{1,n}$ (Fig. 5a,b,c). We remark that the elementary circuit can pass arbitrarily often through the remaining nodes of the first row.

2. The original elementary circuit π_{1j} is so situated in the net that, once having started out from one node of the first row of longitudinal elements, it again passes, at least once, through nodes of this row which are comprised in the set of nodes situated between $\alpha_{1,1}$ and $\alpha_{1,n}$, including $\alpha_{1,n}$ (Fig. 5 d,e).

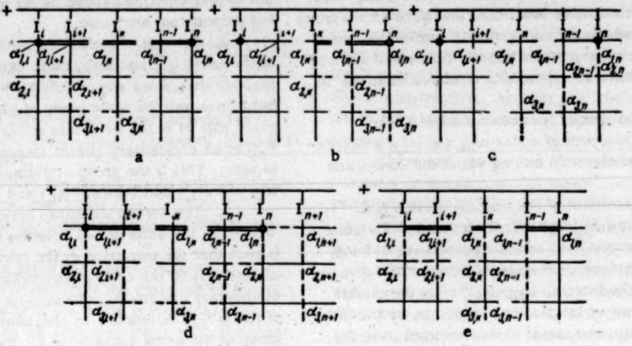

Fig. 5.

We now show that, in these two cases, the conversion operation in the first row from π_{1j} to π_{nj} does in fact lead from π_{1j} to π_{nj}. The graphical proof of this is shown on Fig. 5 where, to avoid encumbering the figure, no elements are shown in the sides of the net's meshes. These latter are understood to be present. Only the nodes occurring in the path of the elementary circuit are notated. The dashed lines represent the initial elementary circuit, while those of its parts which pass through elements participating in the conversion operation are shown by solid lines. Double solid lines denote the circuit paths through the remaining elements in the group subject to conversion. Thus, the results of this operation are clearly visible.

There are obviously three possible diverse circuits for the first case, mentioned above, of the behavior of the original elementary circuit in the neighborhood of the first row. The conversion operations for them are treated in Fig. 5 a,b, and c, from which it is clear that these operations indeed lead to π_{nj}.

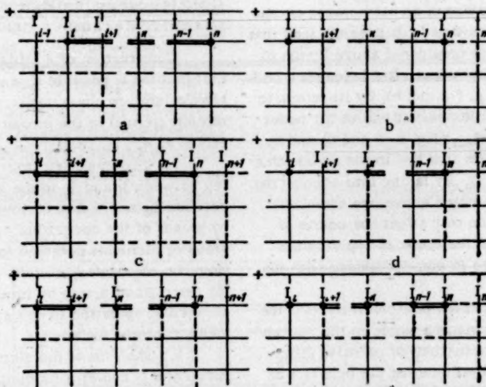

Fig. 6.

We must consider two diverse circuits (Fig. 5d and e) for the second case cited above, finding that in both of them the conversion operation leads to π_{nj}, although with the addition of a closed contour.

In order to extend this proof to the general case of the theorem, we first consider which special features of the behavior of the original circuit in the net affect the course and the result of the operation of converting from π_{ij} to π_{nj}. With this, we shall take into account the group of elements in which the conversion is carried out, the make-up of the subgroups of elements (discarded and added) and the absence or appearance of closed contours in series with π_{nj}.

Among the special features considered are:

1) the placement of nodes $\alpha_{1,i}$ and $\alpha_{1,n}$ which define the group of elements among which the conversion is carried out;

2) the placement of the node $\alpha_{1,k}$ via which π_{ij} leaves the first row of longitudinal elements, by which the subgroups of discarded and added elements are defined;

3) the presence or absence of a return of π_{ij} to one of the nodes in the interval $\alpha_{1,i}-\alpha_{1,n}$ after the circuit leaves the first row of longitudinal elements, by which is determined the appearance of closed contours in series with π_{nj}.

It is also essential that the behavior of π_{ij} in the middle portion of the net in no way affects the course of the operation of conversion from π_{ij} to π_{nj} and, as was stated earlier, that this operation occurs independently in the first and the tth rows.

By taking these data into account, we conclude that all the possible variants of the behavior of an elementary circuit in the neighborhood of the first row, from the point of view of the character of the conversion operation and its results, lead to the two cases considered above. This becomes obvious from a consideration of Fig. 6, where all possible variants of the behavior of an elementary circuit close to the first row are represented. It is easily seen that they differ from the two cases considered above by the direction of the circuit's path in the net after it leaves a node in the interval $\alpha_{1,i}-\alpha_{1,n}$ (Fig. 6 a and b), by its returns to the first row of longitudinal elements at one of the nodes outside of the interval $\alpha_{1,i}-\alpha_{1,n}$ (Fig. 6 c and d) and by the number of its returns to the first row in the nodal interval $\alpha_{1,i}-\alpha_{1,n}$ (Fig. 6 e and f). By taking into account the essential special features presented above, we establish that all these differences in no way affect the course of the conversion operation, and the result of applying this operation to them will also be in correspondence with the theorem given above.

Finally, it is obvious that all possible variants of the course of the elementary circuit as a whole in the net can be given as the different combinations of pairwise different variants of these two general cases of the behavior of a circuit in the vicinity of the first and of the tth row, in conjunction with an arbitrary behavior in the remaining portion of the net. But, since the theorem is valid for all variants of these two cases, it is then valid for all forms of elementary circuits which are possible in a net.

Corollary. In presenting the corollary, we shall deal only with full nets, bearing in mind that it can be extended to any bridge circuit as a particular case of a net.

For some net, let a table of correspondences analogous to that described above be set up. Then, the following propositions are valid.

1. Between the elementary circuits of any two cells of the table I_iF_j and I_nF_p, there exists such an interrelationship that, from any circuit π_{ij} by a conversion carried out in one and the same group of elements common to the given pair of cells, we obtain either one of the circuits π_{np} or an elementary circuit longer than π_{np}, i.e., equal to zero. This is the group of elements connected between $\alpha_{1,i}$ and $\alpha_{1,n}$ and between $\alpha_{t,j}$ and $\alpha_{t,p}$.

2. The interrelationship between the elementary circuits of the cells of two columns I_i and I_n of this table is such that the transition in the rows from the elementary circuits π_{ij} of the cells of one column of the table to the elementary circuits π_{nj} of the cells of the other column of the table corresponds to the conversion in the one group of elements common to all the rows. In this group there appear the elements which are connected between $\alpha_{1,i}$ and $\alpha_{1,n}$ in the first row of longitudinal elements.

3. The connection between the elementary circuits of two rows F_j and F_p of the table is such that transition in the column from the elementary circuits of the cells of one row to the elementary circuits of the cells of the other row corresponds to the conversion in the group of elements which are common to all columns, this group containing elements connected between $\alpha_{t,j}$ and $\alpha_{t,p}$ in the tth row.

Sufficient Grounds for the Possibility of Constructing Bridge Circuits by the Short-Circuit Method

Construction of a bridge circuit by the short-circuit method is possible if, and only if, the following interrelationships characterize the individual elementary circuits (terms) in the circuit's original structural formula F(I, F, a, b, . . . , w).

1. The transition from the elementary circuits passing between I_i and F_j to the elementary circuits passing between I_n and F_j can be implemented, for given i and n, by means of the conversion operation in one and the same group of elements common for any j, and the transition from the elementary circuits passing between I_i and F_p, for given j and p, can be implemented by means of the conversion operation in one and the same group of elements common for any i.

2. The sum of the elementary circuits passing between any I_i and F_j must contain all the circuits necessary for the construction of the bridge circuit which is equivalent to this sum.

It is necessary to convince ourselves that the holding of these two conditions is sufficient for the construction of the bridge circuit by the short-circuit method. It is obvious that the holding of the second condition allows one to construct the bridge circuit of the middle portion f(a_{ij},

b_{IIIn}) (cf. Fig. 3 a), and the holding of the first condition guarantees the possibility of seeking such nodes in this middle portion that, upon their being connected to all initial and final elements, they will form the bridge circuit sought.

Practical Investigation of the Possibility of Constructing a Bridge Circuit by the Short-Circuit Method

Let there be given the structural formula $F(a, b, \ldots, w)$ of the circuit, the bridge circuit variant of which it is necessary to construct.

In order to verify the possibility of employing the short-circuit method, one must:

a) determine the complete group of initial and final elements;

b) set up the table of correspondences;

c) convince oneself that the make-up of the elements in all the cells of the table is identical;

d) verify that the aforementioned sufficient conditions hold, wherein the second condition is verified only for an arbitrary one of the table's cells.

If these conditions do not hold immediately for the original structural formula, one may then introduce, in the table's cells, additional elementary circuits which are equal to zero (containing mutually inverse elements or containing completely one of the pre-existing elementary circuits in the particular cell) and certain elements of the individual elementary circuits can be repeated.

When the necessary conditions have finally been met, the table obtained may be considered as the result of expanding the bridge circuit sought by initial and final elements where, in any cell I_iF_j of the table, are to be found all the elementary circiuts by which the corresponding complete circuit Π_{ij} can be expanded.

Starting from this, we construct, for any arbitrarily chosen cell of the table, its partial bridge circuit Π_{ij}, which we then join to the initial and final nodes via I_j and F_j. On the circuit thus obtained we then find the nodes which, when the remaining initial and final elements are connected to them, allow the elementary circuits of the remaining cells of the table to be realized.

However, the use of this methodology leads simply and rapidly to the desired result only in those rare cases when the bridge circuit sought contains no repeated elements and no mutually inverse elements. In the overwhelming majority of actual cases, bridge circuits contain both repeated elements and mutually inverse elements, as a result of which the initial structural formula lacks a significant portion of the elementary circuits necessary for the construction. Another part of these circuits is present in altered form due to the repetition of identical elements.

Therefore, for the use of this methodology, it is necessary to employ special means and an additional construction condition.

This latter condition is suggested by the fact that, generally speaking, there is no unique bridge circuit equivalent to some series-parallel circuit. However, in analogy with the usual requirement that a circuit be realized with the minimum number of elements, one can propose a universal requirement on the construction of bridge circuits, to wit, that there be a minimum number of repeated identical elements.

It seems reasonable to consider the methodology treated above, together with the additional means of construction, in terms of a concrete example.

Let there be given some structural formula for a circuit whose bridge variant must be constructed:

$$
\begin{aligned}
F = {} & a\{b(\bar{g}l + m) + c(ehl + gm) + \\
& + l[e + h(\bar{e} + \bar{g})] + m(e\bar{g} + h)\} + \\
& + b\{l(eh + \bar{e}) + m[h(e\bar{g} + g) + \bar{e}\bar{g}]\} + \\
& + c\{l[g(eh + \bar{e}) + \bar{g}h] + hm\} = ab\bar{g}l + \\
& + abm + acehl + acgm + ael + a\bar{e}hl + \\
& + a\bar{g}hl + ae\bar{g}m + ahm + behl + b\bar{e}l + \\
& + be\bar{g}hm + bghm + b\bar{e}\bar{g}m + \\
& + cegl + c\bar{e}gl + c\bar{g}hl + chm.
\end{aligned}
$$

TABLE 1

	a_I	b_I	c_I
l_F	$b\bar{g}+ceh+e+\bar{e}h+\bar{g}h$	$eh+\bar{e}+a\bar{g}$	$egh+\bar{e}g+\bar{g}h$
m_F	$b+cg+e\bar{g}+h$	$\bar{e}gh+gh+\bar{e}\bar{g}$	h

This initial structural formula contains 42 elements in grouped form. Other variants of the grouping do not provide any significant gain in the number of elements necessary. After multiplying out the parentheses, we obtain a structural formula in the form of a sum of 18 elementary circuits.

Without stopping to seek the initial and final elements, methods of finding which are described in detail in the literature [1], we state that the initial elements are a, b and c and that the final elements are l and m. We denote them by a_I, b_I, c_I, l_F, and m_F.

We now set up the table of correspondences (Table 1), writing in it successively the elementary circuits from the structural formula (without the initial and final elements).

A scan of the terms in the individual cells of the table by make-up of elements and make-up of individual terms shows that the bridge circuit being sought must contain both mutually inverse elements and repetitions. This means, that the construction problem now entails dealing with the minimum number of repeated elements and mutually inverse elements which are present in the original structural formula.

TABLE 2

	a_I	h	b_I	g	c_I
l_F	$e+\bar{e}h+\bar{g}ha+g\bar{g}hh_1+$ $+aegh_1$		$eh+\bar{e}+a\bar{g}+g\bar{g}h_1+$ $+aeghh_1$		$egh+\bar{e}g+\bar{g}h_1+aehh_1+$ $+ag\bar{g}$
$\bar{g}$					
m_F	$e\bar{g}+ha+\bar{e}\bar{g}h+ghh_1+$ $+aeg\bar{g}h_1$		$e\bar{g}h+\bar{e}\bar{g}+gh_1+a+$ $+aeg\bar{g}hh_1$		$h_1+ag+eg\bar{g}h+\bar{e}g\bar{g}+$ $+ae\bar{g}hh_1$

From this point of view, it follows from a comparison of terms in the cells $a_I l_F$ and $a_I m_F$ with the remaining ones that the repeated elements b and c (b_I and b, c_I and c) must appear in the circuit being sought. It is easily remarked that the shift of the elementary circuits $ab\bar{g}l$, acehl, abm, and acgm to the cells, respectively, $b_I l_F$, $c_I l_F$, $b_I m_F$, and $c_I m_F$, i.e., taking as the initial elements in these circuits, not a_I, but b_I and c_I, allows one to deal with the repeated element a (a_I and a) only (Table 2). With this, the make-ups of the cell elements become identical (taking into account the possibility of repetition of the initial element of cells $a_I l_F$ and $a_I m_F$) except for $\bar{g}$, which does not appear everywhere.

A comparision of cells $b_I l_F$ and $b_I m_F$ (Table 2), which contain the greatest numbers of terms, leads to the conclusion that the group of elements in which conversion is to be carried out for the cells of rows l_F and m_F consists of $\bar{g}$.

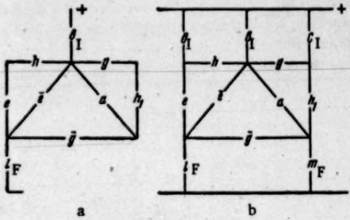
In the corresponding pairs of cells of rows l_F and m_F, we verify that this correspondence of terms holds, adding the deficiencies if they equal zero. A comparison of the cells of columns a_I and b_I leads to the acceptance of h as the sole element of the group in which conversion is carried out in columns a_I and b_I, with the condition that element a repeats, since otherwise a term equal to unity would appear in cell $b_I m_F$. Element h is also repeated (h and h_1) (Table 2).

In Table 2, all the added elementary circuits either contain mutually inverse elements or are longer ($a_I ghh_1 m_F$) than those already in the circuit ($a_I ahm_F$). In Table 2, all the added elements, circuits, and subscripts are given in boldface type.

Analogously, by considering the circuits of the table's cells $b_I l_F$ and $c_I l_F$, and $b_I m_F$ and $c_I m_F$, we find the most probable makeup of the group of elements to be converted, namely, g, for the cells of columns b_I and c_I.

We then fill all cells of the table until complete correspondence of all terms is attained. Now, the make-up of elements in the circuits of all the table's cells is the same for all, namely, a, e, $\bar{e}$, g, $\bar{g}$, h, and h_1. After this, we construct the equivalent bridge circuit for the elementary circuits of one of the table's cells, with the purpose of obtaining the middle portion of the bridge circuit being sought. In general, this construction could have been carried out earlier, without complete correspondence, i.e., when the first of the sufficient conditions for the possibility of constructing a bridge circuit was unfulfilled. This construction sometimes allows one to determine the make-up of the group of elements in which conversion is carried out. Thus, we consider the cell $b_I l_F$ of the table, since it contains the shortest elementary circuit. For this, we shall consider that elements h and g are connected in the first, and g in the last, row of longitudinal elements, since they enter into the groups of elements in which conversion is carried out.

In the general case, this construction must be carried out by a method analogous to the one presented here.



a b

Fig. 7

However, in the majority of cases, the number of terms in the table's cells is small, and this construction can be carried out from the information obtained from all the cells' elementary circuits. Thus

$$f_{b_I l_F} = eh + \bar{e} + a\bar{g} + g\bar{g}h_1 + aeghh_1$$

and the equivalent bridge circuit is represented on Fig. 7 a. In it, one easily determines the nodes for connecting the remaining initial and final elements, since one already knows the elements of the first and last rows of the circuit which are connected between these nodes. The final bridge circuit is shown on Fig. 7 b.

By considering the different elementary circuits of the scheme obtained, we convince ourselves that it is equivalent to the original structural formula F.

We note that there are, in the table, elementary circuits ($aegh_1$, $aeghh_1$, etc.) which consist of a somewhat shorter circuit from the same cell plus a closed contour (agh_1) abutting the first or last row of longitudinal elements. This is in complete agreement with the theorem proved earlier; such a circuit, naturally, does not violate equivalence. It should be added that, in seeking the group of elements in which conversion is to be carried out for the circuits of some pair of cells, it is ordinarily a good first move to consider a group which is contained completely in at least one term of each cell, and which is completely absent from a least one term.

To convince oneself of the truth of this regularity, it suffices to recall that among the elementary circuits of any cell there will always be a circuit of the form shown in Fig. 5 a, as well as a circuit of the form shown in Fig. 5 c.

When there are mutually inverse elements in this group, the rule given is false. The rule can also be violated in other cases of special locations of mutually inverse elements.

NOISE STABILITY OF A FREQUENCY TELEMETERING SYSTEM FOR WEAK PULSE NOISE

Yu. I. Chugin

(Moscow)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 1, pp. 93-105, January, 1960)
Original article submitted April 28, 1959

The noise stability of a telemetering frequency receiver is investigated for pulse noise of arbitrary duration. The threshold of noise stability and the optimal deviation frequency are determined.

The noise stability of the various forms of modulation have been most fully investigated (both theoretically and experimentally) for the case of fluctuation noise. Questions of noise stability for pulse noise, for frequency modulation in particular, have been treated with insufficient completeness in the literature.

In a number of the works devoted to this question, the treatment was mainly qualitative [1, 2]. There are works which contain incorrect initial assumptions [3] (as shown in [4]). There is definite interest inhering in the investigation of δ - function type noise in FM receivers which was given in [4, 5], but the action of such noise, so far from the actual noise encountered, very inadequately discloses the phenomena which occur in the receiver, and so the results thus obtained have a limited domain of applicability.

In the present paper we present the investigation of the effect of weak pulse noise of arbitrary duration on a frequency receiver. The results of the analysis are used for calculating the noise stability of a frequency telemetering system. The use of a narrow band output device allows one to use, as the criterion of noise stability of the telemetering system, the reduced mean-square error, defined as the ratio of the effective noise voltage V_n at the receiver's output to the maximum voltage of the output signal obtained by varying the signal frequency from $-\omega_d$ to $+\omega_d$, where ω_d is the maximum deviation frequency. The noise voltage V_n can be determined by the energy spectrum of the pulse noise at the discriminator's output. If a sequence of random noise pulses act at the receiver's input, then the phase φ_0 of the carrier frequency at the moment when a noise pulse acts can be considered a random variable, and the result of the noise's action at the discriminator's output can be considered a random pulsed process.

1. Reduced Mean-Square Error at the Receiver's Output

By definition, the magnitude of the reduced error at the output of the frequency receiver (Fig. 1) with pulse noise equals

$$\delta = \frac{V_n}{2U_{\max}}, \qquad (1)$$

where $U_{\max}$ is the maximum voltage of the receiver's output signal, equal to ω_d (for an ideal discriminator with characteristic slope of $s = 1$), V_n is the noise voltage at the receiver's output, defined as $V_n = \sqrt{P_n}$, where

$$P_n = \frac{1}{2\pi}\int_0^\infty W(\omega)\,K(\omega)\,d\omega \qquad (2)$$

is the noise power at the receiver's output, $W(\omega)$ is the energy spectrum of the sequence of random noise pulses at the discriminator's output and $K(\omega)$ is the frequency characteristic of output filter F_2.

We now determine δ for an ideal and for a bell-shaped form of the output filter's frequency characteristic.

a. The Ideal Filter Form

By substituting in (2) the value of $W(\omega)$ obtained in Appendix II (formula II.16) and then integrating, we obtain the noise power at the output of a filter with pass band 0 to F_f and $K(\omega) = 1$:

$$P_n = 0.425\,\frac{m\omega_f^3}{\omega_0^2}\left(\frac{U_n}{U_s}\right)^2 \Phi_I. \qquad (3)$$

Here,

$$\Phi_I = 1 - 3\left[\frac{2}{\alpha^2}\cos\alpha + \left(\frac{1}{\alpha} - \frac{2}{\alpha^3}\right)\sin\alpha\right]\times$$

$$\times\cos(\omega_0 + \lambda\omega_d)\tau -$$

$$-\frac{3\pi}{2}\left(\frac{\lambda\omega_d}{\Delta\omega}\right)\left[\left(-1 + \frac{6}{\alpha^2}\right)\times\right.$$

$$\left.\times\cos\alpha + 3\left(\frac{1}{\alpha} - \frac{2}{\alpha^3}\right)\sin\alpha\right]\frac{\sin(\omega_0 + \lambda\omega_d)\tau}{\Delta\omega\tau},$$

U_s is the amplitude of the sinusoidal signal at the receiver's input, U_n is the amplitude of the noise pulse at the receiver's input, τ is the duration of the noise pulse, $\underline{m}$ is the average number of pulses per second, λ is the transmitted parameter, varying from −1 to +1, ω_0 is the mean frequency of the input filter, $\alpha = \omega_f\tau$, $\omega_f = 2\pi F_f$, and $\Delta\omega = 2\pi\Delta f$.

By substituting the values of $V_n = \sqrt{P_n}$ and $U_{\max}$ in formula (1), we obtain the expression for the reduced

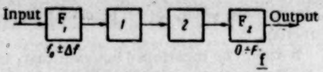

Fig. 1. Block schematic of the frequency receiver. F_1 is the input filter, 1 is a limiter, 2 is the discriminator, and F_2 is the output filter.

mean-square error at the output of a receiver with ideal output filter in the form

$$\delta_I = 0.33 \frac{\sqrt{m}\, \omega_f^{3/2}}{\omega_d \omega_0} \frac{U_n}{U_s} \sqrt{\Phi_I}. \qquad (4)$$

As follows from (II.17), the magnitude of the systematic error at the receiver's output equals zero.

On the basis of (I.12) and (I.13), formula (4) can be written in the form

$$\delta_I = 0.37 \frac{\sqrt{m}\, \omega_f^{3/2}}{\omega_d \omega_0} \left(\frac{A_0}{U}\right) e^{-\frac{\pi}{8}\left(\frac{\lambda\omega_d}{\Delta\omega}\right)^2} \sqrt{\Phi_I}, \qquad (5)$$

where A_0 is the maximum amplitude of the transient response at the output of the input filter to a voltage jump (or to a noise pulse of long duration, where the transient responses to the noise's leading and trailing edges do not overlap) and U is the signal amplitude at the filter's output.

The expression for Φ_1 is simplified if $\alpha \leq 2.5$. In this case,

$$\xi_1 = \frac{2}{\alpha^2}\cos\alpha + \left(\frac{1}{\alpha} - \frac{2}{\alpha^3}\right)\sin\alpha \approx \frac{1}{3} - \frac{1}{10}\alpha^2,$$

$$\xi_2 = \left(-1 + \frac{6}{\alpha^2}\right)\cos\alpha + 3\left(\frac{1}{\alpha} - \frac{2}{\alpha^3}\right)\sin\alpha \approx$$

$$\approx \frac{1}{5}\alpha^2 - \frac{1}{42}\alpha^4.$$

If $\alpha > 10$, then $\xi_1 \approx \sin\alpha/\alpha$ and $\xi_2 \approx -\cos\alpha + 3\sin\alpha/\alpha$. It is clear from formula (4) that the magnitude of the reduced error increases linearly with increasing amplitude of the noise pulses U_n and decreases with increasing mean signal frequency ω_0 and maximum deviation frequency ω_d. The error depends very little on the bandwidth of the input filter (the third term in the expression for Φ_I is small in comparison with unity). For $\lambda = 0$, $\delta \neq \varphi(\Delta f)$. The relationship of the error to the noise duration is expressed in a complicated manner. Formula (4), as follows from its derivation, is valid under the conditions when the maximum amplitude of the transient response to pulse noise at the input filter's output $B_{max}(t)$ does not exceed the amplitude of the signal $U(k_{max} = B_{max}(t)\, U \leq 1)$.

b. The Bell-Shape Filter Form

By carrying out the analogous computation for the bell-shaped form of the output filter's frequency characteristic

$$K(\omega) = e^{-\frac{\pi}{8}\left(\frac{\omega}{\omega_f}\right)^2}$$

we obtain the following formula:

$$P_n = \frac{2.3 m \omega_f^3}{\omega_0^2}\left(\frac{U_n}{U_s}\right)^2 \Phi_b, \qquad (6)$$

where

$$\Phi_b = 1 - e^{-\frac{2}{\pi}\alpha^2}\left(1 - \frac{4}{\pi}\alpha^2\right)\cos(\omega_0 + \lambda\omega_d)\tau -$$

$$- \frac{\pi}{2}\left(\frac{\lambda\omega_d}{\Delta\omega}\right) e^{-\frac{2}{\pi}\alpha^2} \cdot \frac{4\alpha^2}{\pi}\left(3 - \frac{4\alpha^2}{\pi}\right)\frac{\sin(\omega_0 + \lambda\omega_d)\tau}{\Delta\omega\tau},$$

$$\delta_b = 0.76 \frac{\sqrt{m}\cdot \omega_f^{3/2}}{\omega_d \omega_0}\left(\frac{U_n}{U_s}\right)\sqrt{\Phi_b}, \qquad (7)$$

or

$$\delta_b = 0.85 \frac{\sqrt{m}\, \omega_f^{3/2}}{\omega_d \Delta\omega}\left(\frac{A_0}{U}\right) e^{-\frac{\pi}{8}\left(\frac{\lambda\omega_d}{\Delta\omega}\right)^2} \sqrt{\Phi_b}. \qquad (8)$$

2. Dependence of the Error on the Duration of the Noise Pulses

Figure 2 gives the square of the reduced mean-square error, computed from formulas (4) and (7) as a function of the noise duration for the ideal and bell-shaped output filter forms, respectively,

$$\phi_I = 0.33 \frac{\sqrt{m}\,\omega_f^{3/2}}{\omega_d \omega_0}\left(\frac{U_n}{U_s}\right), \quad \phi_b = 2.3\phi_I, \quad \frac{\lambda\omega_d}{\Delta\omega} < 1.$$

It is clear from Fig. 2 that the curve for the relationship of the error and $\alpha = \omega_f\tau$ has the character of a modulated high-frequency oscillation. The high-frequency component depends on the relationship of the noise duration and the signal's frequency, i.e., on $\cos(\omega_0 + \lambda\omega_d)\tau$, and the envelope of the error variation curve depends on the relationship of the noise duration and the pass band of the output filter (on α).

As α increases, the error tends to a constant value, determined by the action on the receiver of the two pulse edges independently. The laws of variation of the error as a function of noise duration are similar for the ideal and the bell-shaped form of the output filter but, in the case of the bell-shaped form, the error's high-frequency component decays much more rapidly.

It follows from formulas (4) and (7) that, for a definite duration of the noise pulse [for $(\omega_0 + \lambda\omega_d)\tau = \pi$)], the magnitude of the error is a maximum, and equals

$$\delta_{I\max} = 0.466 \frac{\sqrt{m}\,\omega_f^{3/2}}{\omega_d \omega_0}\left(\frac{U_n}{U_s}\right), \qquad (9a)$$

$$\delta_{B\max} = 2.3\delta_{I\max}. \qquad (9b)$$

For very long durations of the noise, when $\alpha \to \infty$ (in practice, even for $\alpha > 30$),

$$\delta_{I_{\alpha\to\infty}} = 0.33 \frac{\sqrt{m}\,\omega_f^{3/2}}{\omega_d \omega_0}\left(\frac{U_n}{U_s}\right), \qquad (10a)$$

$$\delta_{B_{\alpha\to\infty}} = 2.3\,\delta_{I_{\alpha\to\infty}}. \qquad (10b)$$

It is clear from (9) and (10) that $\delta_{\max} = \sqrt{2}\,\delta_{\alpha\to\infty}$. This relationship is self-evident since, by definition, $\delta \equiv \sqrt{P_n}$ and, as follows from physical considerations, $P_{n\max} = 2P_{n\,\alpha\to\infty}$.

If the noise pulse has a duration much less than the period of the high-frequency carrier, i.e., if $\omega_0\tau \ll 1$, and the noise may be approximated by delta functions, then

$$\delta I_{\omega_0\tau<1} = 0.233\,\frac{\sqrt{m}\,\omega_f^{3/2}}{\omega_d}\left(\frac{U_n\tau}{U_s}\right), \tag{11a}$$

$$\delta b_{\omega_0\tau<1} = 2.3\,\delta I_{\omega_0\tau<1}. \tag{11b}$$

As follows from Fig. 2 and from formulas (4) and (7), the influence of the phase relationships (of the high frequency) on the magnitude of the error exists, not only in the case when the transient responses from the leading and trailing edges of the noise pulse overlap [as follows from (1.13) for $\sqrt{\beta}\tau < 4$], but also in the case when these transient responses have a significant separation between them, i.e., in the case when, for all practical purposes, they do not overlap.

It should be mentioned however that, in actual conditions, due to the instability of the duration of the noise pulses (this instability being of significant magnitude when the durations are long), an averaging of the error within the limits of variation of the noise pulses $\Delta\tau$ can occur and for $\Delta\tau > (0.5/f_0)$, the averaged error will be close to $\delta_{\alpha\to\infty}$. In practice, one frequently has to do with noise pulses of unknown duration. In these cases, it is most reasonable to carry out the computations for the worst case (i.e., for that duration of the noise which maximizes the error). From formulas (9a) and (9b), one can determine the maximum error (for the critical τ) which is possible when the full bandwidth of the input filter is used, when $\omega_d = \Delta\omega - \omega_f = \text{const}$, with the conditions that the transient responses from the individual noise pulses at the output of filter F_1 do not overlap and that $m \to 2\Delta f$ and $k_{\max} \to 1$. If these conditions hold (cf. II.15), formulas (9a) and (9b) will have the form:

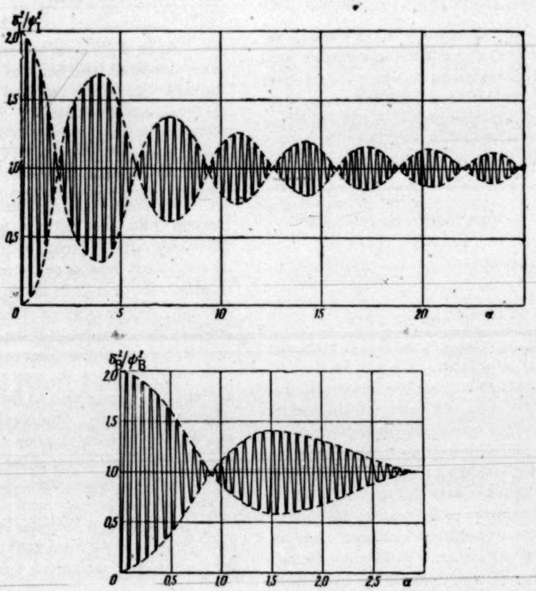

Fig. 2.

$$\delta^{\bullet}_{I\max} \leqslant \frac{0.1}{(\gamma-1)\sqrt{\gamma}}, \tag{12a}$$

$$\delta^{\bullet}_{b\max} \leqslant \frac{0.23}{(\gamma-1)\sqrt{\gamma}}, \tag{12b}$$

where $\gamma = \Delta\omega/\omega_f = \Delta f/F_f$. For telemetry systems, one ordinarily has $\gamma \geq 5$ and, as follows from (12), $\delta^{\bullet}_{I\max} \leq 1.1\%$ and $\delta^{\bullet}_{B\max} \leq 2.5\%$. The maximum error obtainable in the very worst conditions, cited above, is thus relatively small.

It is clear from the formulas given above that the error quantities $\delta_{\max}$, $\delta_{\alpha\to\infty}$, $\delta_{\omega_0\tau\ll1}$ and $\delta^{\bullet}_{\max}$ are

2.3 times greater for the bell-shaped form of the output filter than for the case of the ideal filter form.

It is necessary to note that the taking off experimentally of the function $\delta = \varphi(\tau)$ gives rise to technical difficulties related to the necessity of a high stability of τ, particularly for large values of f_0 but, nonetheless, the character of the curves of Fig. 2 was substantiated experimentally.

3. Noise Stability Threshold for Noise Pulses

As was stated earlier, the formulas for the reduced mean-square error are valid for $k_{max} = B_{max}(t)/U \leq 1$. Since the theoretical analysis of the case when $k_{max} > 1$ gives rise to mathematical difficulties, noise stability under these conditions was investigated experimentally. Figure 3 shows the function $\delta_{max} = \varphi(k_{max})$, taken off experimentally for the following values of the parameters: $\tau = 15.5$ msec, $m = 17$, $f_0 = 1$ kc, $2\Delta f = 150$ cps, $F_f = 2$ cps, $\gamma = 0$. The dashed line gives the same relationship computed from the theoretical formula (9b). It is clear from Fig. 3 that, for $k_{max} < 1$, the error is of small magnitude (less than 0.1%) and increases linearly with increasing k_{max}, a rapid growth in the error occurring for $k_{max} > 1$. The experimental results bear out the assertion of [1] that the condition $k_{max} = 1$ corresponds to the threshold of noise stability for frequency modulation for pulse noise. For the condition to hold that $k_{max} \leq 1$ (the equal sign corresponds to the noise stability threshold), the following conditions must be met [cf. formulas (II.13)-(II.15)]:

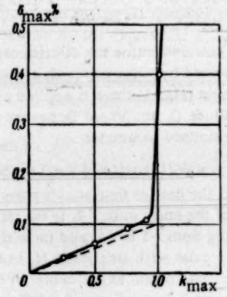

Fig. 3.

1) For the duration of the noise pulses much less than one period of the high frequency, i.e., for $\omega_0\tau \ll 1$,

$$\frac{U_n}{U_s}\Delta\omega\tau \leqslant 0.75;$$

2) for virtual nonoverlapping of the transient processes from the leading and trailing edges of the individual noise pulses, i.e., for $\Delta f\tau > 0.8$,

$$\frac{U_n}{U_s}\frac{\Delta\omega}{\omega_0} \leqslant 0.75;$$

3) for overlapping of the transient responses from the edges of the noise pulses and a doubled total reaction,

$$\frac{U_n}{U_s}\frac{\Delta\omega}{\omega_0} \leqslant 0.375.$$

4. Optimal Deviation Frequency for Pulse Noise

Figure 4 shows the curves for the relationship of the maximum error (for the critical duration of the noise pulses)

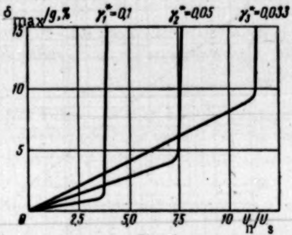

Fig. 4.

and the ratio U_n/U_s at the receiver input for various values of $\gamma = \Delta f/F_f$, constructed on the basis of theoretical (with $k_{max} < 1$) and experimental (for $k_{max} > 1$) data (the sharp bends in the curves correspond to the condition $k_{max} = 1$):

$$g = \frac{17.5\sqrt{m}\,\omega_f^{3/2}}{\omega_d\Delta\omega}, \gamma^* = \gamma\frac{\omega_f}{\omega_0}.$$

It is clear from Fig. 4 that, if it be required to provide a small error for a large amount of noise (small δ_{max}/g), then it is advisable to work with large values of γ, since this error will be attained for the greatest amount of noise.

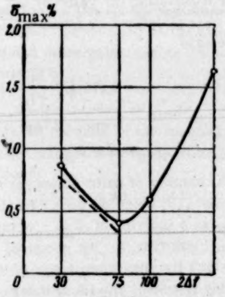

Fig. 5.

However, if δ_{max}/g is large, it is then more advantageous to reduce the input filter's bandwidth (reduce γ). Thus, for constant U_n/U_s, there exists an optimal pass band of the input filter and, consequently, an optimal deviation frequency for which the mean-square error at the receiver's output will be minimal. The determination of the conditions corresponding to the optimal deviation frequency was carried out experimentally. Figure 5 shows the function $\delta_{max} = \varphi(2\Delta f)$, obtained experimentally for τ = 35.5 msec, m = 17, f_0 = 1 kc, F_f = 2 cps, and k_{max} = = 1 for $2\Delta f$ = 80 cps. The dashed line gives the theoretical function, constructed from formula (9b). It is obvious from Fig. 5 that the minimum error occurs for $k_{max} = 1$. The value of the optimum pass band can thus be defined from expressions (II.13)-(II.15).

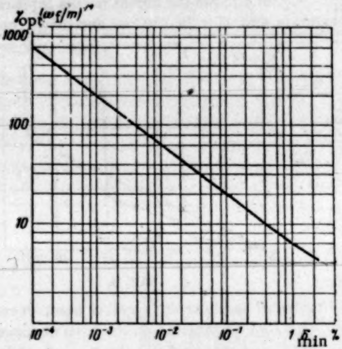

Fig. 6.

The optimal deviation frequency will equal $\omega_{d\ opt} = \Delta\omega_{opt} - \omega_f$ and, for small ω_f, $\omega_{d\ opt} \approx \Delta\,\omega$. The presence of the optimal deviation frequency for $k_{max} = 1$ also follows from the curves of Figs. 3 and 4, if one takes into account the sharply increasing error for $k_{max} > 1$.

Knowing $\omega_{d\ opt}$, one can determine the least value of error possible for a given ratio U_n / U_s at the receiver input. By substituting the value of $\omega_{d\ opt} = \Delta\,\omega_{opt} - \omega_f$, where $\Delta\,\omega_{opt}$ is defined by formula (II.15), in (9a) and (9b), we obtain

$$\delta_{I\,min} = \frac{0.175\sqrt{\frac{m}{\omega_f}}}{(\gamma_{opt} - 1)\,\gamma_{opt}}, \tag{13a}$$

$$\delta_{b\,min} = 2.3\,\delta_{I\,min}. \tag{13b}$$

If the number of noise pulses per second $m \to 2\Delta f$, then formulas (13) coincide with formulas (12). Figure 6 shows γ_{opt} as a function of δ_{min}, obtained from formula (13b). It is clear that, for the choice of the optimal pass band for which the maximum range of the action of the telemetering system is provided, it suffices to know the system's error, its speed of response (the quantity ω_f), and the average number of noise pulses per unit time. After γ_{opt} has been chosen, it is necessary to verify the condition of nonoverlap of the transient responses from the individual noise pulses at the input filter's output, since the formulas obtained are rigorously valid only for this condition. The question of the receiver's noise stability when this condition of nonoverlap is violated requires additional investigation.

SUMMARY

1. With operation of a frequency receiver of a telemetering system under conditions of weak noise pulses of arbitrary duration (without special noise-protection measures having been taken), when the maximum amplitude of the transient response to the noise does not exceed the signal amplitude ($k_{max} < 1$), the reduced mean-square error at the receiver's output depends slightly on the input filter's bandwidth, decreases with increasing maximum deviation frequency, and depends on the duration of the noise pulses in a complicated way.

2. With frequency modulation and noise pulses, there exist a threshold of noise stability and an optimal value of deviation frequency, both occurring when k_{max} = = 1. The conditions under which $k_{max} \leq 1$ are defined by formulas (II.13)-(II.15).

3. The maximum value of the error (for the critical duration of the noise pulses), obtained for complete employment of the input filter's bandwidth and with the condition of nonoverlap of the transient responses to individual noise pulses at the input filter's output and the conditions that $k_{max} \to 1$ and $\gamma \geq 5$, does not exceed 1.1% for an ideal characteristic of the output filter and 2.5% for a bell-shaped characteristic.

4. For $k_{max} > 1$, the error exceeds the admissible one for telemetry, and it is necessary to take special measures to limit the noise pulses.

APPENDIX I

Discriminator's Output Voltage with Noise Pulses Acting on the Receiver

We now determine the discriminator's output voltage engendered by noise pulses if, at the frequency receiver's input (Fig. 1) there is applied a sinusoidal signal with amplitude U_s and whose frequency depends linearly on the transmitted parameter λ:

$$u = U_s \cos[(\omega_0 + \lambda\omega_d)\,t + \varphi_0]. \tag{I.1}$$

where φ_0 is the carrier frequency's phase at the moment of action of the noise pulse, λ is the transmitted parameter, varying from -1 to +1, and there simultaneously acts a noise pulse with amplitude U_n and duration τ. By placing the time origin at the center of the noise pulse, we can present it in the form of a difference of two dc voltage jumps, one of which acts at time $t = -\tau/2$, the other at time $t = \tau/2$. When one voltage jump acts on input filter F_1, the filter's output voltage can be given as

$$u_s = A(t)\cos\omega_0 t. \tag{I.2}$$

where A(t) is the voltage envelope of the transient response.

Using the principle of superposition for the action of two jumps, i.e., the noise pulse, we can write the filter's output voltage as

$$u_n = A\left(t + \frac{\tau}{2}\right)\cos\omega_0\left(t + \frac{\tau}{2}\right) - A\left(t - \frac{\tau}{2}\right)\cos\omega_0\left(t - \frac{\tau}{2}\right).$$

We give this expression in the form

$$u_{\mathrm{n}} = B(t)\cos[\omega_0 t + \theta(t)]. \qquad (I.3)$$

where B(t) is the voltage envelop of the transient response engendered by the noise pulse of duration τ; $\theta(t)$ is the phase of the transient response voltage,

$$B(t) = \left[A^2\left(t+\frac{\tau}{2}\right) + A^2\left(t-\frac{\tau}{2}\right) - 2A\left(t+\frac{\tau}{2}\right)A\left(t-\frac{\tau}{2}\right)\cos\omega_0\tau\right]^{\frac{1}{2}}. \qquad (I.4)$$

$$\theta(t) = \operatorname{arctg}\frac{A\left(t+\frac{\tau}{2}\right) + A\left(t-\frac{\tau}{2}\right)}{A\left(t+\frac{\tau}{2}\right) - A\left(t-\frac{\tau}{2}\right)}\operatorname{tg}\frac{\omega_0\tau}{2}. \qquad (I.5)$$

The resulting voltage from signal and noise at the output of filter F_1 will equal

$$U_{\mathrm{p}} = U\cos[(\omega_0 + \lambda\omega_{\mathrm{d}})t + \varphi_0] + B(t)\cos[\omega_0 t + \theta(t)] = S\cos[\omega_0 t + \psi(t)], \qquad (I.6)$$

where U is the signal amplitude at the filter's output.

The phase of this oscillation is

$$\psi(t) = \operatorname{arctg}\frac{U\sin(\lambda\omega_{\mathrm{d}}t + \varphi_0) + B(t)\sin\theta(t)}{U\cos(\lambda\omega_{\mathrm{d}}t + \varphi_0) + B(t)\cos\theta(t)}. \qquad (I.7)$$

The deviation of the frequency of the resulting oscillation from the mean frequency ω_0 is determined by the time derivative of the function $\psi(t)$, i.e., by the magnitude of $d\psi/dt$, and the deviation of the frequency of this oscillation from the signal's frequency (equal to $\omega_0 + \lambda\omega_{\mathrm{d}}$) is defined by the expression $\Delta\omega_{\mathrm{r}}(t) = d\psi/dt - \lambda\omega_{\mathrm{d}}$.

By differentiating, we obtain

$$\Delta\omega_{\mathrm{r}}(t) = \frac{-\frac{dk}{dt}\sin\gamma}{1+k^2+2k\cos\gamma} - \left(\lambda\omega_{\mathrm{d}} - \frac{d\theta}{dt}\right)\frac{k^2 + k\cos\gamma}{1+k^2+2k\cos\gamma}, \qquad (I.8)$$

where

$$k = k(t) = \frac{B(t)}{U}, \qquad \gamma = \lambda\omega_{\mathrm{d}}t + \varphi_0 - \theta(t).$$

For k < 1, the fractions in (I.8) can be expanded in simple series:

$$\frac{\sin\gamma}{1+k^2+2k\cos\gamma} = \sum_{n=1}^{\infty} k^{n-1}\sin n\gamma,$$

$$\frac{k^2 + k\cos\gamma}{1+k^2+2k\cos\gamma} = \sum_{n=1}^{\infty} k^n\cos n\gamma.$$

With this, formula (I.8) is written in the form

$$\Delta\omega_{\mathrm{r}}(t) = (-1)^n\left\{\frac{dk}{dt}\sum_{n=1}^{\infty}k^{n-1}\sin n\gamma - \left(\lambda\omega_{\mathrm{d}} - \frac{d\theta}{dt}\right)\sum_{n=1}^{\infty}k^n\cos n\gamma\right\}. \qquad (I.9)$$

By assuming an ideal frequency discriminator, i.e., one whose output voltage is directly proportional to the deviation of the frequency from the mean value ω_0:

$$u_{\mathrm{out.\,d}} = s(\omega - \omega_0), \qquad (I.10)$$

we get from (I.9) that the discriminator's output voltage, when noise pulses act on the receiver's input, will equal

$$u_{\mathrm{out}}(t) = s\Delta\omega_{\mathrm{r}}(t). \qquad (I.11)$$

In what follows, we shall assume the slope of the discriminator's characteristic to be s = 1. For the case of a bell-shaped frequency characteristic $C(\omega)$ of input filter F_1

$$C(\omega) = C_0 e^{-\frac{\pi}{2}\frac{(\omega-\omega_0)^2}{(2\Delta\omega)^2}}, \qquad (I.12)$$

where $\Delta\omega = 2\pi\Delta f$ and $2\Delta f$ is the bandwidth; the voltage envelope of the transient response at the filter's output when a dc voltage of magnitude U_{n} acts at the input is determined by the formula [6]

$$A(t) = A_0 e^{-\beta t^2} = \frac{\sqrt{8}}{\pi}U_{\mathrm{n}}C_0\frac{\Delta\omega}{\omega_0}e^{-\frac{2}{\pi}\Delta\omega^2 t^2}. \qquad (I.13)$$

APPENDIX II

Energy Spectrum of a Sequence of Noise Pulses at the Discriminator Output

The expression for the energy spectrum of the sequence of noise pulses appearing at the discriminator's output when random noise pulses act at the receiver's input has the form [7]:

$$W(\omega) = 2m\,|F(\omega)|^2, \qquad (II.1)$$

where $|F(\omega)|$ is the modulus of the spectral density of an individual noise pulse and m is the average number of pulses per second.

The spectral density of an individual noise pulse

$$F(\omega) = \int_{-\infty}^{\infty} u_{\mathrm{out}}(t)e^{-i\omega t}dt \qquad (II.2)$$

can be written in the form

$$F(\omega) = A(\omega) - iB(\omega) = |F(\omega)|\,e^{-\eta(\omega)}, \qquad (II.3)$$

where

$$A(\omega) = \int_{-\infty}^{\infty} u_{\mathrm{out}}(t)\cos\omega t\,dt, \quad B(t) = \int_{-\infty}^{\infty} u_{\mathrm{out}}(t)\sin\omega t\,dt, \qquad (II.4)$$

and $u_{\mathrm{out}}(t)$ is defined by formula (I.11).

By substituting the value of $u_{out}(t)$ in (II.4) and computing the integrals, we obtain the expressions for the real and imaginary parts of the spectral density in the form

$$A(\omega) = \sum_{n=1}^{\infty} A_n(\omega) = \sum_{n=1}^{\infty} \frac{(-1)^n \omega}{n} \int_{-\infty}^{\infty} \left[\frac{B(t)}{U}\right]^n \sin n\,[\lambda\omega_d t + \varphi_0 - \theta(t)] \sin \omega t\, dt, \tag{II.5}$$

$$B(\omega) = \sum_{n=1}^{\infty} B_n(\omega) = \sum_{n=1}^{\infty} -\frac{(-1)^n \omega}{n} \int_{-\infty}^{\infty} \left[\frac{B(t)}{U}\right]^n \sin n\,[\lambda\omega_d t + \varphi_0 - \theta(t)] \cos \omega t\, dt.$$

By carrying out a number of trigonometric transformations, and by taking into account, as follows from (I.3), that

$$B(t)\cos\theta(t) = \left[A\left(t+\frac{\tau}{2}\right) - A\left(t-\frac{\tau}{2}\right)\right]\cos\frac{\omega_0\tau}{2},$$

$$B(t)\sin\theta(t) = \left[A\left(t+\frac{\tau}{2}\right) + A\left(t-\frac{\tau}{2}\right)\right]\sin\frac{\omega_0\tau}{2}, \tag{II.6}$$

we get, for $A(\omega)$ and $B(\omega)$, that

$$A(\omega) = \sum_{n=1}^{\infty} A_n(\omega) = \sum_{n=1}^{\infty} [A_{2n-1}(\omega) + A_{2n}(\omega)], \tag{II.7}$$

where

$$A_{2n-1}(\omega) = \frac{(-1)^{2n-1}\omega \sin(2n-1)\varphi_0}{2n-1} \left[\int_{-\infty}^{\infty} \left[\frac{B(t)}{U}\right]^{2n-1} \cos(2n-1)\theta \cos(2n-1)\lambda\omega_d t \sin\omega t\, dt + \right.$$

$$\left. + \int_{-\infty}^{\infty} \left[\frac{B(t)}{U}\right]^{2n-1} \sin(2n-1)\theta \sin(2n-1)\lambda\omega_d t \sin\omega t\, dt\right],$$

$$A_{2n}(\omega) = \frac{(-1)^{2n}\omega \cos 2n\varphi_0}{2n}\left[\int_{-\infty}^{\infty} \left[\frac{B(t)}{U}\right]^{2n} \cos 2n\theta \sin n\lambda\omega_d t \sin\omega t\, dt - \int_{-\infty}^{\infty} \left[\frac{B(t)}{U}\right]^{2n} \sin 2n\theta \cos 2n\lambda\omega_d t \sin \omega t dt\right],$$

$$B(\omega) = \sum_{n=1}^{\infty} B_n(\omega) = \sum_{n=1}^{\infty} [B_{2n-1}(\omega) + B_{2n}(\omega)], \tag{II.8}$$

where

$$B_{2n-1}(\omega) = -\frac{(-1)^{2n-1}\omega \cos(2n-1)\varphi_0}{2n-1}\left[\int_{-\infty}^{\infty} \left[\frac{B(t)}{U}\right]^{2n-1} \cos(2n-1)\theta \sin(2n-1)\lambda\omega_d t \cos\omega t\, dt - \right.$$

$$\left. - \int_{-\infty}^{\infty} \left[\frac{B(t)}{U}\right]^{2n-1} \sin(2n-1)\theta \cos(2n-1)\lambda\omega_d t \cos\omega t\, dt\right],$$

$$B_{2n}(\omega) = -\frac{(-1)^{2n-1}\omega \sin 2n\varphi_0}{2n-1}\left[\int_{-\infty}^{\infty} \left[\frac{B(t)}{U}\right]^{2n} \cos 2n\theta \cos 2n\lambda\omega_d t \cos\omega t\, dt + \int_{-\infty}^{\infty} \left[\frac{B(t)}{U}\right]^{2n} \sin 2n\theta \sin 2n\lambda\omega_d t \cos\omega t\, dt\right].$$

It follows from (II.7) and (II.8) that, after averaging over the phase angle φ_0 for its equiprobable values, one obtains the following valid relationships

$$\overline{[A(\omega)]^2} = \sum_{n=1}^{\infty} \overline{[A_n(\omega)]^2}, \quad \overline{[B(\omega)]^2} = \sum_{n=1}^{\infty} \overline{[B_n(\omega)]^2},$$

since $\overline{\sin n\varphi_0 \cos l\varphi_0} = 0$, $\overline{\sin k\varphi_0 \sin l\varphi_0} = 0$ and $\overline{\cos k\varphi_0 \cos l\varphi_0} = 0$.

With this, the energy spectrum of (II.1) can be written in the form

$$W(\omega) = 2m \sum_{n=1}^{\infty} \overline{|F_n(\omega)|^2}, \tag{II.9}$$

where $\overline{|F_n(\omega)|^2} = \overline{[A_n(\omega)]^2} + \overline{[B_n(\omega)]^2}$.

We now express the values of $B(t)^n \cos n\theta(t)$ and $B(t)^n \sin n\theta(t)$ in terms of their values for $n = 1$ (II.6), substitute them in the expressions for $A_n(\omega)$ (II.7) and $B_n(\omega)$ (II.8) and then integrate. In finding $[A_n(\omega)]^2$ and $[B_n(\omega)]^2$ and substituting in these expressions the values of A_0, β, and C_0 / U, defined in accordance with (I.12) and (I.13) by the formulas

$$A_0 = \frac{\sqrt{8}\, U_n C_0 \Delta\omega}{\pi\omega_0}, \quad \beta = \frac{2\Delta\omega^2}{\pi}, \quad \frac{C_0}{U} = \frac{e^{\frac{\pi}{8}\left(\frac{\lambda\omega_d}{\Delta\omega}\right)^2}}{U_s},$$

we get that the following real relationships hold for telemetering systems in which $\omega_{max} / \Delta\omega = \omega_f / \Delta\omega \leq 0.2$ and $\omega_d \leq \Delta\omega - \omega_f$:

$$|\overline{F_1(\omega)}|^2 = 4\left(\frac{\omega}{\omega_0}\right)^2 \left(\frac{U_n}{U_s}\right)^2 \left\{1 - \cos(\omega_0 + \lambda\omega_d)\tau \cos\omega\tau - \frac{\pi}{2}\left(\frac{\lambda\omega_d}{\Delta\omega}\right)\left(\frac{\omega}{\Delta\omega}\right) \sin(\omega_0 + \lambda\omega_d)\tau \sin\omega\tau\right\} \qquad (II.10)$$

$$|\overline{F_2(\omega)}|^2 = 4\left(\frac{\omega}{\omega_0}\right)\left(\frac{U_n}{U_s}\right)^2 \left[\frac{1}{\pi^2}\left(\frac{\Delta\omega}{\omega_0}\right)^2 \left(\frac{U_n}{U_s}\right)^2\right] \left\{1 - \cos 2(\omega_0 + \lambda\omega_d)\tau \cos\omega\tau + \right.$$

$$+ \frac{\pi}{2}\left(\frac{\lambda\omega_d}{\Delta\omega}\right)\left(\frac{\omega}{\Delta\omega}\right) \sin 2(\omega_0 + \lambda\omega_d)\tau \sin\omega\tau - 4e^{-\frac{\beta\tau^2}{2}}\left[\cos(\omega_0 + \lambda\omega_d)\tau \cos\frac{\omega\tau}{2} + \right.$$

$$\left.\left. + \frac{\pi}{2}\left(\frac{\lambda\omega_d}{\Delta\omega}\right)\left(\frac{\omega}{\Delta\omega}\right) \sin(\omega_0 + \lambda\omega_d)\tau \sin\frac{\omega\tau}{2}\right] + 2e^{-\beta\tau^2}\right\}, \qquad (II.11)$$

$$|\overline{F_3(\omega)}|^2 = 4\left(\frac{\omega}{\omega_0}\right)\left(\frac{U_n}{U_s}\right)^2 \left[\frac{2.38}{\pi^4}\left(\frac{\Delta\omega}{\omega_0}\right)^4 \left(\frac{U_n}{U_s}\right)^4\right] \left\{1 - \cos 3(\omega_0 + \lambda\omega_d)\tau \cos\omega\tau - \right.$$

$$\left. - \frac{\pi}{2}\left(\frac{\lambda\omega_d}{\Delta\omega}\right)\left(\frac{\omega}{\Delta\omega}\right) \sin 3(\omega_0 + \lambda\omega_d)\tau \sin\omega\tau\right\}. \qquad (II.12)$$

Formulas (II.10)-(II.12) are valid for $k_{max} = B(t)_{max}/U < 1$. We now determine the maximum value of $U_n \Delta\omega / U_s \omega_0$ for which the condition $k_{max} < 1$ holds.

The signal amplitude at the output of filter F_1

$$U = U_s C(\omega) = U_s C_0 e^{-\frac{\pi}{2}\frac{(\omega-\omega_0)^2}{(2\Delta\omega)^2}}$$

has its maximum value for $\omega - \omega_0 = \lambda\,\omega_d = \omega_d$. Since $\omega_d = \Delta\omega - \omega_f \approx \Delta\omega$ (for small ω_f), then $U_{min} = 0.677\, U_s C_0$.

If $\omega_0 \tau \ll 1$ then, as follows from (II.4), $B(t)_{max} = A_0 \omega_0 \tau$ and, for the condition $k_{max} < 1$ to hold, it is necessary that the following inequality hold

$$\frac{U_n}{U_s}\Delta\omega\tau < 0.75. \qquad (II.13)$$

If the transient responses from the leading and trailing edges of the individual noise pulses virtually do not overlap, which occurs, as follows from (I.13), for $\sqrt{\beta}\,\tau > 4$, then $B(t)_{max} = A_0$ and, in order for the inequality $k_{max} < 1$ to hold, it is necessary that the following condition be met

$$\frac{U_n}{U_s}\frac{\Delta\omega}{\omega_0} < 0.75. \qquad (II.14)$$

When the transient responses from the noise pulse edges do overlap, i.e., when $\sqrt{\beta}\,\tau < 4$ and when, for definite values of noise pulse duration, the responses may overlap in phase and the total reaction be doubled, one must assume that $B(t)_{max} = 2A_0$. Then, to obtain the condition that $k_{max} < 1$, one must have the relationship

$$\frac{U_n}{U_s}\frac{\Delta\omega}{\omega_0} < 0.375. \qquad (II.15)$$

By taking into account that condition (II.15) must hold for $0 < \sqrt{\beta}\,\tau < 4$, we obtain the following formulas for the coefficients of expressions (II.10)-(II.12)

$$\nu_1 = 1, \quad \nu_2 = \frac{1}{\pi^2}\left(\frac{\Delta\omega}{\omega_0}\right)^2 \left(\frac{U_n}{U_s}\right)^2 < 0.0143,$$

$$\nu_3 = \frac{2.38}{\pi^4}\left(\frac{\Delta\omega}{\omega_0}\right)^4 \left(\frac{U_n}{U_s}\right)^4 \leqslant 0.000487.$$

For $\sqrt{\beta}\,\tau > 4$ and condition (II.14) being met,

$$\nu_1 = 1, \qquad \nu_2 = 0.057, \qquad \nu_3 = 0.00768.$$

From the values obtained for the ν, it is clear that, with an accuracy sufficient for our purposes, we can set

$$|\overline{F(\omega)}|^2 \approx |\overline{F_1(\omega)}|^2,$$

since

$$|\overline{F_1(\omega)}|^2 \gg |\overline{F_2(\omega)}|^2 \gg |\overline{F_3(\omega)}|^2.$$

Thus, the energy spectrum of the sequence of noise pulses at the discriminator output for $\omega_{max}/\Delta\omega = \omega_f/\Delta\omega \leq 0.2$ and $k_{max} = B(t)_{max} / U < 1$ is defined by the equation

$$W(\omega) \approx 2m\,|\overline{F_1(\omega)}|^2, \qquad (II.16)$$

where $\overline{|F_1(\omega)|}^2$ is found from formula (II.10)

The constant (dc) component of the sequence of noise pulses at the discriminator [7]

$$U_{\text{const}} = mF(0), \qquad \text{(II.17)}$$

equals zero, it following from (II.5) that $F(0) = A(0) - iB(0) = 0$.

Due to the absence of the constant component of (II.17), the discrete portion of the energy spectrum of the sequence of noise pulses at the discriminator output (consisting, in the general case, of a discrete and a continuous portion) will equal zero, and formula (II.1), defining the spectrum's continuous portion, will be valid, for equiprobable values of φ_0, both for chaotic and for periodic trains of noise pulses.

ON AMPLIFIERS OF ERROR SIGNALS OF ELECTRICAL AUTOMATIC CONTROL SYSTEMS

L. L. Dekabrun
(Moscow)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 1, pp. 106-111, January, 1960)
Original article submitted February 16, 1959

A new principle of designing synchronous detector circuits is presented which permits a significant lowering in the magnitude of the lag* introduced in the transmission of a signal by amplifiers of slowly varying voltage. The circuits permit the broadening of the domain of applicability of such amplifiers in automatic control systems where amplifiers with galvanic connections cannot provide high accuracy.

A qualitative analysis is given of the lag introduced by amplifiers in existing synchronous detection circuits.

The simplest amplifiers of error signals in automatic control systems are amplifiers with galvanic connections. Their disadvantage is that the drift of the output voltage [1, 2] and the indeterminacy of the initial state determine the limits of the accuracy with which the system can maintain a given value of the controlled quantity. Amplifiers with preliminary transformation of error signal voltages to ac carrier-frequency voltages [3] allow the system accuracy to be increased by at least two orders of magnitude and, with very good regulation, even higher, although in theory there is also drift in these amplifiers [4]. However, such amplifiers transmit signals with significant lag which, in some cases, can lead to a loss of system stability.

The "inertia" of amplifiers with transformed input voltages has received little treatment in the literature [5]. Below, we give an approximate quantitative estimate of this quantity, and present a significantly less "inertial" principle for designing such amplifiers.

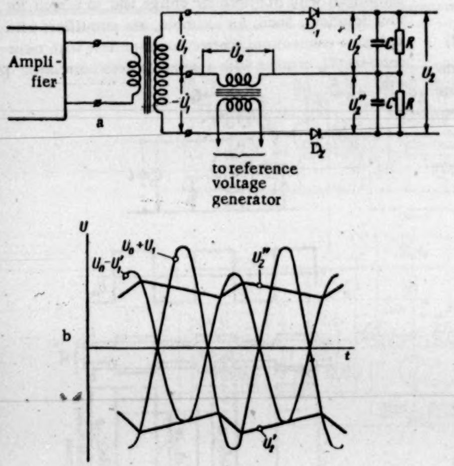

Fig. 1.

The lag in amplifiers with transformed input voltage is induced by the filters which smooth the voltage at the output of the synchronous detector circuit following the amplifiers. Figure 1 a shows one of the widely used synchronous detector circuits; Fig. 1 b shows a somewhat simplified graph of the output voltages U_2' and U_2'' of each section of this circuit. The difference of these voltages constitutes the output voltage U_2 of the synchronous detector and amplifier as a whole.

For adequate smoothing of the output voltage, it is necessary that the following condition hold

$$T_0 < \tau, \tag{1}$$

where T_0 is the period of the carrier frequency voltage off which the transformer of the input voltage operates and $\tau = RC$ is the smoothing filter's time constant. When condition (1) holds, the dc component of voltage U_2 will have the magnitude

$$U_{20} = 2U_1\left(1 - \frac{T_0}{2\tau}\right), \tag{2}$$

and the relative magnitude of the pulsation is found from the formula

$$\varepsilon = \frac{(U\text{pulse})_{\max}}{U_{20}} \doteq \frac{\frac{T_0}{\tau}}{2\left(1 - \frac{T_0}{2\tau}\right)}. \tag{3}$$

Figure 2 shows U_{20} and ϵ as functions of the smoothing filter's time constant.

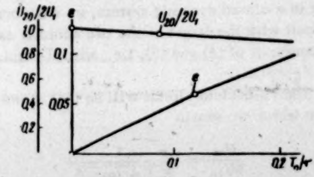

Fig. 2.

---

* In this paper, we understand by the terms "lag" and "inertia" a sum of factors which give rise to any distortion, other than scale-factor changes, of the output signal as compared to the input signal.

The transient response of the synchronous detector (and, consequently, of the amplifier as a whole), i.e., its reaction to an abrupt change in amplitude of the detected voltage U_1, is a complicated function of the circuit parameters and of time. By simplifying the outlines, we can show that

a) for an abrupt decrease of U_1, the fall of the output voltage will follow a law close to an exponential one with a time constant somewhat larger than

$$\tau_f = RC; \qquad (4)$$

b) for an abrupt increase in U_1, the rise of the output voltage will follow a law close to an exponential one with a time constant somewhat larger than

$$\tau_r = \frac{RR_1}{R + R_1} C. \qquad (5)$$

Here, R_1 is the resulting resistance of the circuit through which the condenser charges (the resistance of the diode, the transformer, etc.).

The rise and fall of the output voltage do not follow purely exponential laws because, in the given circuit, they are not continuous processes, e.g., with rising voltage, the condensers only charge during fractions of the positive half-periods while, during the rest of the time, they discharge through their load resistances.

We now construct the amplitude and phase frequency characteristics of the amplifier, with the assumption that its input voltage, i.e., the error signal voltage, varies harmonically

$$U_{in} = U_M \cos \omega_1 t. \qquad (6)$$

For a given frequency ω_0 of the modulating voltage, the frequency ω_1 of the input voltage must lie within the limits of

$$0 \leqslant \omega_1 \leqslant (0.1 \div 0.2)\omega_0, \qquad (7)$$

since otherwise the amplifiers's modulating device could not transmit the form of the input voltage with sufficient accuracy [3]. With this, the detected voltage U_1 will be a sinusoid with variable amplitude

$$U_1 = (U_M \cos \omega_1 t) \sin \omega_0 t. \qquad (8)$$

For estimating the possibilities of using the amplifier in a closed dynamic system, we shall consider its circuit with the larger of the two actually existing time constants of (4) and (5), i.e., with the time constant τ_f = RC.

The equivalent circuit will be that shown on Fig. 3, from which we obtain

$$\frac{U_{20}}{kU_{in}} = \frac{1}{\sqrt{1 + (\omega_1 \tau_f)^2}}, \qquad (9)$$

$$\operatorname{tg} \psi = -\omega_1 \tau_f. \qquad (10)$$

Here, k is the over-all gain and ψ is the phase shift of the amplifier's output voltage with respect to its input voltage.

Figure 4 shows the amplitude and phase frequency characteristics of the amplifiers computed by these formulas. The parameter of the characteristics is the relative time constant of the detector's smoothing circuit, $\beta = T_0/\tau$. These characteristics are universal, being valid for all forms of synchronous detector circuits, including the so-called fast-acting variants of [6]. It is clear from the curves of Fig. 4 that, for good smoothing, the amplifier's output voltage reacts only to very slow changes in the input voltage, while even in this region, i.e., the region of very small values of ω_1, the phase shift of the output voltage with respect to the input voltage retains a significant size. These disadvantages of amplifiers with transformers oblige one to search for new solutions. Such, for example, are amplifiers with galvanic connections, corrected amplifiers with transformers [7], circuits with automatic zero correction [8], etc.

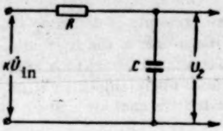

Fig. 3.

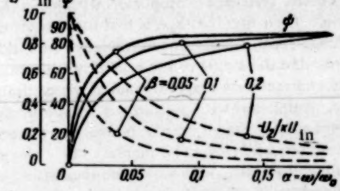

Fig. 4.

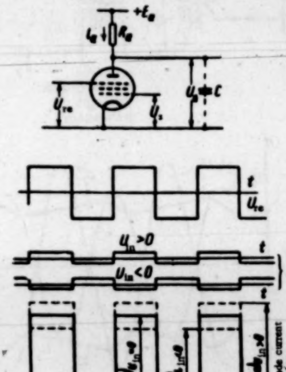

Fig. 5.

The "inertia" of an amplifier with transformation of the input voltage can be significantly decreased if the smoothing of the output voltage is implemented, not by means of accumulators of energy (on the circuit of Fig. 1, the capacitor C is such an accumulator of energy), but by the filling of the "holes" between the pulses of output voltage by pulses obtained from a detection circuit. If the transforming device transforms the input voltage to rectangular pulses (as, for example, in the case of transformation by means of a contact chopper) and the reference voltage also has the form of rectangles, one could then theoretically get rid of the smoothing condensers at the output. Figure 5 shows the block schematic of a synchronous detector and the graphs characterizing its operation in the case when the reference and the detected voltages have the form of rectangular pulses. We assume that there is a second such circuit, operating on the same load resistance R_a but at those intervals of time when the first circuit is cut off by the reference voltage, i.e., the operating cycle of the second circuit is shifted by π with respect to the operating cycle of the first circuit. Then, in the ideal case, the output voltage (the voltage on load R_a) will have no pulsations. Figure 6 gives the functional block schematic of an amplifier with a transformer of the input voltage and an inertialess two-cycle synchronous detector, while Fig. 7 gives the graphs which characterize its operation. ties related to the realization of this principle have to do, principally, with the accuracy of synchronization of the operating cycles, and with the accuracy of matching the characteristics of the two channels. Figure 8 shows a circuit which is one of the possible variants of the solution to this problem. The basis of the circuit is a two-cycle synchronous detector (tubes L_7 and L_8) analogous to that considered above. The circuit's rhythm of operation is given by the independently driven multivibrator $L_{1a}L_{1b}$ in whose circuit there is the capability of tuning symmetric cycles. The reference voltage of the synchronous detection circuit is formed by amplifier-limiter L_{2a} and split by phase-inverter L_{2b}. The contact transformer of the error signal voltage, implemented by polarized relay PR-4, is connected at the output of the symmetric cathode follower $L_{5a}L_{5b}$. The adjustment of the equality of the intervals of open and closed states of the contacts is regulated by the delay time of single flip-flop oscillator $L_{4a}L_{4b}$, from which the controlling pulses for the grid of the cathode follower are obtained. Synchronization of the input voltage pulses with the reference voltage pulses is so performed, that triggering of single flip-flop oscillator $L_{4a}L_{4b}$ is carried out with some lag with respect to the reference voltage pulses. The delay time is established by means of regulation single flip-flop oscillator $L_{3a}L_{3b}$, triggered by the edges of the reference voltage pulses. Tubes L_{6a} and L_{6b} form an amplifier-phase-inverter for the transformed error signal voltage.

With inexact adjustment, there are some pulsations in the amplifier's output voltage, for the smoothing of which capacitor C must be connected, as shown with a dashed line on the circuit diagram. However, even with comparatively inexact adjustment, to attain smoothing of the output voltage in the given circuit which is comparable with the smoothing obtained in the ordinary synchronous detector circuits, there is required a time constant of the smoothing circuit which is less than the usual one by several tens.

The gain of the system shown on Fig. 8 is about 400. To increase the gain, it is necessary to include one or more amplifying stages before the circuit of phase-inverter $L_{6a}L_{6b}$.

DETERMINATION OF MAGNETIC CONDUCTANCE WITH GEARED STATOR AND ROTOR

L. A. Sribner

(Odessa)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 1, pp. 112-118, January, 1960)
Original article submitted May 28, 1959

A method is considered for the calculation of magnetic conductance for a geared stator and rotor, with flux leakage being taken into account. Functional relationships are established for the determination both of the total magnetic conductance and of the coefficients which take into account flux leakage.

The method developed can be used for designing electric hammers, geared inductive transducers, pitch and pulsed motors, and other electromagnetic systems, and also for the computation of the flux pulsation in the teeth of electrical machines with geared rotors and stators.

In contemporary technology, broad use is made of various electromagnetic mechanisms with moving and immovable geared portions.

The computation of the magnetic circuits of such mechanisms is virtually untreated in the literature. Ordinarily, for computing the magnetic conductance of an air gap, it is recommended that one use awkward graphical methods. The greatest difficulty is presented by the accounting for flux leakages. If one knows the magnetic conductance with flux leakages taken into account, the problem is significantly simplified. An extensive literature [1-3] is devoted to computational methods for this case.

The flux leakage in certain mechanisms with geared rotors and stators is large, and sometimes exceeds significantly the basic flux. In some of these mechanisms the flux leakage is almost constant [4], but it varies sharply in the overwhelming majority of the cases. Sometimes, Carter's formula [5, 6] is used for calculating leakage fluxes, but for small air gaps its use gives understated results.

In the present paper we present a formula for calculating the magnetic conductance of an air gap for geared stators and rotors.

Definition of the Fictitious Air Gap

We shall agree to give the name "rotor" to the moving part of a magnetic circuit, independently of whether its motion is reciprocating or rotational. The nonmoving part of the circuit we call the stator. The flux between the teeth of the stator and rotor we shall call the basic magnetic flux. The magnetic fluxes in the grooves, in the face ends, and through the ribs of the teeth we shall call the leakage fluxes. It must be said at once that, in many cases (for example, in electrical machines), the leakage flux is not a parasitic flux, but is added to the useful basic flux. However, even in this case, we shall call it a leakage flux.

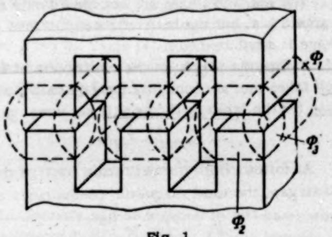

Fig. 1.

There are the following leakage fluxes between the stator and rotor teeth (Fig. 1): 1) lateral leakage flux Φ_1; 2) face end leakage flux Φ_2; 3) leakage flux through the ribs of the teeth Φ_3; 4) the leakage flux of the coil, i.e., the leakage flux through the air around the coil.

The leakage flux of the coil is constant for practical purposes, and may be computed by multiplying the greatest value of the basic flux by the coefficient $\sigma = 0.05$ to 0.2. The coefficient σ depends on the design characteristics of the magnetic circuit. In the sequel, we shall not consider the leakage flux of the coil.

We now introduce the concept of the fictitious air gap δ'. For this we shall consider the air gap to be uniformly distributed (by considering the rotor and stator to be smooth), and a change in the magnetic conductance of the air gap will be taken into account by a change in the fictitious air gap.

If the flux leakages are ignored, then the fictitious air gap will equal

$$\delta' = \frac{\delta_0}{\frac{a}{t}\left(1 - \frac{l}{a}\right)} = \frac{\delta_0}{0.5\left(1 - \frac{l}{a}\right)}, \quad (1)$$

where δ_0 is the actual air gap, a is the width of the teeth, $t = 2a$ is the pitch of the teeth, i.e., the total width of the tooth plus the groove, and l is the relative shift of the rotor and stator teeth.

We now consider how one may take leakage fluxes into account with the determination of the fictitious air gap δ'. For simplicity of the reasoning, we shall assume that the rotor teeth are against the stator teeth, i.e., that $l = 0$.

The magnetic conductance of the basic flux on unit tooth length equals

$$g = \frac{\mu_0 S}{\delta_0} = \frac{\mu_0 a}{\delta_0}, \qquad (2)$$

where μ_0 is the magnetic permeability of air and S is the area through which the basic flux passes. In our case, $S = a$.

Moreover, the flux leakages induce additional magnetic conductance. This conductance, per unit tooth length, equals

$$g_1 = k_1 \frac{\mu_0 2a}{\delta_0}. \qquad (3)$$

The leakage fluxes are not closed only through the area $S = a$, but the magnetic conductance of the leakage is attributed to it.

In formula (3), k_1 is the coefficient of leakage which takes into account that the equivalent air gap $\delta_{0\,\text{equ}}$ for the leakage fluxes will not equal gap δ_0:

$$\delta_{0\,\text{equ}} = \delta_0/k_1.$$

As follows from the definition itself of the fictitious air gap, the total magnetic conductance equals

$$g_t = \frac{\mu_0 2S}{\delta'} = \frac{\mu_0 2a}{\delta'}. \qquad (4)$$

On the other hand, the total magnetic conductance is

$$g_t = g + g_1.$$

By substituting the values of the conductances from formulas (2), (3), and (4), we get that

$$\frac{\mu_0 2a}{\delta'} = \frac{\mu_0 a}{\delta_0} + k_1 \frac{\mu_0 2a}{\delta_0}, \qquad (5)$$

or, after some transformations,

$$\delta' = \frac{\delta_0}{0.5 + k_1}.$$

If the rotor teeth are shifted relative to the stator teeth, i.e., if $l \neq 0$, then, by taking formula (1) into account, we get

$$\delta' = \frac{\delta_0}{0.5\left(1 - \frac{l}{a}\right) + k_1}. \qquad (6)$$

Taking into Account the Magnetic Conductance of the Lateral Flux Leakage

The coefficient which takes into account the magnetic conductance of the lateral (side) flux leakage depends, in addition to everything else, on the shift of the rotor teeth relative to the stator teeth. We shall therefore first determine it for the case when the rotor teeth are against the stator teeth.

It is clear from expression (3) that the computation of the coefficient of side leakage $k_s = k_1$ reduces to the computation of the magnetic conductance of the lateral leakage per unit length $g_s = g_1$, since the remaining quantities of expression (3) are already known.

If we assume that the magnetic lines of forces are semicircles, then the conductance equals [2]

$$g_1 = \frac{\mu_0}{\pi} \ln\left[1 + \frac{2a}{\delta_0}\right]. \qquad (7)$$

If they are assumed to be semi-ellipses, then [2]

$$g_1 = \frac{\mu_0}{\pi} \ln\left[1 + 2\,\frac{a + \sqrt{a^2 + a\delta_0}}{\delta_0}\right]. \qquad (8)$$

If they are considered to consist of four portions of circles and straight lines, we then obtain [2]

$$g_1 = \frac{\mu_0}{\pi} \ln\left[1 + \frac{\pi a}{\delta_0}\right]. \qquad (9)$$

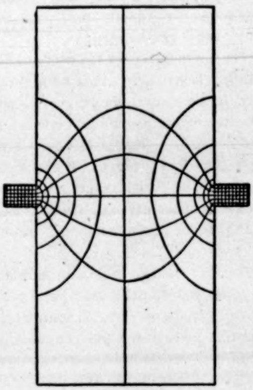

Fig. 2.

We now consider what form the actual lines of force might have. On Fig. 2, we have constructed the outlines of the magnetic field in the grooves for the groove depth equal to its width. For this construction, the steel surface was taken as an equipotential surface which, in the given case, is completely admissible, even for comparatively large values of induction.

It is clear from Fig. 2 that the magnetic lines of force differ significantly from semicircles or parts of ellipses. Moreover, for various values* of x, the magnetic lines of force are described by different equations and, for $x = a$, reduce to straight lines. In this case, the mean length of the magnetic lines of force equals approximately $l_x = 3x + \delta_0$; for small x the length is $l_x > 3x + \delta_0$ and, for large x, $l_x < 3x + \delta_0$ and, for increasing x, approximates to the value $l_x = 2x + \delta_0$.

---

*We denote by x the distance between the magnetic lines of force and the beginning of the groove for equipotential surfaces equally spaced from the teeth.

The area through which the magnetic flux passes is not constant, but varies per unit length from 0.5 to 1.5a, there being a corresponding change in the area of the elementary force tubes from 0.5 to 1.5 dx; in the mean, this area equals dx.

The estimates given are also approximately valid for other relationships of the size of the air gap and the teeth dimensions.

By substituting these mean values of length and area of the elementary force tubes in the formula for computing magnetic conductance, we get

$$g_s = g_1 = \mu_0 \int_0^a \frac{dx}{3x + \delta_0} =$$

$$= \frac{\mu_0}{3} \left| \ln (3x + \delta_0) \right|_0^a = \frac{\mu_0}{3} \ln \left(1 + \frac{3a}{\delta_0}\right). \qquad (10)$$

Finally, we take the following formula which gives the results coinciding most exactly with experimental results:

$$g_s = \frac{\mu_0}{\pi} \ln \left(1 + \frac{3a}{\delta_0}\right). \qquad (11)$$

From expressions (3) and (11), we obtain the expression for the coefficient of lateral (side) leakage

$$k_s = \frac{\delta_0 \ln \left(1 + \frac{3a}{\delta_0}\right)}{\pi a}. \qquad (12)$$

We now consider how the coefficient of lateral conductance varies as the rotor teeth are shifted (displaced) with respect to the stator teeth.

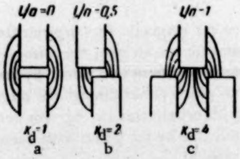

Fig. 3.

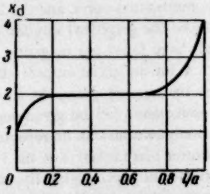

Fig. 4.

Let the rotor teeth be displaced relative to the stator teeth by half a tooth (Fig. 3 b). In this case the conductance $g_1 = \mu_0 \int_0^a dx/l_x$ will be twice as large as in the case with nondisplaced teeth (Fig. 3 a), since here the length of the magnetic lines of force is twice as small. Consequently, the coefficient of side conductance will be twice as large here. The coefficient of side (lateral) conductance will be exactly the same if there are teeth only on the stator, the rotor being smooth, or conversely.

We now consider the case when the rotor teeth are against (opposite) the stator grooves (Fig. 3 c). Here, the coefficient of lateral conductance will be twice as large as in the previous case, i.e., four times larger than for nondisplaced teeth. We take the variation of the coefficient of lateral displacement into account by introducing a coefficient of teeth displacement k_d, which is defined by the graph of Fig. 4. This graph was constructed with experimental results being taken into account, these results showing that the curve of the magnetic flux of such electromagnetic mechanisms is a straight line when the teeth displacement lies within the limits of $l/a = 0.2$ to 0.7 and, for larger and for smaller values of l/a, becomes curved. Analogous curves of the flux were also given by Yasse [4] (for two teeth).

The formula for determining the fictitious air gap takes the following form:

$$\delta' = \frac{\delta_0}{0.5\left(1 - \frac{l}{a}\right) + k_d k_s}. \qquad (13)$$

This formula can be applied in all cases when there are narrow and long grooves. If the grooves are only on the rotor, or only on the stator, then the coefficient k_s must be doubled, whereby it no longer depends on the position of the rotor. Then, the formula is written in the following form:

$$\delta' = \frac{\delta_0}{0.5 + k_s}. \qquad (14)$$

For electrical machines, formulas (13) and (14) give results which coincide closely with those computed by Carter's formula [7].

Further Refinement of the Formula for Determining the Fictitious Air Gap

Formula (13) gives incorrect results for short grooves. In this case it is necessary to take into account the face leakage flux and the leakage flux through the ribs of the teeth.

The coefficient of face end leakage can be computed analogously to the coefficient of lateral leakage, assuming the depth of the grooves to be significantly greater than the width, but the active depth equal to the groove width.

The length of the magnetic lines of force can be taken equal to $l_x = 3.5x \pm \delta_0$, on the average, and the cross section of an elementary magnetic force tube per unit length equal, on the average, to approximately dx.

The magnetic conductance of the face end flux leakage equals

$$g_f = \mu_0 \int_0^a \frac{dx}{l_x} = \mu_0 \int_0^a \frac{dx}{3.5x + \delta_0} =$$

$$= \frac{\mu_0}{3.5} |\ln (3.5x + \delta_0)|_0^a = \frac{\mu_0}{3.5} \ln \left(1 + 3.5 \frac{a}{\delta_0}\right), \quad (15)$$

from whence we obtain, for the coefficient of face end conductance,

$$k_f = \frac{\delta_0 \ln \left(1 + 3.5 \frac{a}{\delta_0}\right)}{3.5a} \frac{a}{b} = \frac{\delta_0 \ln \left(1 + 3.5 \frac{a}{\delta_0}\right)}{3.5b}, \quad (16)$$

where b equals the groove length.

As the rotor teeth are displaced relative to the stator teeth, the coefficient of face end conductance, i.e., the leakage flux through the face end, just as with the basic flux, decreases linearly.

We now take into account the conductance of the teeth ridges. If one equates the conductance of the ridges with the conductance of the face end, it is then easily calculated that the coefficient of ridge flux for undisplaced teeth equals $0.6k_f$. When the rotor teeth are opposite the stator grooves, this coefficient is doubled, since the flux contains an angle twice as large. We assume that the coefficient of flux leakage through a ridge varies linearly as the rotor teeth as shifted with respect to the stator teeth (although, in actuality, it varies in accordance with a more complicated law).

The formula for calculating the fictitious air gap when one takes into account the coefficients of face end flux leakage and ridge flux leakage takes the following form:

$$\delta' = \frac{\delta_0}{\left(1 - \frac{l}{a}\right)(0.5 + k_f) + 0.6k_f\left(1 + \frac{l}{a}\right) + k_d k_s}, \quad (17)$$

where k_s and k_f are defined by formulas (12) and (16).

Taking the Reluctance of the Magnetic Circuit into Account

Formula (17) makes it possible to calculate the magnetic conductance of an air gap with the flux leakages taken into account. However, for small air gaps δ_0, the reluctance of the magnetic circuit becomes commensurable with the reluctance of the air gap, and must therefore be taken into account.

As is well known, for ferromagnetic materials the dependence on ampere-turns of the magnetic flux is nonlinear, and is given by the magnetization curve. Consequently, the magnetic circuit's reluctance is not constant, but depends on the ampere-turns applied.

It is simplest to take the magnetic circuit's reluctance into account graphically. For this, we decompose the magnetic circuit into a series of portions (segments) such that the cross-section of the magnetic circuit will be invariant on each segment. For each portion one constructs, from the magnetization curve for the given type of steel, the magnetization curve of the segment multiplied by the value of induction from the first curve on the segment's cross section, and the field strength (specific ampere-turns) on the segment's length.

Thereafter, one constructs the magnetization curve of the entire magnetic circuit, adding up, for arbitrary values of magnetic flux, the ampere-turns of the segments of the magnetic circuit.

After this, it is necessary to construct the dependence of the magnetic flux on the ampere-turns for the air gap. For this, we give ourselves the ampere-turns iw and compute the magnetic flux Φ_0 in the air gap under the assumption that the magnetic circuit's reluctance equals zero:

$$\Phi_0 = \frac{iw}{\delta'} \mu_0 S, \quad (18)$$

where S is the area of the air gap.

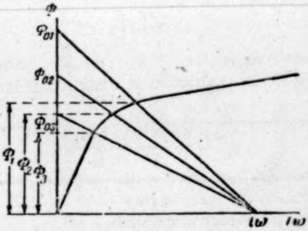

Fig. 5.

Since the magnetic flux depends linearly on the ampere-turns for the air gap, the corresponding graph can be constructed from two points by drawing the straight line which passes through the origin and through the point with coordinates iw, Φ_0. For convenience, we construct this line by the points with coordinates iw, 0, and 0, Φ_0 (Fig. 5).

Then, the point of intersection of the magnetic circuit's magnetization curve and the line for the air gap will also be the graphical solution of the problem, i.e., we shall have found the magnetic flux of the magnetic system Φ for the given ampere-turns. If the flux is divided by the ampere-turns, the quotient will be the magnetic conductance for the given conditions.

Such computations can be repeated for various shifts of the rotor teeth relative to the stator teeth, i.e., for various fictitious gaps. Naturally, the magnetization curve of the magnetic circuit will not thereby be varied.

The data thus obtained can be employed in the design of all the possible electromagnetic devices.

The magnitude of the magnetic conductance and its variations as a function of the displacement of the rotor teeth relative to the stator teeth can be converted to terms of forces, moments (torques), or inductions, depending on the purpose for which the device being designed is intended.

In conclusion, the author wishes to thank L. K. Shrago for reading the manuscript and for making a number of valuable comments.

THE EFFECT OF NONUNIFORMITY OF MAGNETIZATION ON THE STATIC CHARACTERISTICS OF CORES. I

G. D. Kozlov

(Moscow)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 1, pp. 119-134, January, 1960)
Original article submitted June 4, 1959

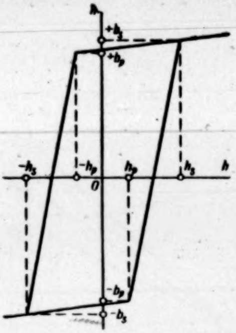
The effect of nonuniformity of magnetization on the static characteristics of cores is considered. The computations are given for the limiting magnetization polarity reversal loop of a core, the symmetric and biased magnetization polarity reversal loops, and the "basic magnetization curve".

Recently, in various branches of automation, remote control, and computing technology, wide use has been made of magnetic amplifiers employing cores with complicated forms of magnetic circuits (magnetic circuits with variable cross sections, ramified or multibranched magnetic circuits, etc.). Among the magnetic devices with ramified magnetic circuits are the "transfluxers" which can be used as decoders, logical elements, memory devices without destructive read-out, etc. The magnetization of the magnetic circuit in such devices occurs nonuniformly, and is fundamentally conditioned by the geometric form and the dimensions of the magnetic circuit, and also by the physical position of the magnetizing windings. In [1, 2] was considered the question of taking into account the effect of nonuniform core magnetization on its static characteristics, the present work being a development of the earlier ones. In [1, 2], the authors determine the magnitude of the magnetic induction of a toroidal core as a function of the field strength, B = f(H). With this, the field strength, is taken, in [1], relative to the mean core radius $R = (R_0 + R_1)/2$ and, in [2], relative to the mean harmonic radius $R_h = (R_0 - R_1/ \ln(R_0/R_1)$.* From our point of view, one can more simply and more graphically derive conclusions by using the relationship B = f(F) instead of B = f(H), where F is the number of ampere-turns of the magnetization. The advantage of introducing such a relationship is particularly clearly seen when one takes into account the nonuniformity of magnetization in a multibranched magnetic circuit, where the relationship B = f(H) loses its meaning, since it is not known relative to which length of lines of force the field strengths are defined.

The present work is devoted to accounting for the effect of nonuniformity of core magnetization on its static characteristics for various core geometries and for various modes of magnetic polarity reversal. In this portion of the work, all the basic relationships are derived for toroidal magnetic circuits when they undergo complete, and partial, reversal of their magnetic polarity.

Basic Statements

The hysteresis loops of all magnetic material can, with sufficient accuracy, be presented by two forms of idealized hysteresis loops (Figs. 1 and 2). Each form of loop corresponds to a definite group of materials. Within each group, the materials can be distinguished from each other by the following parameters; b_s, the saturation induction; b_p, the induction at the beginning of magnetic polarity reversal; h_s the saturation field



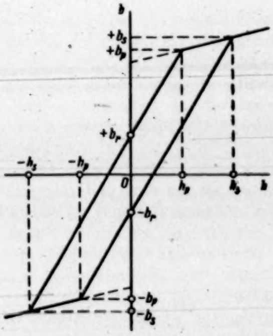


Fig. 2.

---

* Publishers' note – "o" and "i" are "outside diameter" and "inside diameter," respectively.

strength; h_p the field strength at the beginning of magnetic polarity reversal. Such idealized material hysteresis loops permit one to determine, not only qualitatively, but also quantitatively, the effect of nonuniformity of core magnetization on its static characteristics. The process of magnetic polarity reversal of a core presents itself as the reversal of magnetic polarity of individual concentric layers of material lying one within the other. The reversal of magnetic polarity begins with the inner levels, when the induced field strength becomes greater than the quantity h_p. The reversal of magnetic polarity ceases when the magnitude of the field strength reaches the value h_s.

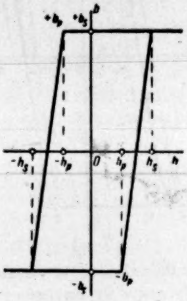

Fig. 3.

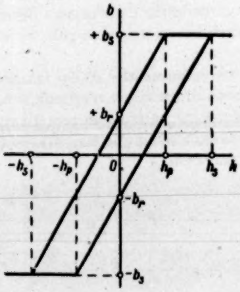

Fig. 4.

For simplicity, we shall consider the material hysteresis loops shown on Figs. 3 and 4, for which the ascending and descending arms of the hysteresis loops are expressed mathematically as follows:

For the case of Fig. 3,

$$b = \frac{2b_s}{h_s - h_p}\left(h - \frac{h_s + h_p}{2}\right), \tag{1}$$

$$b = \frac{2b_s}{h_s - h_p}\left(h + \frac{h_s + h_p}{2}\right); \tag{2}$$

for the case of Fig. 4,

$$b = \frac{2b_s}{h_s + h_p}\left(h - \frac{h_s - h_p}{2}\right), \tag{3}$$

$$b = \frac{2b_s}{h_s + h_p}\left(h + \frac{h_s - h_p}{2}\right). \tag{4}$$

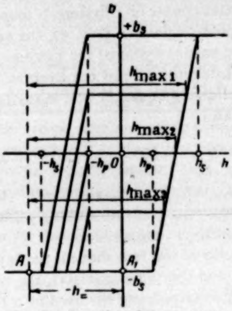

Fig. 5. Family of symmetric cycles of a hysteresis loop.

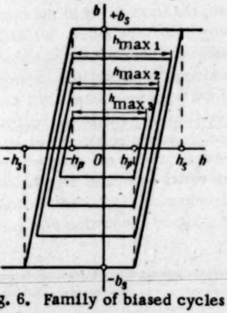

Fig. 6. Family of biased cycles of a hysteresis loop.

For the consideration of the process of reversal of a material's magnetic polarity, we shall henceforth assume that the ascending and descending arms are symmetric and have the same slope in the partial hysteresis loops as the arms of the limiting hysteresis loop. This assertion is borne out to a significant degree by the experimental data provided in the literature. We shall therefore assume that the characteristic slope of the material, $b = f(h)$, is constant for the ascending and descending arms, and equal to $2b_s/(h_s - h_p)$ (for the case of Fig. 3) independently of the form of the hysteresis loop by which the process of magnetic polarity reversal occurs. The quantity h_p remains constant both for symmetric and for biased partial cycles of a hysteresis loop (Figs. 5 and 6). This permits the ascending and descending arms of the family of symmetric cycles of a hysteresis loop (Fig. 5) to be described by the following equations:

$$b = \frac{2b_s}{h_s - h_p}\left(h - \frac{h_{\max} + h_p}{2}\right), \tag{5}$$

$$b = \frac{2b_s}{h_s - h_p}\left(h + \frac{h_{\max} + h_p}{2}\right). \qquad (6)$$

Here, $h_{\max}$ is the maximum value of the magnetizing field strength.

In reversing a material's magnetic polarity by biased partial cycles of a hysteresis loop, when the initial working point is point A (Fig. 6), the ascending arm of the biased partial cycle of the hysteresis loop coincides with the ascending arm of the limiting hysteresis loop, but the following equation will actually hold for the descending arm

$$b = -b_s - \frac{2b_s}{h_s - h_p}(h' - h_{\max}'), \qquad (7)$$

where $h'_{\max} = h_{\max} - h_=$ and $h' = h - h_=$ is the value of the field strength if the working point is translated to A_1 (Fig. 6).

In spite of the fact that all the layers of a core are of one and the same material, the core as a whole has its magnetic polarity reversed by a loop which differs from the material's hysteresis loop. The explanation of this is that, for one and the same number of ampere-turns, the inner layer of the core has a greater field strength than the outer. We shall therefore distinguish henceforth between terms which relates to the material (limiting hysteresis loop, family of symmetric cycles of the hysteresis loop, etc.) and terms referring to the core (limiting magnetic polarity reversal loop, symmetric magnetic polarity reversal loop family, etc.).

For determining the magnetic polarity reversal loop of an entire core, one uses the concept of the mean magnetic induction [1, 2]. We define the magnitude of the mean magnetic induction of a core by the equation

$$B = \frac{1}{R_0 - R_1}\int_{R_1}^{R_0} b\,dR, \qquad (8)$$

where R_0 and R_1 are the core's outer and inner radius and $\alpha = R_0/R_1$ is the ratio of the radii.

To find the relationship $B = f(F)$, we substitute the transformed Eqs. (1)-(7) in Eq. (8).

The Core's Magnetic Characteristics

Depending on the maximum number of magnetizing ampere-turns $F_{\max}$, the core will have different modes of magnetic polarity reversal, defining the form of the function $B = f(F)$.

We initially consider the operation of a core in the mode of its limiting magnetic polarity reversal loop, if the materials's hysteresis loop has the form shown on Fig. 3.

a) Magnetic Polarity Reversal by the Limiting Loop ($F_{\max} \geq \alpha F_s$)

Figure 7 shows the construction of the core's limiting magnetic polarity reversal loop in terms of the coordinates B and F. We denote by the lines aa_1 and cc_1 the ascending and descending arms of the hysteresis loops for the inner and outer layers of the material, respectively. The values of F_p and F_s define the ampere-turns of the inner layer's magnetic polarity reversal and saturation, respectively. The values of αF_p and αF_s serve similarly for the outer layer. In considering Fig. 7, one may note that the values of the ampere-turns for the beginning and the end of the magnetic polarity reversal for different core layers do not coincide. For a given magnetic material and for different core geometries, one can consider three cases of core induction variation when the core has its magnetic polarity reversed along its limiting loop.

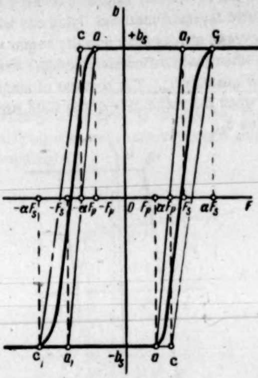

Fig. 7.

For the determination of the function $B = f(F)$, i.e., the magnitude of the core's magnetic induction as a function of the magnetizing ampere-turns, it is necessary to substitute, in Eq. (8), Eqs. (1) and (2), transformed to the form:

$$b = \frac{2b_s}{F_s - F_p}\left(F\frac{R_1}{R} - \frac{F_s + F_p}{2}\right), \qquad (9)$$

$$b = \frac{2b_s}{F_s - F_p}\left(F\frac{R_1}{R} + \frac{F_s + F_p}{2}\right). \qquad (10)$$

In the first case (Fig. 7), the core's geometry is such that $\alpha F_p < F_s$, i.e., the beginning of the material's magnetic polarity reversal along the outer perimeter occurs sooner that the saturation of the material along the inner perimeter. This case is optimal, since the function $B = f(F)$, for such a core geometry, is linear on a significant portion.

For this case, the following condition must hold

$$\alpha < \frac{h_s}{h_p} \qquad (11)$$

or

$$\alpha < \frac{F_s}{F_p}. \qquad (12)$$

To determine the function B = f(F), we substitute Eqs. (9) and (10) in Eq. (8). For different values of F, the function B = f(F) has segments with different characters of variation.

First segment. For the values $-F_{max} \leq F \leq F_p$,

$$B_1 = \frac{1}{R_0 - R_1} \int_{R_1}^{R_0} -b_s dR, \quad B_1 = -b_s. \tag{13}$$

Second segment. For the values $F_p \leq F \leq \alpha F_p$,

$$B_2 = \frac{1}{R_0 - R_1}\left[\int_{R_1}^{R} \frac{2b_s}{F_s - F_p}\left(F\frac{R_1}{R} - \frac{F_s + F_p}{2}\right) dR + \right.$$

$$\left. + \int_{R}^{R_0} -b_s dR \right]$$

(here, $R = R_1 F/F_p$ is the radius dividing the core into two parts, in one of which the process of magnetic polarity reversal has already begun, while in the other it has not).

$$B_2 = \frac{1}{\alpha - 1}\frac{b_s}{F_s - F_p}\left[2F\left(\ln\frac{F}{F_p} - 1\right) - \right.$$

$$\left. - F_s(\alpha - 1) + F_p(\alpha + 1)\right]. \tag{14}$$

Third segment. For the values $\alpha F_p \leq F \leq F_s$,

$$B_3 = \frac{1}{R_0 - R_1} \int_{R_1}^{R_0} \frac{2b_s}{F_s - F_p}\left(F\frac{R_1}{R} - \frac{F_s + F_p}{2}\right) dR,$$

$$B_3 = \frac{1}{\alpha - 1}\frac{b_s}{F_s - F_p}\left[2F\ln\alpha - (F_s + F_p)(\alpha - 1)\right]. \tag{15}$$

Fourth segment. For the values $F_s \leq F \leq \alpha F_s$,

$$B_4 = \frac{1}{R_0 - R_1}\left[\int_{R_1}^{R} b_s dR + \right.$$

$$\left. + \int_{R}^{R_0} \frac{2b_s}{F_s - F_p}\left(F\frac{R_1}{R} - \frac{F_s + F_p}{2}\right) dR\right]$$

(here, $R = R_1 F/F_s$ is the radius dividing the core into two parts, in one of which saturation has already occurred, while it has not in the other),

$$B_4 = \frac{1}{\alpha - 1}\frac{b_s}{F_s - F_p}\left[2F\left(1 + \ln\frac{\alpha F_s}{F}\right) - \right.$$

$$\left. - F_s(\alpha + 1) - F_p(\alpha - 1)\right]. \tag{16}$$

Fifth segment. For the values $\alpha F_s \leq F \leq F_{max}$ and for the reverse variation of F to value zero,

$$B_5 = \frac{1}{R_0 - R_1} \int_{R_1}^{R_0} b_s dR, \quad B_5 = b_s. \tag{17}$$

For negative ampere-turns of magnetization, the function B = f(F) is determined analogously.

By increasing the quantity α ($\alpha = R_0/R_1$), we obtain a second case, when $\alpha F_p = F_s$. This case is characterized by the absence of a linear portion of the function B = f(F) on the ascending and descending arms of the magnetic polarity reversal loop.

A further increase in α leads to the third case, when $\alpha F_p > F_s$. With this, the function B = f(F) has linear portions when the core has its magnetic polarity reversed in the narrow ring extending from the inner layers to the outer ones. In these last two cases, the limiting magnetic polarity reversal loops are determined by the same method as in the first case. For purposes of comparison, Fig. 8 shows the limiting magnetic polarity reversal loops for the first, second, and third cases of values of α:

$$\alpha = 0.75\frac{h_s}{h_p}, \quad \alpha = \frac{h_s}{h_p}, \quad \alpha = 1.5\frac{h_s}{h_p}$$

(curves I, II, III, respectively).

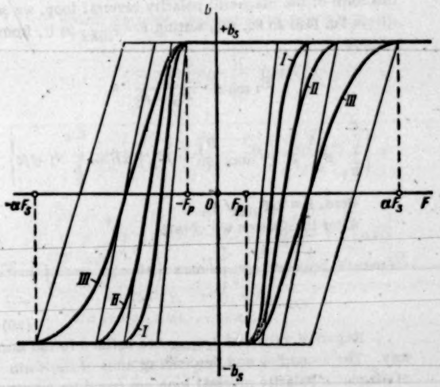

Fig. 8.

b. Magnetic Polarity Reversal by a Symmetric Loop ($F_{max} < \alpha F_s$)

When the maximum value of the magnetizing ampere-turns is inadequate for the magnetic polarity reversal of all the layers of the core material by the limiting hysteresis loop, the core will have its magnetic polarity reversed by symmetric loops. In connection with the circumstance that the individual layers of core material will have their magnetic polarities reversed by different symmetric cycles of the hysteresis loop, the mean maximum variation of the induction of the entire core B_{max} will be less than b_s. For the determination of the symmetric magnetic polarity reversal loops, it is necessary to determine, in addition to the ascending and descending arms of the magnetic polarity reversal loop, the value of $\pm B_{max}$. As a function of the value of F_{max}, the symmetric magnetic polarity reversal loops will differ, not only in magnitude, but also by configuration, where this configuration will also depend on the core's geometry.

We consider only the first case, where $\alpha F_p < F_s$. With further increase in α, the picture does not change qualitatively. To determine the function B = f(F) for symmetric magnetic polarity reversal loops, it is necessary that Eqs. (5) and (6) be transformed to:

$$b = \frac{b_s}{F_s - F_p}\left[(2F - F_{max})\frac{R_1}{R} - F_p\right], \tag{18}$$

$$b = \frac{b_s}{F_s - F_p}\left[(2F + F_{max})\frac{R_1}{R} + F_p\right]. \tag{19}$$

As a function of the size of F_{max}, the symmetric magnetic polarity reversal loops will have three forms.

First Form of the Symmetric Magnetic Polarity Reversal Loops ($F_p < F_{max} \le \alpha F_p$)

To determine B_{max} of the function B = f(F) for this form of the magnetic polarity reversal loop, we substitute Eq. (18) in Eq. (8), setting $F = F_{max}$ in it, from whence

$$B_{1\,max} = \frac{1}{R_0 - R_1} \times$$

$$\times \left\{\int_{R_1}^{R} \frac{b_s}{F_s - F_p}\left(F_{max}\frac{R_1}{R} - F_p\right) dR + \int_{R}^{R_0} 0 \cdot dR\right\}.$$

Here, $R = R_1 F_{max}/F_p$.

After integration we obtain

$$B_{1\,max} = \frac{1}{\alpha - 1}\,\frac{b_s}{F_s - F_p}\left[F_{max}\left(\ln\frac{F_{max}}{F_p} - 1\right) + F_p\right]. \tag{20}$$

Negative values of $B_{1\,max}$ are defined in the same way. The ascending and descending arms of this form of magnetic polarity reversal loop are found by substituting Eqs. (18) and (19) in Eq. (8).

By knowing the ascending and descending arms, and also $\pm B_{1\,max}$, one can construct the entire magnetic polarity reversal loop.

First segment. For values of $-F_{max} \le F \le F_p$,

$$B_1 = -B_{1\,max}. \tag{21}$$

Second segment. For values of $F_p \le F \le F_{max}$,

$$B_2 = \frac{1}{R_0 - R_1}\left\{\int_{R_1}^{R} \frac{b_s}{F_s - F_p} \times\right.$$

$$\times \left[(2F - F_{max})\frac{R_1}{R} - F_p\right] dR +$$

$$\left. + \int_{R}^{R_1} -\frac{b_s}{F_s - F_p}\left(F_{max}\frac{R_1}{R} - F_p\right) dR + \int_{R_1}^{R_0} 0 \cdot dR\right\}.$$

Here,

$$R = R_1\frac{F}{F_p}, \quad R_1 = R_1\frac{F_{max}}{F_p}.$$

After integration, we get

$$B_2 = \frac{1}{\alpha - 1}\,\frac{b_s}{F_s - F_p}\left[2F\left(\ln\frac{F}{F_p} - 1\right) + \right.$$

$$\left. + F_{max}\left(1 - \ln\frac{F_{max}}{F_p}\right) + F_p\right]. \tag{22}$$

Third segment. For values of $-F_p \le F \le F_{max}$,

$$B_3 = B_{1\,max}. \tag{23}$$

For negative values of F, the corresponding portions of the function B = f(F) are determined analogously.

Second Form of the Symmetric Magnetic Polarity Reversal Loops ($\alpha F_p \le F_{max} \le F_s$)

We first determine B_{max} of the function B = f(F) for this form of the magnetic polarity reversal loop:

$$B_{2\,max} = \frac{}{R_0 - R_1}\int_{R_1}^{R_0} \frac{b_s}{F_s - F_p}\left(F_{max}\frac{R_1}{R} - F_p\right) dR$$

or

$$B_{2\,max} = \frac{b_s}{F_s - F_p}\left(\frac{\ln\alpha}{\alpha - 1}F_{max} - F_p\right). \tag{24}$$

We now determine the ascending and descending arms of the function B = f(F) for this form of the magnetic polarity reversal loop.

First segment. For values of $-F_{max} \le F \le F_p$,

$$B_1 = -B_{2\,max}$$

Second segment. For values of $F_p \le F \le \alpha F_p$,

$$B_2 = \frac{1}{R_0 - R_1}\left\{\int_{R_1}^{R} \frac{b_s}{F_s - F_p} \times\right.$$

$$\times \left[(2F - F_{max})\frac{R_1}{R} - F_p\right] dR -$$

$$\left. - \int_{R}^{R_0} \frac{b_s}{F_s - F_p}\left(F_{max}\frac{R_1}{R} - F_p\right) dR\right\}.$$

Here, $R = R_1 F/F_p$.

After integration, we get

$$B_2 = \frac{1}{\alpha - 1}\,\frac{b_s}{F_s - F_p}\left[2F\left(\ln\frac{F}{F_p} - 1\right) - \right.$$

$$\left. - F_{max}\ln\alpha + F_p(\alpha + 1)\right]. \tag{25}$$

Third segment. For values of $\alpha F_p \le F \le F_{max}$,

$$B_3 = \frac{1}{R_0 - R_1} \times$$

$$\times \int_{R_1}^{R_0} \frac{b_s}{F_s - F_p} \left[(2F - F_{\max}) \frac{R_1}{R} - F_p \right] dR,$$

$$B_3 =$$

$$= \frac{1}{\alpha - 1} \frac{b_s}{F_s - F_p} [(2F - F_{\max}) \ln \alpha - F_p (\alpha - 1)]. \quad (26)$$

__Fourth segment.__ For values of $-F_p \leq F \leq F_{\max}$,

$$B_4 = B_2 \max.$$

For negative values of F, the descending arm is determined analogously.

Third Form of the Symmetric Magnetic Polarity Reversal Loops ($F_s \leq F_{\max} \leq \alpha F_s$)

We determined $B_{\max}$ of the function B = f(F) for this form of the magnetic polarity reversal loop:

$$B_{3\max} = \frac{1}{R_0 - R_1} \left[\int_{R_1}^{R_1} b_s \, dR + \right.$$

$$\left. + \int_{R_1}^{R_0} \frac{b_s}{F_s - F_p} \left(F_{\max} \frac{R_1}{R} - F_p \right) dR \right].$$

Here, $R_1 = R_1 F_{\max}/F_s$.
Integration gives

$$B_{3\max} = \frac{1}{\alpha - 1} \frac{b_s}{F_s - F_p} \times$$

$$\times \left[F_{\max} \left(1 + \ln \frac{\alpha F_s}{F_{\max}} \right) - F_s - F_p (\alpha - 1) \right]. \quad (27)$$

We now determine the ascending and descending arms of the function B = f(F) for this form of magnetic polarity reversal loop.

__First segment.__ For the values $-F_{\max} \leq F \leq F_p$,

$$B_1 = -B_3 \max.$$

__Second segment.__ For values $F_p \leq F \leq \alpha F_p$,

$$B_2 = \frac{1}{R_0 - R_1} \left\{ \int_{R_1}^{R_1} \frac{2b_s}{F_s - F_p} \left(F \frac{R_1}{R} - \frac{F_s + F_p}{2} \right) dR + \right.$$

$$+ \int_{R_1}^{R} \frac{b_s}{F_s - F_p} \left[(2F - F_{\max}) \frac{R_1}{R} - F_p \right] dR +$$

$$\left. + \int_{R}^{R_0} - \frac{b_s}{F_s - F_p} \left(F_{\max} \frac{R_1}{R} - F_p \right) dR \right\}.$$

Here, $R_1 = R_1 F_{\max}/F_p$ and $R = R_1 F/F_p$. After integration, we obtain

$$B_2 = \frac{1}{\alpha - 1} \frac{b_s}{F_s - F_p} \left[2F \left(\ln \frac{F}{F_p} - 1 \right) - \right.$$

$$\left. - F_{\max} \left(1 + \ln \frac{\alpha F_s}{F_{\max}} \right) + F_s + F_p (\alpha + 1) \right]. \quad (28)$$

__Third segment.__ For values of $\alpha F_p \leq F \leq F_s$,

$$B_3 = \frac{1}{R_0 - R_1} \left\{ \int_{R_1}^{R_1} \frac{2b_s}{F_s - F_p} \left(F \frac{R_1}{R} - \frac{F_s + F_p}{2} \right) dR + \right.$$

$$\left. + \int_{R_1}^{R_0} \frac{b_s}{F_s - F_p} \left[(2F - F_{\max}) \frac{R_1}{R} - F_p \right] dR \right\}.$$

Here, $R_1 = R_1 F_{\max}/F_s$.
Integration gives

$$B_3 = \frac{1}{\alpha - 1} \frac{b_s}{F_s - F_p} \left[2F \ln \alpha - \right.$$

$$\left. - F_{\max} \left(1 + \ln \frac{\alpha F_s}{F_{\max}} \right) + F_s - F_p (\alpha - 1) \right]. \quad (29)$$

__Fourth segment.__ For values of $F_s \leq F \leq F_{\max}$,

$$B_4 = \frac{1}{R_0 - R_1} \left\{ \int_{R_1}^{R} b_s dR + \right.$$

$$+ \int_{R}^{R_1} \frac{2b_s}{F_s - F_p} \left(F \frac{R_1}{R} - \frac{F_s + F_p}{2} \right) dR +$$

$$\left. + \int_{R_1}^{R_0} \frac{b_s}{F_s - F_p} \left[(2F - F_{\max}) \frac{R_1}{R} - F_p \right] dR \right\}.$$

Here, $R = R_1 F/F_s$ and $R_1 = R_1 F_{\max}/F_s$.
After integration, we obtain

$$B_4 = \frac{1}{\alpha - 1} \frac{b_s}{F_s - F_p} \left[2F \left(1 + \ln \frac{\alpha F_s}{F} \right) - \right.$$

$$\left. - F_{\max} \left(1 + \ln \frac{\alpha F_s}{F_{\max}} \right) - F_s - F_p (\alpha - 1) \right]. \quad (30)$$

__Fifth segment.__ For values of $F_{\max} \leq F$ and $-F_p \leq F \leq F_{\max}$,

$$B_5 = B_3 \max.$$

For negative values of F, the descending arm is found analogously.

By giving various values of $F_{\max}$ we can, by Eqs. (20), (24), and (27), compute the "basic magnetization curve." Figure 9 gives the computed family of symmetric magnetic polarity reversal loops and the "basic magnetization curve."

c) Magnetic Polarity Reversal by a Biased Loop ($F_= \geq \alpha F_s$)

We now consider the mode of magnetic polarity reversal where, at the initial position, all of the core material is magnetized by saturation $F_{=} \geq \alpha F_s$ (Fig. 6 for $h_{=} \geq h_s$). In this mode, the magnetization proceeds by the ascending arm of the limiting magnetic polarity reversal loop and returns to the original state by the descending arm of a biased loop. We shall consider the character of the variation of the function B = f(F) only for the reverse magnetic polarity reversal (the return). For the determination of the function B = f(F), it is necessary to transform Eq. (7) to the form

$$b = -b_s - \frac{2b_s}{F_s - F_p}\left(F' - F_{\max}\right)\frac{R_1}{R}. \qquad (31)$$

Here, $F' = F - F_{=}$ are the ampere-turns for magnetization (after compensation of the constant magnetizing ampere-turns, the working point moves from A to A_1); $F'_{\max} = F_{\max} - F_{=}$.

As in the case of symmetric magnetic polarity reversal loops, the biased loops, as a function of the value of $F'_{\max}$, will have various magnitudes and configurations. We shall therefore distinguish the individual forms of the biased magnetic polarity reversal loops.

First Form of the Biased Magnetic Polarity Reversal Loops ($F_p \leq F'_{\max} \leq \alpha F_p$)

We substitute Eq. (31) in Eq. (8). The function B = = f(F) on the descending arm of a biased magnetic polarity reversal loop will have individual functional segments, determined by the magnitude of F'.

First segment. For values of $-F_p \geq F' \leq F'_{\max}$,

$$B_1 = B_{\max}.$$

Second segment. For values of $-F_p \leq F' \leq -F'_{\max}$.

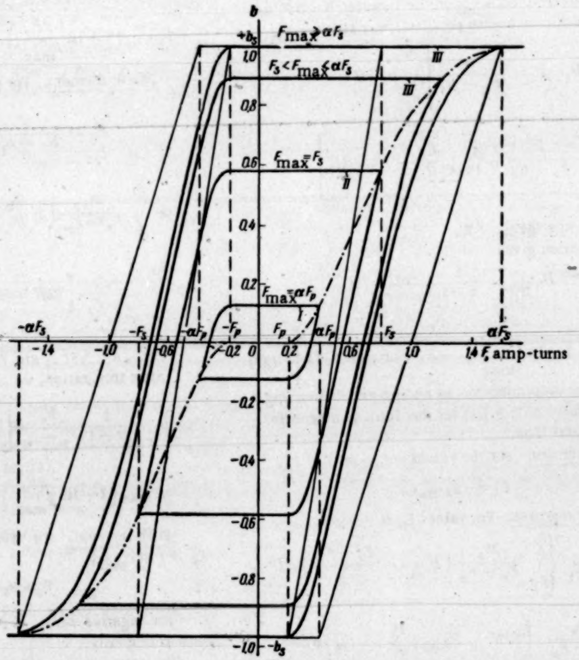

Fig. 9. Family of symmetric magnetic polarity reversal loops and the "basic magnetization curve" computed for the values α = 2, $F_p = 0.2$ ampere-turns, $F_s = 0.8$ ampere-turns. I is the first form of the magnetic polarity reversal loop; II and III are the second and third forms, respectively.

$$B_2 = \frac{1}{R_0 - R_1} \times$$

$$\times \left\{ \int_{R_1}^{R} \left[-b_s - \frac{2b_s}{F_s - F_p} (F' - F'_{\max}) \frac{R_1}{R} \right] dR + \right.$$

$$+ \int_{R}^{R_1} \frac{2b_s}{F_s - F_p} \left(F'_{\max} \frac{R_1}{R} - \frac{F_s + F_p}{2} \right) dR +$$

$$\left. + \int_{R_1}^{R_0} -b_s dR \right\}.$$

Here, $R = R_1 F'/F_p$ and $R_1 = R_1 F'_{\max}/F_p$.
Integration gives

$$B_2 = \frac{1}{\alpha - 1} \frac{b_s}{F_s - F_p} \left[2F' \left(1 - \ln \frac{F'}{F} \right) + \right.$$

$$+ 2F'_{\max} \left(\ln \frac{F'_{\max}}{F_p} - 1 \right) -$$

$$\left. - (F_s - F_p)(\alpha - 1) \right]. \qquad (32)$$

Third segment. For values of $-F'_{\max} \leq F' \leq -F_{\max}$,

$$B_3 = -b_s.$$

Second Form of the Biased Magnetic Polarity Reversal Loops ($\alpha F_p \leq F'_{\max} \leq F_s$)

First segment. For values of $-F_p \geq F' \leq F'_{\max}$,

$$B_1 = B_{\max}.$$

Second segment. For values of $-F_p \leq F' \leq -\alpha F_p$,

$$B_2 = \frac{1}{R_0 - R_1} \left\{ \int_{R_1}^{R} \times \right.$$

$$\times \left[-b_s - \frac{2b_s}{F_s - F_p} (F' - F'_{\max}) \frac{R_1}{R} \right] dR +$$

$$\left. + \int_{R}^{R_0} \frac{2b_s}{F_s - F_p} \left(F'_{\max} \frac{R_1}{R} - \frac{F_s + F_p}{2} \right) dR \right\}.$$

Here, $R = R_1 F'/F_p$; $R_1 = R_1 \frac{F'_{\max}}{F_p}$.
After integration we get

$$B_2 = \frac{1}{\alpha - 1} \frac{b_s}{F_s - F_p} \left[2F' \left(1 - \ln \frac{F'}{F_p} \right) + \right.$$

$$\left. + 2F'_{\max} \ln \alpha - F_s (\alpha - 1) - F_p (\alpha + 1) \right]. \qquad (33)$$

Third segment. For values of $-\alpha F_p \leq F' \leq -F'_{\max}$,

$$B_3 = \frac{1}{R_0 - R_1} \times$$

$$\times \int_{R_1}^{R_0} \left[-b_s - \frac{2b_s}{F_s - F_p} (F' - F'_{\max}) \frac{R_1}{R} \right] dR$$

or

$$B_3 = \frac{1}{\alpha - 1} \frac{b_s}{F_s - F_p} \times$$

$$\times \left[(2F'_{\max} - 2F') \ln \alpha - (F_s - F_p)(\alpha - 1) \right]. \qquad (34)$$

Fourth segment. For values of $-F'_{\max} \leq F' \leq -F_=$,

$$B_4 = -b_s.$$

Third Form of the Biased Magnetic Polarity Reversal Loops ($F_s \leq F'_{\max} \leq \alpha F_s$)

First segment. For values of $-F_p \leq F' \leq \alpha - F_p$,

$$B_1 = B_{\max}.$$

Second segment. For values of $-F_p \leq F' \leq \alpha - F_p$,

$$B_2 = \frac{1}{R_0 - R_1} \times$$

$$\times \left\{ \int_{R_1}^{R_1} - \frac{2b_s}{F_s - F_p} \left(F' \frac{R_1}{R} - \frac{F_s + F_p}{2} \right) dR + \right.$$

$$+ \int_{R_1}^{R} \left[-b_s - \frac{2b_s}{F_s - F_p} (F' - F'_{\max}) \frac{R_1}{R} \right] dR +$$

$$\left. + \int_{R}^{R_0} \frac{2_s}{F_s - F_p} \left(F'_{\max} \frac{R_1}{R} - \frac{F_s + F_p}{2} \right) dR \right\}.$$

Here, $R = R_1 F'/F_p$ and $R_1 = R_1 F'_{\max}/F_s$. Integration gives

$$B_2 = \frac{1}{\alpha - 1} \frac{b_s}{F_s - F_p} \left[2F' \left(1 - \ln \frac{F'}{F_p} \right) + \right.$$

$$+ 2F'_{\max} \left(1 + \ln \frac{\alpha F_s}{F'_{\max}} \right) -$$

$$\left. - (F_s - F_p)(\alpha + 1) \right]. \qquad (35)$$

Third segment. For values of $-\alpha F_p \leq F' \leq -F_s$,

$$B_3 = \frac{1}{R_0 - R_1} \times$$

$$\times \left\{ \int_{R_1}^{R_1} - \frac{2b_s}{F_s - F_p} \left(F' \frac{R_1}{R} - \frac{F_s + F_p}{2} \right) dR + \right.$$

$$\left. + \int_{R_1}^{R_0} \left[-b_s - \frac{2b_s}{F_s - F_p} (F' - F'_{\max}) \frac{R_1}{R} \right] dR \right\}.$$

Here, $R_1 = R_1 F'_{\max}/F_s$.
After integration we obtain

$$B_3 = \frac{1}{\alpha - 1} \frac{b_s}{F_s - F_p} \left[-2F' \ln \alpha + \right.$$

$$\left. + 2F'_{\max} \left(1 + \ln \frac{\alpha F_s}{F'_{\max}} \right) - F_s (\alpha + 1) + F_p (\alpha - 1) \right]. \qquad (36)$$

Fourth segment. For values of $-F_s \le F' \le -F'_{\max}$,

$$B_4 = \frac{1}{R_0 - R_1}\left\{\int_{R_1}^{R} -b_s dR \; - \right.$$

$$-\int_{R}^{R_1} \frac{2b_s}{F_s - F_p}\left(F'\frac{R_1}{R} - \frac{F_s + F_p}{2}\right) dR +$$

$$\left. + \int_{R_1}^{R_0}\left[-b_s - \frac{2b_s}{F_s - F_p}(F' - F'_{\max})\frac{R_1}{R}\right] dR\right\}.$$

Here, $R = R_1F'/F_s$ and $R_1 = R_1F'_{\max}/F_s$.

Integration gives

$$B_4 = \frac{1}{\alpha - 1}\frac{b_s}{F_s - F_p}\left[-2F'\left(1 + \ln\frac{\alpha F_s}{F'}\right) + \right.$$

$$\left. + 2F'_{\max}\left(1 + \ln\frac{\alpha F_s}{F'_{\max}}\right) - (F_s - F_p)(\alpha - 1)\right]. \tag{37}$$

Fifth segment. For values of $-F'_{\max} \le F' \le -F_=$,

$$B_5 = -b_s.$$

Figure 10 shows the family of biased magnetic polarity reversal loops.

By giving different values to $F_= \ge \alpha F_s$, we can compute the family of static characteristics $B = f(F, F_=)$ (Fig. 11).

Taking into account the nonuniformity of core magnetization as it affects its static characteristics when the material has a hysteresis loop of another form (for example, Figs. 1 and 3) can be done in an analogous fashion. Figure 12 shows the limiting magnetic polarity reversal loop of a core whose material has the hysteresis loop shown in Fig. 3.

CONCLUSIONS

On the basis of what has been presented here, we may draw the following conclusions.

1. When the material's hysteresis loop has the form shown on Fig. 2 or on Fig. 3, the core's magnetic characteristic, B = f(F), can be obtained in analytic form.

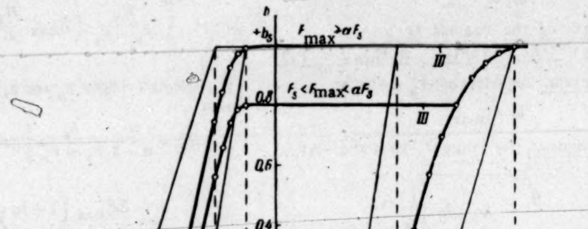

Fig. 10. Family of biased magnetic polarity reversal loops computed for the values $\alpha = 2$, $F_p = 0.2$ ampere-turns, $F_s = 0.8$ ampere-turns, $F_= = \alpha F_s$ = 1.6 ampere-turns.

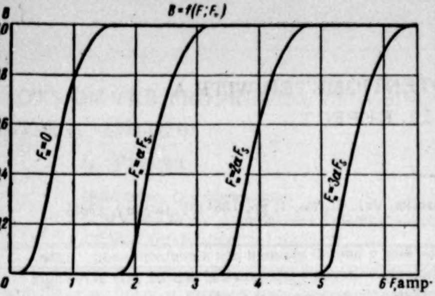

Fig. 11.

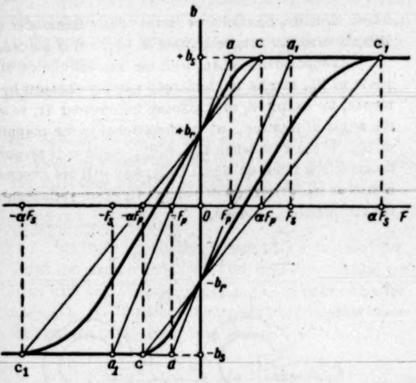

Fig. 12.

2. The form of a core's magnetic characteristic depends on its geometric relationships. There exist three cases of geometric relationships for cores which entail discrepancies in the forms of the magnetic characteristics (Figs. 7 and 8). For $\alpha F_p < F_s$ (the first case), the magnetic polarity reversal loop is characterized by linear segments on the ascending and descending arms. In this case, the outer layers of the core begin to reverse their magnetic polarity until saturation of the inner layers. For $\alpha F_p = F_s$ (the second case), the magnetic polarity reversal loop is characterized by an absence of linear portions on the ascending and descending arms. In this case, at the moment when reversal of the outer layer's magnetic polarity begins, the inner layer is already saturated. For $\alpha F_p > F_s$ (the third case), there is a broadening of the core's magnetic polarity reversal loop. In this case, the core's inner layers have become saturated even before reversal of the outer layers' magnetic polarity has begun. Linear portions of the ascending and descending arms of the magnetic polarity reversal loops are obtained due to the reversal of magnetic polarity of the material in a narrow toroidal sector, beginning at the moment when the inner layers saturate and continuing until the beginning of the reversal of the outer layers' magnetic polarity.

3. The form of the core's magnetic characteristic is also determined by the magnitude of the maximum ampere-turns for magnetization. When the magnitude of the magnetization ampere-turns is inadequate for complete magnetic polarity reversal of the entire core, the core's magnetic polarity is reversed by partial loops. In the modes of core magnetic polarity reversal by symmetric and biased partial loops, there are, as a function of the maximum magnetizing ampere-turns, three forms of loops, differing by their configurations and their dimensions (Figs. 9 and 10). The first loop form, when $F_p < F_{max} \le \alpha F_p$, is characterized by the fact that $\Delta B \ll 2b_s$, and also by the nonlinearity of the function $B = f(F)$ on the ascending and descending arms of the magnetic polarity reversal loop. In this case, only the inner layers have their magnetic polarity reversed. The second loop form, when $\alpha F_p < F_{max} \le F_s$, is characterized by the presence of a linear segment on the ascending and the descending arms of the magnetic polarity reversal loop, and by a larger ratio of $\Delta B / 2b_s$ than in the first case. In this case, the magnitude of the magnetizing ampere-turns is sufficient to reverse the magnetic polarity of the entire core, but inadequate for the saturation even of the inner layers. The third loop form, when $F_s < F_{max} \le \alpha F_s$, is characterized by the fact that all the core's layers have their magnetic polarity reversed, but not all are saturated. With this, the partial loops approximate to the form of the limiting core magnetic polarity reversal loop. All three magnetic polarity reversal loop forms have the same law of variation of the nonlinear segments on the ascending and descending arms.

4. The analytical methods presented can be conveniently employed also for other forms of material hysteresis loops. As an example, Fig. 12 shows the construction of a core's limiting magnetic polarity reversal loop for the material hysteresis loop shown on Fig. 3.

The taking into account of the effect of nonuniformity of core magnetization on its static characteristics for more complicated forms of the material's hysteresis loop, and also the experimental part of the work using ramified cores, will be considered in the second part of the present work.

CONTACTLESS DC AUTOMATIC POTENTIOMETER WITH A TRANSFORMER BASED ON THE HALL EFFECT

V. N. Bogomolov

(Leningrad)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 1, pp. 135-136, January, 1960)
Original article submitted June 29, 1959

The circuit is presented for a dc potentiometer lacking a normal element and a contact system. The potentiometer indications are virtually independent of supply voltage oscillations and depend only very slightly on the ambient temperature. Two identical Hall emf transducers are used as a transformer and as a source of compensating emf.

Automatic dc potentiometers are widely used today. In such potentiometers, the dc voltage $U_{\text{in}=}$ to be measured is compensated by a battery voltage, controlled by a normal element, until the difference becomes sufficiently small. Ordinarily, this difference is transformed to ac by a vibrapack, amplified, and then applied to a motor which moves the compensator's slide wire. The disadvantages of such circuits are the presence of the contact transformer, the slide wire with sliding contacts and the normal element. If a transformer based on the Hall effect [1] is used, then one contact element will be replaced by a contactless one. However, nothing is thereby changed in the remainder of the circuit, since the contact slide wire and the normal element remain. By using a Hall-effect transformer, it is nonetheless possible to construct a completely contactless potentiometer, in which there is no longer a necessity for a normal element, if one uses, for the compensation of the Hall emf, an identical transducer which is placed in a constant magnetic field and supplied by the line voltage.

The superiority of such a potentiometer over the ordinary ones consists in its greater mechanical stability, its greater reliability, simplicity, and length of serviceable life.

The circuit of this potentiometer is shown on the accompanying figure. The input dc signal $U_{\text{in}=}$ is immediately transformed to an ac signal $U_{x\sim}$ by the transformer based on the Hall effect, with transmission factor K_1. With this,

$$U_{x\sim} = K_1 U_{\text{in}=}.$$

If one takes into account that K_1 depends both on the temperature, t°, and on the supply (line) voltage U_s, then one may write

$$U_{x\sim} = K_1(t^\circ, U_s)\, U_{\text{in}=} = A f_1(t^\circ)\, f(U_s)\, U_{\text{in}=}.$$

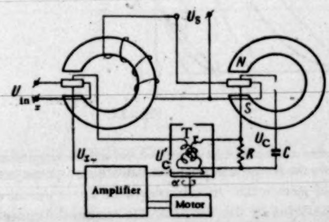
To compensate this alternating emf, one uses the voltage U_c, obtained from an identical transducer, but one immersed in a constant magnetic field and supplied from the line. The RC network is used to shift the phase of U_c by 90°. With this, one may also write

$$U_c = K_2(t^\circ)\, U_s = B f_2(t^\circ)\, f(U_s)\, H,$$

where K_2 is the transmission factor of this transducer and H is the constant magnetic field in which it is placed.

Compensation at ac, with the correct choice of phase of U'_c, can be implemented without contacts by means, for example, of a rotating transformer Tr, in which the angle of rotation, α, is proportional to the magnitude of U'_c. In the case when $U_{x\sim} = U'_c$, angle α is proportional to the input dc signal $U_{\text{in}=}$, and will not depend either on the variations of voltage U_s or on variations of the temperature. Indeed,

$$\frac{U_{x\sim}}{U_{c\sim}} = \frac{A f_1(t^\circ)}{B H f_2(t^\circ)} U_{\text{in}=}.$$



In the case of equality of the temperature dependencies, $f_1(t^\circ)$ and $f_2(t^\circ)$, the ratio just given depends only on $U_{\text{in}=}$ and, consequently, the transformer's angle of rotation α also depends only on $U_{\text{in}=}$. For transducers cut from one rod of germanium, $f_1(t^\circ)$ can differ from $f_2(t^\circ)$ by one to two percent which, in the temperature range of 70° and for a dependency $f(t^\circ)$ equal to 0.4%, gives an error at 1°C [2] for any angle α of rotation of 0.3 to 0.6%. This means that one can, with such a potentiometer, register a measured signal with a temperature error of 0.6% independently of the magnitude of the signal itself.

NOTE ON THE PROPERTIES OF A SIMPLE EXTRAPOLATOR WITH A "SWITCH"

L. Prouza

(Pardubitse, Czechoslovakia)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 1, pp. 137-138, January, 1960)
Original article submitted March 23, 1959

A theorem is proven which relates the properties of a simple extrapolator with a "switch" with lag present with the properties of an extrapolator without lag.

In [1] there was considered the stability of a simple extrapolator with a "switch." The transfer function of the continuous linear portion of such an extrapolator has the form:

$$Y(q) = e^{-\tau q}\left(\frac{\alpha}{q} + \frac{\beta}{q^2}\right) \tag{1}$$

and depends on the lag time τ. We shall now prove a theorem, of which theorem 1 of [1] is a particular case, and shall then consider several applications of it.

General Theorem

Let there be an extrapolator with a "switch" for which the transfer function of the continuous linear portion, with suitable normalization [1], is defined by formula (1). We introduce the generalized impulse transfer function of the open-loop system

$$Y^*(e^q, \varepsilon) = \sum_{n=0}^{\infty} y(n+\varepsilon)\, e^{-nq}, \tag{2}$$

where $y(t) = L^{-1}Y(q)$, $y(0) = 0$, $0 \leq \varepsilon \leq 1$ [2, 3].

Let τ vary in the interval (0,1). One easily convinces oneself that, for $\varepsilon \leq \tau$

$$Y^*(e^q, \varepsilon) = Y_1^*(e^q, \varepsilon) =$$

$$= \frac{[(\alpha - \beta\tau) + \beta(1+\varepsilon)]\, e^q - (\alpha - \beta\tau) - \beta\varepsilon}{(e^q - 1)^2} \tag{3}$$

and, for $\varepsilon > \tau$

$$Y^*(e^q, \varepsilon) = Y_2^*(e^q, \varepsilon) = Y_1^*(e^q\varepsilon) + (\alpha - \beta\tau) + \beta\varepsilon. \tag{4}$$

From (3) and (4) we obtain the ordinary impulse transfer function

$$Y^*(e^q) = Y_1^*(e^q, 0) = e^{-q}Y_2^*(e^q, 1) =$$

$$= \frac{[(\alpha - \beta\tau) + \beta]\, z - (\alpha - \beta\tau)}{(z-1)^2}. \tag{5}$$

Here, we have used the notation $e^q = z$.

Theorem 1 (auxiliary). Let two extrapolators be given, the first with parameters α_1, β_1, and τ_1 and the second with parameters

$$\alpha_2 = \alpha_1 - \beta_1\tau_1, \qquad \beta_2 = \beta_1, \qquad \tau_2 = 0. \tag{6}$$

Then $Y^*(z)$ is identical for the two of them.

The proof follows immediately from the form of expression (5).

Theorem 2. All properties which depend only on transfer function (5) are identical for extrapolators whose parameters are related by relationships (6).

Theorem 2 is an obvious corollary of theorem 1.

Applications

It is clear that theorem 1 of [1] on the deformations of the region of stability is only a particular case of theorem 2.

In [4], one defined the error of tracking a "circular maneuver" for an extrapolator with $\tau = 0$ as a quantity proportional to the expression

$$E = \left|\frac{1}{1 + Y^*(e^{j\lambda})}\right| \tag{7}$$

[cf. [4], formula (30)]. Whence, by theorem 2, it is clear that, for an extrapolator with $\tau > 0$, it suffices to write $\alpha - \beta\tau$ instead of α in formulas (31), (32), and (33) in [4] in order to obtain the expression for the error for $\tau > 0$.

Further, in [4] there was defined a coefficient of error damping for the extrapolation of a unit velocity jump for $\tau = 0$, starting from the formula

$$E^*(z) = \frac{X^*(z)}{1 + Y^*(z)} \tag{8}$$

(cf. formula (8) in [4]), where $X^*(z) = z/(z-1)^2$. It follows from (8) and theorem 2 that the curves of constant damping coefficient (cf. [4], Fig. 4) for $\tau = 0$ are deformed as τ varies in the interval (0, 1) in accordance with relationships (6).

Further, let the noise coefficient of the extrapolator be defined by the formula (cf., for example, formula (53) in [5])

$$\sigma^2 = \frac{1}{2\pi}\int_{-\pi}^{\pi}\left|\frac{Y^*(e^{j\lambda})}{1 + Y^*(e^{j\lambda})}\right|^2 d\lambda. \tag{9}$$

It is clear that expression (9) is identical for parameters related by relationships (6). By computing (9) (for example, by the method described in [6] or by formula (56) in [5]), we obtain, in the general case

$$\sigma^2 = \frac{2(\alpha - \beta\tau)^2 + \beta[(\alpha - \beta\tau) + 2]}{(\alpha - \beta\tau)[4 - 2(\alpha - \beta\tau) - \beta]}. \qquad (10)$$

If we denote $\alpha - \beta\tau = A$, then the minimum of σ^2 for given β and τ is attained for

$$A = \sqrt{\beta} - \frac{\beta}{2}. \qquad (11)$$

Formula (11), for $\tau = 0$, is given in [7]. It is clear from (10) that σ^2 tends to infinity on two sides of the triangle of stability. On the third side, corresponding to $\beta = 0$, σ^2 is defined by the formula

$$\sigma^2 = \frac{A}{2 - A}. \qquad (12)$$

Formula (12) can be derived from formula (86) in [5] where the case of an extrapolator with one integrator is considered in detail.

CONCLUSION

By means of relationships (6), one can, as a function of τ, transform not only the region of stability (theorem 1 in [1]), but other characteristics of the extrapolator system with "switch" considered here as well.

ELECTRETS AND THE PROSPECTS OF THEIR USE IN AUTOMATION (Survey)

V. A. Andryushchenko

(Leningrad)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 1, pp. 139-142, January, 1960)
Original article submitted April 7, 1959

The paper considers the present state of the question of electrets, which are the electrical analogs of magnets, and provides certain practical directions of their use as elements of automatic devices.

The creation of cheaper, more economical, relatively simple in design, and convenient to use automatic systems requires the use of new materials which possess new physical properties. Such a material is the "electret," which is little known in practice.

An electret is the electrical analog of a magnet. This is a dielectric possessing "constant" electrification with opposite charges at the ends.

The first specimens of electrets studied were mixtures of wax and gum whose congealing had occurred in a strong constant electrical field. The disk-shaped electrets thus prepared possess negative charges on the side turned to the anode and a positive charge on the opposite side. If an electret is bifurcated along a neutral line, then two electrets are obtained. Removal of an upper layer of an electret by scraping or shearing does not disturb the electret's properties.

Until today, essentially organic materials have been used for obtaining electrets: wax, gum, hydrocarbons, solid acids, alcohol, etc.

Inorganic materials (glass, porcelain, ceramics, etc.) have been little studied from the point of view of obtaining electrets from them, and the information thus far obtained about them has been contradictory.

TABLE

Material	$MgTiO_3$	$ZnTiO$	$BaO \cdot 4TiO_2$	Bismuth titanate	$CaTiO_3$	$SrTiO_3$	Strontium bismuth titanate	$BaTiO_3$
ε	16	22	28	80	150	175	750	1200

Electrets of inorganic materials have a higher rigidity and thermal stability than electets prepared of organic materials, and can have very diverse dielectric permeabilities (cf. the appended table).

For the preparation of electrets from organic materials there is no particular sense in increasing the temperature of the dielectric very much above the melting point. However, it is very important that the mass be completely converted to the liquid state before being placed in the electric field.

For the preparation of electrets, one ordinarily uses, as the electrodes for the electrization process, tin foil which is easily removed from the surface of the congealed specimens. It turned out that, with a congealed mixture of wax and gum, sufficiently good electrets could be obtained even in the absence of an external polarizing field. In this case, the size of the charge on the poles was 60 to 70% of the charge appearing on electrets obtained from placement in a polarizing field.

The electrets' properties depend, to a certain extent, on the magnitude of the electric field strength.

Once the field strength has reached a magnitude of 10 to 12 kw/cm, further increase of it does not induce any increase in the charge. This is explained by the circumstance that the electrical field on the electret surfaces reaches the maximum size which can exist in air for these gradients, i.e., about 5 CGSE/cm^2. Further increase of the field strength leads to ionization of the air molecules, and discharge commences. There is a corresponding limiting value to the possible density of the charge on the electret's surfaces. For normal atmospheric pressure, temperature, and humidity, the charge density cannot exceed $3 \cdot 10^{-5}$ coul/m^2. With increasing pressure the charge density also increases and, in regions of low pressure, the charge density is proportional to the pressure.

Electrets prepared from organic materials are decomposed by fusion. The quantity of electricity obtained by measuring the current flowing through the external circuit during the time of fusion does not depend on the time elapsed between polarization and fusion. It is almost directly proportional to the strength of the polarizing electrical field. The experimentally obtained maximum current with fusion attained a magnitude of about 10^{-8} amp/cm^2. When all of the specimen of the electret had passed into the liquid state, the current ceased.

For storage, electrets of organic material are sealed. In a humid atmosphere the electret's charge drops sharply, but is reestablished on drying.

In the P. N. Lebedev Institute of Physics of the Academy of Sciences, USSR, the following mode of polarization was used for obtained electrets from inorganic material: The specimen was placed in an electrical field of 20 kw/ cm strength, maintained at room temperature for 30 minutes, and then the temperature was raised to 200°C during 2 hours, after which the specimen was kept at this temperature for another 2 hours, and then the temperature was lowered to 60 to 80°C. The surfaces of the specimens and the electrodes (brass disks were used for the latter) were carefully polished.

The dimensions and the configurations of the specimens can be diverse. The magnitude of the field strength and the seasoning temperature for polarization are limited by the material's stability with respect to thermal disruption. Electrets of inorganic material can be stored either with or without sealing. The charges of electrets of organic and inorganic materials are retained for periods of years. The basic disadvantage of electrets today is the instability of their charge.

We turn now to photoelectrets, which were discovered in 1937 by the Bulgarian academician G. Nadjanoff.

As specimens, sulfur flakes (monocrystalloid or polycrystalloid) were used, these being polished to mirror smoothness by silk moistened with kerosene. A constant voltage of 470 v/ cm was applied to a specimen, and the specimen, after three minutes of remaining in darkness, was exposed to a light of 6000 lux during 12 minutes, after which it was sealed and stored in darkness. The measurement of a photoelectret's charge was carried out by means of its depolarization with repeated illumination. A photoelectret can retain its charge for several days.

Illumination of a photoelectret at low temperatures (−80 to −100°C) leads only to its partial discharge, and complete depolarization occurs only as the result of increasing the specimen's temperature to the temperature at which its polarization occurred. Heating of a photoelectret without simultaneous illumination does not give rise to a discharge of current large enough to be measured, although the total charge on the photoelectret is somewhat decreased. The state of the polarized specimen just described may be called thermophotoelectret.

We now consider instruments (based on electrets) which are elements of automatic systems, or which execute functions of an automatic device.

Figure 1 shows a telephone circuit. If one speaks into microphone A, the sound waves start membrane 1 oscillating. The distance between it and electret 2 will change. As the membrane approaches the electret, the charge induced on it will increase and, as the membrane moves further away, the charge will decrease. These variations of charge induce currents in the telephone circuit which lead to acoustical vibrations of membrane 5 and receiver B. On Fig. 1, 3 is the immovable microphone electrode and 4 is the receiver coil.

One can create ac and dc generators using electrets. A dc generator is shown on Fig. 2 a. During an oscillatory swing of the upper electrode, when the electrodes are close key K_1 will make, i.e., seal the electrodes and key K_2 will break. The charge induced on the electrode by the short circuit will, as the latter moves away, be applied to the plates of condenser C; with this, key K_2 closes and key K_1 opens. By repeating this operation many times, one can charge the condenser up to a potential whose value will be limited only by the breakdown voltage of dielectric e between the condenser plates. In practice, the condenser was charged up to 5 kv.

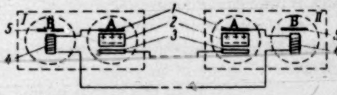

Fig. 1.

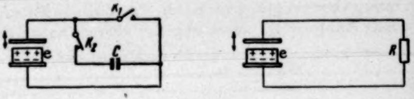
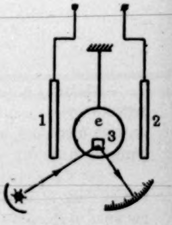


a

b

Fig. 2.



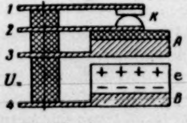


Fig. 3.

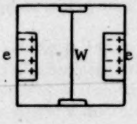
Fig. 4.



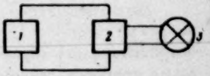


Fig. 5.

Fig. 6.

An ac generator (Fig. 2 b) is obtained by connecting resistor R in the electrical circuit. With oscillatory motion of the electrodes at a frequency of f = 100 cps, an ac current of 10^{-6} amp passes through load R; the effective power on the load in this case equals $P = 10^{-5}$ to 10^{-6} w.

An electrostatic relay based on the use of electrets, and shown schematically in Fig. 3, operates in the following way: As some constant voltage is applied to terminals 3 and 4, the upper electrode A is attracted to electret e attached to immovable electrode B. This causes contacts K to open. Thus, the relay will close or open (depending on the design) a second circuit connected to terminals 1 and 2.

If an electret is suspended on a thread between two metallic electrodes (Fig. 4) on which a charge has been placed, then the electrostatic fields of electrodes 1 and 2 and electret e will interact, turning the electret at a definite angle which is proportional to the charge on the electrodes. A small mirror 3 is fastened to the electret, by means of which mirror readings are made. The instrument, consequently, is a type of mirror galvanometer, in which an electret replaces a moving coil.

In a string voltmeter (Fig. 5) charged to the potential to be measured, wire W is placed between two electrets e which move against each other and have opposite charges. Since electrets change the magnitude of their charge in a radioactive field, after whose removal the charge is again reestablished, then one may judge the degree of radioactivity of a given field as a function of the electret's decrease in charge.

Photoelectrets can be used for danger signaling (Fig. 6). When photoelectret 1 is depolarized, current flows to device 2 which lights signal lamp 3.

Electrets can be used in electronic tubes for applying grid bias, and also in cathode-ray tubes for controlling the electron beam, and also in other instruments where only an electrostatic field is required.

Recently, there has been talk of using electrets in the memory devices of electronic computers.

The theoretical possibility of using electrets is based on the fact that the charges placed on the dielectric's surfaces do not spill over but, as it were, "stick." With this, if an electron falls on an electret's positive pole, it compensates the electret's charge in the given place.

If one could succeed in making an electret in the form of a fine long tape, on one side of which positive charges were placed, with negative charges on the other side, then one could "write," on such an electret tape, a series of definite pulses, using an electron beam. Such a tape, moved past another electron beam, could deflect it in correspondence with the variations in intensity of the first beam.

SUMMARY

The use of electrets in automatic devices allows:

1) the creation of new elements for automatic devices based on the physical properties of electrets;

2) simple design implementation of block schematics of automatic devices;

3) simplification of electric power suplies for automatic devices;

4) decreasing the weight and size of automatic devices.

LETTERS TO THE EDITOR

A NOTE TO A PAPER OF YU. S. SOBOLEV, "ON THE ABSOLUTE STABILITY OF CERTAIN CONTROLLED SYSTEMS," [1]

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 1, pp. 143-144, January, 1960))

In [1], the following theorem was actually proven (below, we retain the symbology and the formula numeration used in [1]).

If, for system (2), satisfying limitations "a"-"e", one can cite a positive definite function $r^2 = V(x_1, \ldots, x_n)$ not depending on h_k ($k = n-m+1, \ldots, n$), whose total derivative with respect to time is, by virtue of (2), negative definite for any $h_k \in (0, +\infty)$, then system (1), satisfying conditions "a"-"e", is absolutely stable.

In fact, in case r^2 depends on h_k, inequality (5) holds, in general, only for sufficiently small h_k ($k = n-m+1, \ldots, n$), and inequality (6) holds only for sufficiently large h_s and sufficiently small h_p. Therefore, there might not exist a system of values of h_k for which both inequalities (5) and (6) would be valid simultaneously. In exactly the same manner, it is impossible to assert anything as to the simultaneous holding of inequalities (7) or (9).

In the case of a linear system (2), the Routh-Hurwitz conditions do not guarantee the presence of a Lyapunov function, mentioned in the conditions of the theorem proven in [1]. We consider, for example, the equation

$$a_3 \frac{d^2x}{dt^2} + a_2 \frac{dx}{dt} + a_1 x = -\varphi(\sigma), \quad \sigma = b_2 \frac{dx}{dt} + b_1 x \tag{I}$$

($\varphi(\sigma)$ is a class A function).

Following [1], we replace (I) by the equation

$$a_3 \frac{d^2x}{dt^2} + a_2 \frac{dx}{dt} + a_1 x = -h\left(b_2 \frac{dx}{dt} + b_1 x\right), \; h \in (0, +\infty),$$

from which we go to the system

$$\dot{x}_1 = x_2,$$
$$\dot{x}_2 = -\frac{a_2 + hb_2}{a_3} x_2 - \frac{a_1 + hb_1}{a_3} x_1. \tag{II}$$

According to the Routh-Hurwitz conditions, the trivial solution of system (I) is asymptotically stable, at least for

$$a_1, a_2, a_3, b_1 > 0, \; b_2 \geqslant 0. \tag{III}$$

We now show that, among the systems (II) satisfying (III), there are such for which it is impossible to construct a positive definite function $V(x_1, x_2) = \sum_{ij=1}^{2} \alpha_{ij} x_i x_j$ with coefficients α_{ij} which do not depend on $\underline{h}$, whose complete derivative with respect to time, dV/dt, by virtue of this system would be negative definite for all $h \in (0, +\infty)$.

Indeed,

$$-0.5 \frac{dV}{dt} = \alpha_{12} \frac{a_1 + hb_1}{a_3} x_1^2 +$$
$$+\left(\alpha_{12} \frac{a_2 + hb_2}{a_3} + \alpha_{22} \frac{a_1 + hb_1}{a_3} - \alpha_{11}\right) x_1 x_2 +$$
$$+\left(\alpha_{22} \frac{a_2 + hb_2}{a_3} - \alpha_{12}\right) x_2^2$$

and the necessary and sufficient conditions that dV/dt be negative definite have the form:

$$\alpha_{22} \frac{a_2 + hb_2}{a_3} - \alpha_{12} > 0, \tag{IV}$$

$$\alpha_{12} \frac{a_1 + hb_1}{a_3} \left(\alpha_{22} \frac{a_2 + hb_2}{a_3} - \alpha_{12}\right) -$$
$$-\frac{1}{4}\left(\alpha_{12} \frac{a_2 + hb_2}{a_3} + \alpha_{22} \frac{a_1 + hb_1}{a_3} - \alpha_{11}\right)^2 > 0$$
$$h \in (0, +\infty). \tag{V}$$

For the holding of (IV) it is necessary ($h \to 0$) that $\alpha_{22} a_2 / a_3 - \alpha_{12} \geq 0$ and, for (V) ($h \to +\infty$), that $-(\alpha_{12} b_2 - \alpha_{22} b_1) = 0$, such that for systems (II)-(III), in which $b_2 a_2 - b_1 a_3 < 0$, (IV)-(V) may not hold for any $h \in (0, +\infty)$.

Thus, the theorem of Yu. S. Sobolev [1] is inadequate for solving the problem posed in [2] of comparing theories of absolute stability.

Dear Editor

We became acquainted with the paper of Yu. S. Sobolev, "On the absolute stability of certain controlled systems," published in number 4 of your journal for 1959. This paper gave rise to a number of remarks, which we provide forthwith.

In the first part of the paper [formulas (1)-(9)], Yu. S. Sobolev proves the following assertion: If there exists a positive definite function $r^2(x_1, x_2, \ldots, x_n)$, not depending on the numbers h_k, whose derivative, by virtue of system (2) is negative definite for all $0 < h_k < \infty$, then the derivative of r^2, by virtue of system (1), is also negative definite. This assertion is obvious, and gives rise to no objections. Further (cf. the fine print, formulas (10)-(12)), the generally known properties of linear systems with constant coefficients are adduced, after which (cf. the normal print up to section 2) the incomprehensible assertion is made: "the existence of a function r^2 whose total derivative, by virtue of system (1), is negative definite, is guaranteed by the Routh-Hurwitz conditions." It is not clear what is meant by the Routh-Hurwitz conditions in the general case for systems (1) and (2).

In examples 1 and 2, Yu. S. Sobolev writes that, "according to what was proven above, the region of absolute stability (13) coincides with the region of asymptotic stability. . . of system . . . (14), where $h \in (0, +\infty)$." It is possible to deduce from this that Yu.S. Sobolev believes, in particular, that the following assertion has been proven: The region of absolute stability of a system described by the set of equations

$$\dot{x}_k = \sum_{\alpha=1}^{n} b_{k\alpha} x_\alpha + n_k f(\sigma),$$

$$\sigma = \sum_{s=1}^{n} j_s x_s, \quad \sigma f(\sigma) > 0, \qquad \text{(A)}$$

where $b_{k\alpha}$, j_s, and n_k are constants, coincides with the region of asymptotic stability of system (A) in which one sets $f(\sigma) = h\sigma$ for all $h > 0$.

As is well known, this assertion is untrue (cf., for example, the book of V.A. Pliss, Some Problems of Stability of Motion as a Whole). The author's error consists in the following. It is tacitly assumed that system (A), in which $f(\sigma) = h\sigma$, always has a Lyapunov function which does not depend on h.

In connection with this, it is impossible to consider as proven this assertion in section 2 of Yu. S. Sobolev's paper.

CHRONICLE

SEMINAR ON THE ENGINEERING APPLICATIONS OF MATHEMATICAL LOGIC (1958-1959)[*]

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 1, pp. 145-148, January, 1960)

In the fall semester of 1958 and the spring semester of 1959, the seminar on the engineering applications of mathematical logic continued its work under the direction of Lecturer V. I. Shestakov. Taking part in the seminar were scientific workers, teachers, and engineers of a number of research institutes and universities, including the Institute of Automation and Remote Control, the Laboratory for Information Transmission Systems, the Department of Applied Mathematics of the Academy of Sciences, USSR, and the Moscow State University. There were 13 sessions of the seminar in all, in which 11 papers were presented and discussed; of these, 10 contained original results and one was a tutorial paper.

Part of the papers touched on general questions of mathematical logic, arising, to be sure, from the requirements of the engineering applications of mathematical logic but having, perhaps, an independent theoretical value. Such were the papers of A. D. Talantsev, G. N. Povarov, and the tutorial paper of V. P. Goncharov.

A. D. Talantsev read two papers. In the first of them, "On the use of several logical operators for the analysis and synthesis of schemes containing differentiating circuits," presented Oct. 2, 1958, A. D. Talantsev dealt with the questions of the analysis and synthesis of potential-pulse circuits in which differentiating circuits entered. He proposed an essentially new algebraic-logical method for investigating such circuits. The basis of the method is the definition of special operators, the application of which to the "and" and "or" functions allowed one to derive relationships forming interesting analogies with the formulas of mathematical analysis.

It was shown in the paper how the relationships derived could be used for the simplification of circuits containing differentiating circuits. The concept of "covariance" of logical functions was introduced, this concept being related to the substantive meaning of the operators introduced; this concept can sometimes be used for transforming circuits. The exposition of the new concepts was illustrated by the example of a logical circuit for recognizing the direction of motion of a quantized scale for a digital control system for a milling machine.

The second paper of A. D. Talantsev, "On the analysis and synthesis of certain electrical circuits by means of special logical operators", was given on Jan. 16, 1959. In this paper there was developed (with account being taken of remarks made by M. L. Tsetlin and V. I. Shestakov) a new method of investigating electrical circuits which was first presented by A. D. Talantsev on Oct. 2, 1958. Specifically, there was derived an expansion formula for $dF(x_1, x_2, \ldots, x_n)$, where F is an arbitrary Boolean function of n variables. The relationship obtained for dF lies beyond the boundaries of Boolean algebra. Further, there were defined the concepts of potential and of pulse logical variables, the concept of a homogeneous potential-pulse circuit, and the potential-pulse form describing such a circuit. The problem was posed of "integrating" potential-pulse forms, and a general method of "integrating" these forms was given. In conclusion, the example was considered of "integrating" the forms describing a circuit which recognizes the direction of motion of a quantized scale.

The work of A. D. Talantsev was published in the journal Avtomatika i Telemekhanika 20, 7 (1959).[**]

G. N. Povarov gave three papers at the seminar. On Oct. 31, 1958, in the paper "On group invariance of Boolean functions," G. N. Povarov considered the group $\mathfrak{T}_n$, transforming monotypic Boolean functions to other such functions. The concept was introduced of the invariance of Boolean functions with respect to subgroups of group $\mathfrak{T}_n$ as well as the concept of regions of invariance of Boolean functions with respect to subgroups of group $\mathfrak{T}_n$.

G. N. Povarov showed that the regions of invariance comprise a Boolean algebra, and form a structure dually homomorphic to the structure of the subgroups of group $\mathfrak{T}_n$; to the conjugate subgroups correspond monotypic regions of invariance. Results were given of an investigation of a type of region of invariance $D(\mathfrak{S}_n)$ with respect to the group $\mathfrak{S}_n \subset \mathfrak{T}_n$ of permutations of arguments of Boolean functions. Also investigated were the types of regions of invariance contained in $D(\mathfrak{S}_n)$. The study of regions of invariance is important for the theory of switching circuits, since it enables one better to understand the types of regularity characteristic of simple circuits. A brief exposition of the work was then published in Russian in the "Annalele Stuntifice ale Universitatu Al. I. Cuza" din Iasi" (Rumanian People's Republic) 4, 1, 39-44 (Sept. 1, 1958).

In the next paper, to which two seminar sessions were devoted (Feb. 27 and Mar. 6, 1959), "An abstract algebraic theory of cumulative nets,"[***] G. N. Povarov presented a mathematical theory developed by him, of indirect interactions in control, communications, and planning nets of a very wide class, including various switching circuits, radio communications nets and wire networks, transportation networks, target networks, etc.

---

[*] The proceedings of the seminar prior to October, 1958, were presented Avtomat. i Telemekh. 18, 10 (1957) and 20, 1 (1959) [See English translation of 1959 issue].

[**] See English translation.

[***] In the invitations to this session of the seminar, this paper of G. N. Povarov had the name, "On one mathematical method of investigating operations."

The central concept of the theory is the general combinatorial concept of a cumulative net, which is why G. N. Povarov calls this the theory of cumulative nets. The idea of a cumulative net is analogous to the idea of a normalized graph, but more complicated. It characterizes a definite type of indirect interaction, and the interactions characteristic of the enumerated control, communications, and planning nets. The generality of the treatment is provided by the use of the theory of numeroids [the concept of numeroids was introduced by G. N. Povarov in a paper printed in the journal Uspekhi Matematicheskikh Nauk, 11, 5(71), 195-202,1956].

A cumulative net on the numeroid N is defined as a system $\{M, \|a_{ij}\|, \{P_n\}\}$, consisting of a set $M = \{1, 2, \ldots, p\}, p^2$, a matrix $\|a_{ij}\|$ on N and the sequence of sets $P_n \subseteq \sum_{r=2}^{n+1} M^r$, where $n = 1, 2, \ldots, P_1 = M^2$, and $P_n \subseteq P_{n+1}$ for all n. The matrix $\|a_{ij}\|$ is called the primitive connectivity of the net, and the matrix $\|a_{ij}^{(n)}\|$, where

$$a_{kl}^{(n)} = \sum_{ki_1i_2\ldots i_{r-1}l \in P_n} a_{ki_1}a_{i_1i_2}\ldots a_{i_{r-1}l},$$

is called the nth-degree connectivity of the net, and the sequence $\{\|a_{ij}^{(n)}\|\} = \|a_{ij}^{(1)}\|, \|a_{ij}^{(2)}\|, \ldots$ is the evolution of the net's connectivity. The analysis of a cumulative net consists in finding $\{\|a_{ij}^{(n)}\|\}$ from $\|a_{ij}\|$ for known M and $\{P_n\}$. The interpretation of these quantities is that $\|a_{ij}\|$ is the measure of the immediate interaction between elements of M, $\|a_{ij}^{(n)}\|$ is the measure of indirect interaction via not more than n-2 intermediate elements, and $\{\|a_{ij}^{(n)}\|\}$ is the successive development of indirect interaction. $\{P_n\}$ ("the development of the net") defines the method of combining immediate interactions into indirect ones.

G. N. Povarov also spoke of the matrix methods he had developed for the analysis of various cumulative nets; he investigated such properties of cumulative nets as equivalence, stability, the presence of feedback, etc. G. N. Povarov showed that the theory of cumulative nets allows one to reduce to one framework the results of many authors working on the questions of the analysis of control, communications, and planning nets and analogous problems, in particular, the results obtained in these domains by B. I. Aranovich, A. G. Lunts, O. Plekhi, A. Shimbel, Z. Prikhar, G. Frobenius, and others, and also previous results of G. N. Povarov himself relative to the theory of switching circuits and communications networks.

The third paper of G. N. Povarov, "Phenomenological and juridical aspects of logic in connection with the logical problems of engineering," given on May 15, 1959, contained opinions on the convenience and naturalness of the interpretation of logical algebra in switching theory and in other branches of engineering as an algebra of events, and not as an algebra of judgments (propositions).

On May 29, 1959, V. P. Goncharov presented the contents of a paper by Zemanek, "Solving the equations of switching algebra," printed in the journal Archiv der Elektrischen Übertragung 12, 1,35-44 (Stuttgart, 1958). The paper considered methods of finding inverse Boolean functions and solving the equations of Boolean algebra. Zemanek denotes a Boolean function by y_Z^n, where z is the decimal ordinal number of the function, corresponding to the binary representation of the constituent units entering into the given function, and n is the number of Boolean variables.

For the finding of inverse Boolean functions, a new notation was introduced in the paper: P and !. P can assume either the value 0 or the value 1, i.e., it corresponds to an "indifferent" state, but $\bar{P}$ always takes the value opposite to that of P; rules of action are defined for P. ! means that it is impossible to obtain a solution. Although Zemanek states in the paper that no rules of action will be introduced for !, it follows from Zemanek's reasoning, as pointed out by V. I. Shestakov in the discussion of the paper, that he has implicitly introduced certain rules of action for the sign !. In considering various cases of finding inverse functions, Zemanek presents a schematic representation of two of them; in these schemes, the sign P represents an arbitrarily closed or open key. Further, Zemanek considers the equation

$$y_{Z1}^{n+1}(x_i, y) = y_{Z2}^{n+1}(x_i, y),$$

where $i = 1, 2, \ldots, n$ and $y = y_Z^n$ is the unknown Boolean function. This equation is transformed to the following:

$$yy_{I1}^n + \bar{y}y_{N1}^n = yy_{I2}^n + \bar{y}y_{N2}^n,$$

where

$$y_{I1}^n = y_{Z1}^{n+1}(x_i, 1), \quad y_{N1}^n = y_{Z1}^{n+1}(x_i, 0),$$

and y_{I_2} and y_{N_2} is the similar notation for

$$y_{Z2}^{n+1}(x_i, y).$$

From this, Zemanek obtains the solution for the initial equation:

$$y_Z^n = !\,(y_{I1} \not\equiv y_{I2})(y_{N1} \not\equiv y_{N2}) + \\ + O(y_{I1} \not\equiv y_{I2})(y_{N1} \equiv y_{N2}) + 1\,(y_{I1} \equiv y_{I2})(y_{N1} \not\equiv y_{N2}) + \\ + P(y_{I1} \equiv y_{I2})(y_{N1} \equiv y_{N2}),$$

where $\equiv$ is the equivalence sign and $\not\equiv$ is the sign of its negation.

This solution contains all possible values of the Boolean function being sought. Zemanek showed the application of the method developed by him to the solution of equations in Boolean algebra.

The paper of Zemanek is, so far as is known, the first attempt to give an algebraic representation for the general solution of equations in Boolean algebra.

In the other portion of the papers there were treated various questions of the analysis and synthesis of switching circuits. Such were the papers of Yu.L. Sagalovich, B. Yu. Pil'chak and V. D. Kazakov.

On Oct. 17, 1958, Yu. L. Sagalovich gave the paper "On the number of types of symmetric contact (1,k)-poles." The author recalled that contact (1, k)-poles realize the basic sequence of functions of n variables, and he considers them as coinciding correctly to the numbering of the output poles (terminals). The number of different (1,k)-poles equals the number of combinations $m = C_{\mu}^{k}$, where $\mu = 2^{m}-2$. On all m (1,k)-poles one can carry out the operation of substituting variables and (or) inverting (negating) some of them. The set of these operations forms a group G of order $2^n n!$. (1,k)-poles are considered to be of one type if they are obtained from each other by operations from the group G.

Using the methods of the theory of group representations, the author found the number, $N_{n,k}$, of types of (1,k)-poles of n variables:

$$N_{n,\,k} = \frac{1}{2^n n!} \Sigma\, n_c \chi_c,$$

where n_c is the number of elements of class C of group G, χ_c is the character of class C in the representation of group G by substitution matrices of order m. To determine χ_c, one seeks the cyclical structure of the substitutions of degree m induced in the group G by the elements of class C.

B. Yu. Pil'chak, during two seminar sessions (Nov. 21 and Nov. 28, 1958), spoke on, "The synthesis of quasinonrepeated contact circuits." She gave this name to circuits in which there are connected to each relay not more than one make, and not more than one break, contact. These circuits are synthesized by the method of superposition of subcircuits. The subcircuits are isolated by a method which is a generalization of the method of B. A. Trakhtenbrot which he suggested for finding subcircuits of nonrepeated circuits. B. Yu. Pil'chak introduced the concepts of K-conductance and K-realizability, and suggested the formula for K-conductance. These formulas and concepts are necessary for the synthesis of circuits by the superposition method, and are generalizations of the ordinary concepts of conductance, realizability, and conductance formulas.

On April 17, 1959, V. D. Kazakov gave his paper, "Finding the maximum number of simple implicants of an arbitrary symmetric logical function of n variables." The speaker first recalled that, in the majority of methods for the minimization of logical functions and, consequently, of switching circuits, it is necessary to seek minimal equivalents of the original function which consist of some set of simple implicants of the initial function. For the mechanization of this search for minimal equivalents, it is necessary to know the greatest number of simple implicants I_{max} which can appear with one arbitrarily chosen function of n logical variables; the memory of the minimizing device must be constructed on the basis of such a greatest number I_{max}.

After this, V. D. Kazakov presented the method he had developed for determining the greatest number I_{max} of simple implicants of an arbitrary symmetric function of n variables. He showed that, for such functions, I_{max} is found by the formulas

$$\max\,[C_n^{\alpha} C_{\alpha}^{\beta}] + 2C_n^{\frac{n-\alpha-1}{2}} \quad (\text{ for even } \; n-\alpha-1),$$

$$\max\,[C_n^{\alpha} C_{\alpha}^{\beta}] + C_n^{\frac{n-\alpha}{2}} + C_n^{\frac{n-\alpha-2}{2}} \quad (\text{ for odd } \; n-\alpha-1),$$

where n is the number of variables in the original function, and α and β are quantities for definite values of which the product $C_n^{\alpha}\, C_{\alpha}^{\beta}$ of numbers of combinations becomes maximal. The formulas just given are approximate ones ; V. D. Kazakov also obtained an exact formula, but it is very cumbersome. V. D. Kazakov determined the form of the functions having I_{max} simple implicants, and computed, by the method suggested, the value of I_{max} for n = 1, 2, . . . , 20.

The papers of V. R. Telesnin and B. Ya. Falevich were devoted to the descriptions of new contactless circuits, for whose synthesis mathematical logic was employed.

On December 19, 1958, V. R. Telesnin gave the paper, "The use of magnetic matrices for information processing," in which a device was presented which was destined for both the storage and the processing of information. The basis of this device is a plane magnetic matrix used for a memory device. The total number of active elements is no larger than in matrices designed only for information storage. For the processing of information, there were introduced two special rows to which information could be transmitted from the ordinary rows of the memory device in direct, or complemented, code. Such a device has the capability of realizing any logical functions of the arguments written in the places (bit-positions) of all the rows. The addition of four more special rows allowed the realization of addition, subtraction, and multiplication of the numbers written in the matrice's rows.

On Jan. 30, 1959, B. Ya. Falevich, in the paper, "Electronic machines for games of "wolves and sheep," spoke of the schematic implementation, begun under his direction, of the substantive algorithm he had found for this game.

The algorithm presented by the author is not the very simplest.

Many of the papers gave rise to lively discussion.

V. P. Goncharov

SCIENTIFIC AND ENGINEERING PROBLEMS OF AUTOMATED ELECTRIC DRIVES DURING THE CURRENT SEVEN-YEAR PERIOD

M. G. Chilikin and I. I. Petrov

The far-reaching plan for the development of the national economy of the USSR in the period 1959-1965, put forth at the Twenty-first Congress of the Communist Party of the Soviet Union, envisions an all-around increase in the productivity of national labor on the basis of a strengthening of its electrical sinews and the automation of production. The electrical motive power available determines the degree to which production is mechanized, since the basic and principal form of the prime mover for operating machinery is the electric drive. The productivity of labor depends directly on its electrification (i.e., on the electric motive power available to it): over the past ten years, the productivity of industry in the USSR increased by about the same percentage as its electrification.

By an electric drive we understand a complex device which transforms electrical energy to mechanical energy, and which provides electrical control of the transformed mechanical energy. In this connection, the future development of electric drives must be directed to the implementation of all forms of motion without the use of any mechanical means in achieving these purposes (rotary and reciprocating motion; prolonged discontinuous variable and tracking motion; with fixed speed, and with speeds which change sharply, which vary continuously in accordance with a given law, or which change arbitrarily). The development of electric drives must provide for the broadening of their functions in the automatic control and regulation of the operating machines of technological aggregates (control of the starting, reversing, and braking of operating machines; maintaining constancy of speed, torque and power; program control of operating machines, etc.).

The science of electric drives derives basically from the work of Soviet scientists and, today, this branch of technical knowledge has taken definitive shape in the form of an independent section of applied electrical engineering. In the Soviet Union there has been created, and introduced into industry, a system of electric drives of a high technological level. However, the total volume of research work carried out by research and planning institutes, by higher educational institutions, by the design offices of enterprises and other organizations is still insufficient. There remain unsolved many problems concerning electric drives which are of great significance for the country's national economy.

Among the unsolved problems, the first that should be mentioned is the creation of controlled economical ac electric drives. Of particular significance here are the questions of developing simple and reliable systems of frequency control for ac electric motors and, in particular, of creating ac supplies with controlled frequency. Here, special attention must be given to the development and investigation of static-frequency transformers using ionic, electronic, and semiconductor technologies.

The situation is somewhat better with the development of controlled ac electric drives with choke control. In the last few years there have been created, and introduced into industry, a number of such electric drives, and the scientific and engineering methods for designing them have been adequately developed. However, the domain of possible applicability of electric drives with choke control has been somewhat overestimated, which sometimes leads to incorrect choices in selecting the type of electric drive for productive machines. Thus, for example, on insufficient grounds, a choked electric drive was used for excavators of medium productivity, which led to their uneconomical and unreliable performance. Special resolutions of the State Scientific-Engineering Committee of the Soviet Ministers of the USSR recommended that the production of excavators with such electric drives be halted, and that they be replaced by controlled dc electric drives. The attempt to use choked electric drives for materials-handling vehicles was also adjudged unsuccessful. Seemingly, it is necessary to find reasonable limits of applicability of choke-controlled electric drives, taking into account their relatively low energy efficiency for tight and prolonged control of production-machine speed, and the peculiarities of these machine's load characteristics.

Also requiring further investigation are the questions of the dynamics of choked electric drives, with the nonlinearities of their individual elements taken into account, and also the question of electric-drive heating as the load varies cyclically.

In connection with the intensification of productive processes, the necessity arises for developing electric drives with asynchronous short-circuited electric motors designed for production mechanisms with partial starts and reverses. However, this question remains unsolved. In the near future there must be created, based on normally manufactured asynchronous short-circuited electric motors, a modification of the electric motor with a heat-insulating base and with an extended motor, designed for a high frequency of switching in, and there should also be developed a methodology for designing electric drives with partial starts and reverses. With this, particular attention should be given to the transient responses in electric drives, and to the question of their heating.

There has been an improvement recently in the status of the investigations into the operating properties of ac electric drives supplied from autonomous supplies of commensurable power. Even here, however, there remain many problems in connection with increasing the power of asynchronous electric motors supplied from individual generators. The questions as to the dynamics of the processes transpiring in such electric drives deserve particular attention.

It is also going to be necessary to investigate the questions related to the use of synchronous electric motors for uncontrolled (operating at constant speed) and controlled (operating with variable speed) industrial electric drives. The transition to circuits with direct starting of synchronous motors and starting with permanently connected exciters led to a certain broadening of the domain of applicability of synchronous motors. However, despite their specific properties and their high energy efficiency, synchronous motors have still not been as widely used as they should be. Still, a wide dissemination of synchronous electric motors for drives of operational machines can significantly increase the power factor of electrical stands and provide a high rigidity of electric-drive mechanical characteristics within a wide range of speeds. The use of motors with rotary stators permits the problem of synphasing a synchronous shaft to be solved, etc. There might, therefore, be great interest in works devoted to elucidating new domains of applicability of synchronous electric motors, and to the investigation of new automatic control systems for synchronous electric drives, operating both with constant and, especially with variable speeds of rotation. In particular, interest inheres in the questions of the economic speed control of synchronous electric motors with frequency control, and in questions of automatic excitation control of electric motors for drives with impact loads. Also necessary are further investigation of the transient responses in synchronous electric drives and the development of a scientific method of calculating these processes.

Many problems in the domain of controlled dc electric drives also require solution. In the widely used "motor-generator" (M-G) systems, only dc motors with parallel excitation are used, these being less liable to torque overheating than motors with series and with hybrid excitation. The use of power semiconducting rectifiers, connected in the series-excitation winding circuit, permits one to create new types of M-G systems with improved dynamic characteristics. Analogous systems can also be created by supplying the motor from controlled mercury-arc rectifiers (CMR).

Significant success has been achieved in the development and dissemination of electric drives with ionic transformers (for controlled nonreversible drives). An essential improvement of the dynamic characteristics of an M-G drive system has been attained by the use of controlled mercury-arc rectifiers for the excitation of the system's machine. However, the development and dissemination of such systems have been carried out extremely slowly.

Great difficulties ensue when a CMR-M system is used for reversible electric drives. In this connection, great interest inheres in the question of further development and investigation of an automatic control system for an ionic electric drive, where the ionic transformer must be considered as an element of the over-all control system. These systems must possess a high energy factor, permit operation in the rectifying and inverting modes, be fast-acting, and have little control power.

Development and investigation are required for ionic-drive systems, increasing the power factor for tight speed control, and also for systems for the automatic control of the power factor of ionic aggregates for the purpose of providing the very best conditions for supplying electricity to enterprises.

Recently, magnetic amplifiers have been finding increasing application in electric drives. They are used in "magnetic amplifier – motor" electric drive systems, in M-G systems for generator excitation control, for line control by mercury-arc rectifiers, and also as industrial amplifying links.

The employment of semiconductor amplifiers has also been broadened, these being used advantageously in the form of preamplifier stages in conjuction with rotary and magnetic amplifiers. However, the domain of application of these new types of amplifiers has still not been defined sufficiently clearly. It is necessary to carry out a resolute replacement of rotary amplifiers in electric-drive systems by the more reliable and long-lasting magnetic and semiconductor amplifiers.

Simultaneously, it is necessary to work on the creation of power semiconductor rectifiers for "semiconductor amplifier – motor" electric-drive systems, and also for the control of generator excitation in M-G systems. The new means of automation (rotary and magnetic amplifiers, semiconductor and electronic devices) allow the creation of highly efficient electric-drive control systems, providing the maximum usage of the machines, the accurate maintaining of a given trajectory of motion, etc. Of particular significance here are the so-called optimal systems in which, given limitations on trajectory, speed, acceleration, or heating, there is attained a minimum time of execution of the drive mechanism's operating function.

The investigation of the transient responses in such essentially nonlinear systems presents significant difficulty. Today we are completely capable of solving these complicated tasks by the method of mathematic modeling using analog and digital computers. However, for the creation of automated electric-drive systems, these capabilities are used very weakly. This is explained, on the one hand, by the insufficient quantities of such machines at the disposal of research and planning organizations and, on the other hand, by the shortage of scientific and engineering cadres familiar with the methods of mathematical modeling. The preparation of such cadres is unsatisfactory in the higher institutions of learning which turn out engineers with the "electric drive" specialty. Until now, all the textbooks on electric drives have been based on the classical methods of investigation and do not expound, in adequate measure, the more modern methods, including the methods of mathematical and physical modeling. The laboratory courses in the educational institutions do not provide work with computers. In connection with this, the important problems requiring solution are: equipping research and educational institutes, planning-designing, and other organizations with analog and digital computer-models; improving the knowhow of the scientific and engineering cadres in the domains of mathematical and physical modeling; further developing of research work on the study of transient responses in complex systems of automated electric drives, constructed with the use of the new means of automation, and on the synthesis of the modern, essentially nonlinear, systems which provide optimal electric-drive transient responses; modernization of the university courses in "electric drives" and the related disciplines in the direction of developing in them the more modern methods of theoretical and experimental investigation of electric drives; the creating, in the near future, of manuals and textbooks on electric drives which are designed to make the transition from the older methods of studying electric-drive dynamics to the newer ones, including the methods of mathematical and physical modeling.

Certain problems in the domain of multimotor electric drives are also not solved. Thus, further investigation is required of electric shaft systems with variable speed ratios of the individual elements, for mass-production-line electric drives. It is necessary to develop a theory of the nonsteady-state processes in electric drives with friction coupling between the motors, and to investigate questions of oscillation damping in electric shaft systems with frequency transformers and dual-source machines. There has yet to be created a generalized theory for multimotor electric drives with electrical connections, providing a constant tension on the material being processed, for aggregates with continuous technological processes.

Insufficient attention has been given to the production, and to the use in automated electric drives, of the various electromagnetic clutches, including those with ferromagnetic packing. Nonetheless, their use could lead to the creation of a rational electric-drive system, particularly in cases where it is necessary to have smooth starting of the drive, acceleration of large inertial masses, control of torque, speed, etc. They can also play the roles, in automated electric drive systems, of brake dynamometer, position indexer, torque limiter, etc. Today, electromagnetic clutches are comparatively widely used only in machine-stand construction. It is necessary to translate the experience in machine-stand construction to other branches of the national economy, and to carry out a number of investigative tasks, directed toward the explication of the possibilities of constructing rational electric-drive systems with electromagnetic clutches for diverse productive mechanisms.

During many years, various branches of industry, and particularly the machine-building industry, have put forward the problem of creating electric drives with rotary-reciprocating and vibratory motion. Unfortunately, this problem is still unsolved for practical purposes. Research organizations must necessarily increase the exploratory work in the domains of creating reciprocating electric motors, and of constructing autooscillatory systems with simple control systems for the amplitude and frequency of the vibrations.

Of great interest in both the theory and the practice of electric drives might be an investigation of systems containing elastic links. Today, all system elements are considered to be ideally solid bodies, and therefore the phenomena and processes in which elastic deformations play a part are not taken into consideration. The deformations of elastic links lead, in many cases, to significant errors. It would thus be of great advantage to develop general methods of analyzing automatic-control systems containing elastic links, and to solve the problem of synthesizing electric drives and their control systems for mechanisms with elastic links.

Despite the significant development of this theory in recent years, certain questions in the theory of electric-drive heating are still unsolved. Thus, further investigation is needed of the heating processes of ac motors in normal condtions of use, including the asymmetric mode of supply of three-phase asynchronous electric motors. Also requiring further development are the questions of electric-motor heating in transient responses and for cyclical loads, with account being taken of insulation aging. Work should also be continued on the direct use of heat-conduction equations for the thermal computations for electric-drive motors.

There are also many questions in the domain of microdrives to be resolved. This domain is little studied but, at the same time, this energetically evolving. In the next few years, millions of electric motors will be required for microdrives. In connection with this, there is necessary a further development of the questions of creating economical systems of actual microdrives, of increasing their reliability and noiselessness in use, and also the accuracy and speed of response of microdrives as used in the devices of automation.

The modern electric drive plays a very large role in systems of automated productive processes. The particularly essential question is that of program control of the electric drives of individual productive mechanisms and aggregates. Today, a certain measure of success has been achieved in the introduction of program-control systems for a number of metal-working stands, in the screw-down devices of reversible rolling mills, in the electric drives of charging systems for blast furnaces, etc. However, the general state of work in the areas of creating and disseminating program control systems is unsatisfactory. In these systems, the new means of automation - semiconducting and magnetic elements - are used with inadequate completeness, and one finds little reflection of the recent achievements in the area of creating self-adjusting and self-learning systems. As a rule, the programmed systems in use today have a rigidly given program, which does not always answer to the required technological-economical indicators of the process under conditions of nonconstant external disturbances. The use of devices providing automatic program correction in correspondence with changes in an aggregate's external operating conditions would permit the creation of an automatic-control system which would establish the most efficient mode of operation

A significant obstacle to the widespread introduction of automatic control by mechanisms supplied with electric drives is the inadequacy of existing position transducers of the machines' individual organs and of the material to be processed, and also the inadequacy of manufactured relay-contact apparatus which allows only a limited number of switchings in. Thus, the number of contact operations on an automatic machine-stand line reaches tens of thousands, and sometimes even hundreds of thousands, per hour, which sharply reduces the reliability of electric control systems. In this connection, great importance inheres in the development of new types of contactless automatic control devices which use highly reliable semiconducting and magnetic elements.

Insufficient use is made, in control schemes with drives in production lines, of electric apparatus used for communciations devices. It is necessary to practice a wider use of this apparatus which has small dimensions and increased reliability.

For the purpose of accelerating the large-scale use of modern automatic-control systems by electric drives, it becomes necessary to accelerate the utilization, in the electrical industry's standard assemblies, of new control systems, including digital and programmed devices, and also complex control systems for standard electric drives.

The enumeration of problems in the domain of electric drives which has been given here is far from exhaustive, and contains only the first-priority problems.

STATISTICAL THEORY OF GRADIENT SYSTEMS OF AUTOMATIC OPTIMIZATION FOR OBJECTS WITH QUADRATIC CHARACTERISTICS

A. A. Fel'dbaum

(Moscow)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 2, pp. 167-179, February, 1960)
Original article submitted June 12, 1959

The paper formulates the problem of investigating gradient systems of automatic optimization in the presence of random factors. Methods are given for determining the steady-state error and estimating the duration of the transient response for gradient systems with several input variables. The results are illustrated by examples of systems with one and with two variables.

INTRODUCTION

The near future will be marked by a significant development of self-adjusting (adaptive) systems. Great value, therefore, inheres in the development of a theory of automatic serach, which is the basic process in such systems, and which differs essentially from the process of error liquidation in automatic-control systems. One of the classes of adaptive systems which promises to be of importance practically is that of automatic optimization systems. We present below the theory of one of the forms of such systems.

The problem of an automatic optimization system consists of automatically finding and maintaining a minimum of some quantity y with, generally speaking, additional conditions imposed. The quantity y is a function of the variables u_i:

$$y = y(u_1, u_2, \ldots, u_m). \tag{1}$$

The process of automatic search for a minimum is slowed when there is random noise present, and the minimum itself will be determined, and maintained, with some error under these circumstances. The duration of the transient response of the search process, and the steady-state error, are the fundamental symptomatic indicators of the system's process.

The most general problem consists of synthesizing such a controlling portion which will implement the best (in some sense) process of automatic search. We shall consider below the more restricted problem of determining the indicators of the process for a given controlling portion, and also of choosing the optimal values of this portion's parameters.

In the automatic serach for a minimum, tentative movements are made – "experiments" with the object, as it were – and thereafter the operational movement is made on the basis of an analysis of the results of the tentative trial motions. Various combinations of operationa and trial movements are possible. In the sequel, we consider systems of the discrete type in which, during one cycle, a series of trial steps is taken, and then followed by an operational step; in the following cycle, there is again taken a series of trial steps followed by an operational step, etc.

Figure 1 shows an example of an automatic optimization system. Here, C is the controlling portion; at the output of part F_0 of object 0 there is the quantity y which must be minimized. It is joined, in part F of the object, by an error z. At the object's input, the controlling quantities u_i are joined by random-noise quantities, z_{0i}. The sums thus obtained

$$x_i = u_i + z_{0i} \tag{2}$$

are applied to the input of part F_0 of the object. In carrying out trials on the ith input variable, one adds to the quantity x_i the quantity $+\alpha_{0i}$ in the first trial interval and $-\alpha_{0i}$ in the second trial interval. Thus, a trial consists of two intervals. If the total number of input variables is m, the entire cycle is composed of 2m intervals. We shall assume that the variations of the object's input quantities require the expenditure of no time, but that the carrying out of an "experiment," as a result of which the quantity y appears at the object's output, requires some time interval of constant duration.

The presence of the noise z_{0i} at the input gives rise to a random displacement of the minimum point y in the space $u_1, u_2, \ldots, u_m$, which imitates a slow "drift" of the characteristics, which occurs in actual objects. It is possible to set $z_{0i} = \gamma_i n$, where n is discrete time or the number of cycles ($n = 0, 1, 2, \ldots$) and the γ_i are random variables. The noise z at the object's output (for example, in a measuring block) is a random noise of comparatively high frequency. We shall suppose that the increments of these quantities are independent random variables with known distribution law $\psi(v)$, zero mean value and finite dispersion σ^2. Such a form for the noise was introduced for these systems in [1].

The Markov Process in a Gradient System of Automatic Optimization

Let the dependence of the output y^* of portion F_0 of the object on the input quantities x_k^* be described by the formula

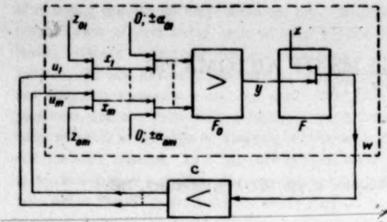

Fig. 1.

$$y' = \sum_{i,k=1}^{m} b'_{ik} x'_i x'_k + \sum_{k=1}^{m} c'_{ik} x'_k + d'. \tag{3}$$

By applying a linear transformation to each variable separately, we can take this formula to the form

$$y = f(x_1, \ldots, x_m) = \sum_{i,k=1}^{m} b_{ik} x_i x_k, \tag{4}$$

where $b_{ik} = b_{ki}$. We shall assume that quadratic form (4) is positive definite. Then y has a unique minimum at the origin of coordinates.

During the ith pair of intervals, whose ordinal numbers within the cycle are j and j + 1, where j = 2i − 1, measurements are made of the quantity y. We denote the values of the quantities x_i in the jth interval by $x_i^{(j)}$, and the value of y by $y^{(j)}$ In the first interval of the ith pair, there is the quantity $x_i^{(j)} + \alpha_{0i}$ at the ith input, while the second interval finds the quantity $x_i^{(j+1)} - \alpha_{0i}$ at this input.

After these two intervals, we determine the difference

$$\Delta_i y_n = f(x_{1,n}^{(j)}, \ldots, x_{i,n}^{(j)} + \alpha_{0i}, \ldots, x_{m,n}^{(j)}) - f(x_{1,n}^{(j+1)}, \ldots, x_{i,n}^{(j+1)} - \alpha_{0i}, \ldots, x_{m,n}^{(j+1)}). \tag{5}$$

The subscripts n denote that the measurements were made in the nth cycle. The corresponding quantity at the output of controlling portion C (Fig. 1) is defined by the expression

$$\Delta_i w_n = \Delta_i y_n + \Delta_i z_n = \Delta_i y_n + v_i. \tag{6}$$

The gradient method consists of this: that after a series of trials, as a result of which one determines the direction of the gradient of the quantity y – the vector with components $\partial y / \partial x_i \cong \Delta_i y_i$, the operational step is taken in this direction. Obviously, the increments of the quantities $u_{i,n+1} - u_{i,n}$, where n is discrete time, must be proportional to the quantities $\Delta_i w$, found in the nth cycle:

$$u_{i,n+1} - u_{i,n} = -\alpha_i (\Delta_i w_n) = -\alpha_i (\Delta_i y_n + v_i). \tag{7}$$

By taking into account (2) and (5), and the formula $z_{0i} = \gamma_i n$, we find that

$$x_{i,n+1} = x_{i,n} + \gamma_i - \alpha_i [f(x_{1,n}^{(2i-1)}, \ldots, x_{i,n}^{(2i-1)} + \alpha_{0i}, \ldots, x_{m,n}^{(2i-1)}) - f(x_1^{(2i)}, \ldots, x_i^{(2i)} - \alpha_{0i}, \ldots, x_m^{(2i)}) + v_i] \tag{8}$$

Here, we have denoted $x_{i,n}^{(1)}$ simply by $x_{i,n}$. Since

$$x_i^{(j)} = \widehat{x_i^{(1)}} + \gamma_i \frac{j-1}{2m} = x_i + \gamma_i \frac{i-1}{m},$$

$$x_i^{(j+1)} = x_i + \gamma_i \frac{2i-1}{2m}, \tag{9}$$

then

$$x_{i,n+1} = x_{i,n} + \gamma_i - \alpha_i \Big[f\Big(x_1 + \gamma_1 \frac{i-1}{m}, x_2 + \gamma_2 \frac{i-1}{m}, \ldots, x_i + \gamma_i \frac{i-1}{m} + \alpha_{0i}, \ldots, x_m + \gamma_m \frac{i-1}{m}\Big) - f\Big(x_1 + \gamma_1 \frac{2i-1}{2m}, \ldots, x_i + \gamma_i \frac{2i-1}{2m} - \alpha_{0i}, \ldots, x_m + \gamma_m \frac{2i-1}{2m}\Big) + v_i \Big]. \tag{10}$$

For brevity, we denote $x_{i,n} = \xi_i$ and $x_{i,n+1} = x_i$; we introduce the vector x in the m-dimensional space Ω_x, the vector ξ with coordinates ξ_i in the space $\Omega_\xi = \Omega_x$ and the vector γ with coordinates γ_i and the vectors ξ_{0i}, again in space Ω_x. Then (10) can be rewritten in the form

$$x_i = \xi_i + \gamma_i - \alpha_i \Big\{ f\Big(\xi + \alpha_{0i}\xi_{0i} + \gamma \frac{i-1}{m}\Big) - f\Big(\xi - \alpha_{0i}\xi_{0i} + \gamma \frac{2i-1}{2m}\Big) + v_i \Big\}. \tag{11}$$

We now take the form of function f(x) [cf., (4)] into account. By substituting (4) in (10) or (11), we obtain after some transformation,

$$x_i = \gamma_i - \alpha_i r_i + \sum_{j=1}^{m} A_{ij} \xi_j + B_i, \tag{12}$$

where

$$A_{ij} = \delta_{ij} + \frac{\alpha_i}{m} \sum_{\substack{k=1 \\ k \neq i}}^{m} b_{kj} \gamma_k + \alpha_i b_{ji} \Big(\frac{\gamma_i}{m} - 4\alpha_{0i} \Big),$$

$$B_i = \frac{4i-3}{2m} \alpha_i \Big\{ \frac{1}{2m} \sum_{\substack{j,k=1 \\ j,k \neq i}}^{m} b_{jk} \gamma_j \gamma_k + \Big(\frac{\gamma_i}{m} - 2\alpha_{0i} \Big) \sum_{\substack{j=1 \\ j \neq i}}^{m} b_{ji} \gamma_j + b_{ii} \gamma_i \Big(\frac{\gamma_i}{2m} - 2\alpha_{0i} \Big) \Big\}. \tag{13}$$

Here, $\delta_{ij} = 1$ for i = j and $\delta_{ij} = 0$ for $i \neq j$; i.e., δ_{ij} is a Kronecker delta.

The sequence $x_{i,n}$ (n = 0, 1, 2, . . .), or the vector x_n, is a random Markov process (cf. [2,3]) since the probability distribution for x_{n+1} depends on the value of x_n.

Initially, let the γ_i be fixed quantities. In view of the independence of the γ_i and the v_i, we can compute the distribution $W(\gamma)$ for γ at any subsequent stage. Further, let the v_i now be all zero. We first investigate the convergence of the automatic search process when the random noises are lacking. Equation (12) can be rewritten as:

$$\mathbf{x} = A\xi + \mathbf{B}, \tag{14}$$

where A is the matrix with elements A_{ij}, and B is the vector with coordinates $\gamma_i + B_i$. If the system converges to a steady state x_{ste}, then this latter state may be found from the equation

$$x_{ste} = A x_{ste} + B. \tag{15}$$

Let E be the unit matrix, and let the inverse $(E-A)^{-1}$ of the matrix E-A exist. Then

$$x_{ste} = (E - A)^{-1} B. \tag{16}$$

We consider the differences

$$x_{n+1} - x_{ste} = \Delta_{n+1}, \quad x_n - x_{ste} = \Delta_n. \tag{17}$$

If follows, from (14), (16), and (17) that

$$\Delta_{n+1} = A\Delta_n. \tag{18}$$

The necessary and sufficient conditions for the convergence of the search process, i.e., for the holding of the condition $\Delta_n \to 0$ as $n \to \infty$, are the inequalities

$$|\lambda_k| < 1, \tag{19}$$

where the λ_k (k = 1, . . . , m) are the roots of the characteristic equation $|A - E\lambda| = 0$ of the matrix A. As is well known, these inequalities reduce to condtions of the Routh-Hurwitz type. We shall assume that these conditions are satisfied.[•] With this, the speeds γ_i can not be arbitrary; the vector γ must lie within a certain region Ω_γ of the m-dimensional space.

We turn now to the general equation, in which random noise is present. Let the transition probability from the point $\xi = \{x_{1,n}, x_{2,n}, \ldots, x_{m,n}\}$ in the interval $x_i \leq x_{i,n+1} \leq x_i + dx_i$ (i = 1, . . . , m) equal $\varphi(\xi, x)$. $dx_1 \ldots dx_m = \varphi(\xi, x)\, d\Omega_x$, where $d\Omega_x = dx_1, \ldots, dx_m$.

Then, $p_{n+1}(x)$, the probability density that x_{n+1} appear in the interval $x_i \leq x_{i,n+1} \leq x_i + dx_i$ (i = 1, . . . , m), is defined by the formula

$$p_{n+1}(x) = \int_{-\infty}^{+\infty} \cdots \int_{-\infty}^{+\infty} \varphi(\xi, x)\, p_n(\xi)\, d\xi_1 \ldots d\xi_m = \\ = \int_{\Omega_\xi} \varphi(\xi, x)\, p_n(\xi)\, d\Omega_\xi, \tag{20}$$

where $d\Omega_\xi = d\xi_1, \ldots d\xi_m$. If this linear integral transformation has a fixed point to which the sequence $p_n(x)$ tends, then by denoting

$$P(x) = \lim_{n \to \infty} p_n(x), \tag{21}$$

we may find this function from the linear integral equation

$$P(x) = \int_{\Omega_\xi} (\xi, x) P(\xi)\, d\Omega_\xi. \tag{22}$$

We find $\varphi(\xi, x)$, assuming now that the γ_i are fixed. From (12) we get

$$v_i = \frac{1}{\alpha_i}\left[\gamma_i - x_i + \sum_{j=1}^{m} A_{ji}\,\xi_j + B_i\right]. \tag{23}$$

The conditional probability that $x_{i,n+1}$ is found in the interval $x_i \leq x_{i,n+1} \leq x_i + dx_i$ if $x_{j,n} = \xi_j$ (j = 1, . . . , m) equals $\psi(v_i)\, dx_i/\alpha_i$, where the v_i are determined from (23). Since, for different x_i, the v_i are independent, we have that

$$p(\xi, x) = \prod_{i=1}^{m} \frac{\psi(v_i)}{\alpha_i} = \prod_{i=1}^{m} \frac{1}{\alpha_i} \psi\left\{\frac{1}{\alpha_i}\left[\gamma_i - x_i + \right.\right. \\ \left.\left. + \sum_{j=1}^{m} A_{ij}\,\xi_j + B_i\right]\right\}. \tag{24}$$

Determination of the Indicators of the Automatic Search Process

We now find the mathematical expectation of the random variable y_n, by which we understand the arithmetic mean over the nth cycle:

$$M[y_n] = \int_{\Omega_x} \frac{1}{2m} \sum_{i=1}^{m} \left[f\left(x + \alpha_{0i}\,\xi_{0i} + \gamma\frac{i-1}{m}\right) + \right. \\ \left. + f\left(x - \alpha_{0i}\,\xi_{0i} + \gamma\,\frac{2i-1}{2m}\right)\right] p_n(x)\, d\Omega_x. \tag{25}$$

We consider separately the expression in the square brackets. By substituting (2) for f(x) we obtain, after some transformations,

$$\frac{1}{2m}\sum_{i=1}^{m}\left[f\left(x + \alpha_{0i}\,\xi_{0i} + \gamma\frac{i-1}{m}\right) + f\left(x - \alpha_{0i}\,\xi_{0i} + \gamma\frac{2i-1}{2m}\right)\right] = \\ = \sum_{j,k=1}^{m} b_{jk}\, x_j x_k + \left(1 - \frac{1}{2m}\right) \sum_{j,k=1}^{m} b_{jk}\, \lambda x_{j\,k} + C, \tag{26}$$

where

$$C = \frac{\frac{2}{3}\,(m+1)(4m-7) + 5}{8m^2} \sum_{j,k=1}^{m} b_{jk}\gamma_j\gamma_k + \\ + \frac{1}{m}\sum_{i=1}^{m} b_{ii}\,\alpha_{0i}^2 - \frac{1}{2m^2}\sum_{i,j=1}^{m} b_{ij}\,\alpha_{0i}\,\gamma_j. \tag{27}$$

Therefore,

$$M[y_n] = \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} \left\{\sum_{j,k=1}^{m} b_{jk}\, x_{j,n}\, x_{k,n} \right. \\ \left. + \left(1 - \frac{1}{2m}\right) \sum_{j,k=1}^{m} b_{jk}\, x_{j,n}\, \gamma_k + C\right\} + \\ p_n(x_{1,n}; x_{2,n}; \ldots; x_{m,n})\, dx_{1,n}\, dx_{2,n} \ldots dx_{m,n} \tag{28}$$

or

$$M[y_n] = \sum_{j,k=1}^{m} b_{j,k} \int_{\Omega_x} x_j x_k\, p_n(x)\, d\Omega_x + \\ + \left(1 - \frac{1}{2m}\right) \sum_{j,k=1}^{m} b_{jk}\,\gamma_k \int_{\Omega_x} x_j\, p_n(x)\, d\Omega_x + C, \tag{29}$$

[•] The stability conditions for continuous gradient systems, derived in [6], have well-known similarities to those given above for $\gamma_i = 0$.

since

$$\int\limits_{\Omega_x} p_n(\mathbf{x})\, d\Omega_x = 1.$$

We introduce the notation

$$I_{jk,\,n} = \int\limits_{\Omega_x} x_j x_k\, p_n(\mathbf{x})\, d\Omega_x,$$

$$J_{j,\,n} = \int\limits_{\Omega_x} x_j\, p_n(\mathbf{x})\, d\Omega_x \qquad (30)$$

Then,

$$M[y_n] = \sum_{j,\,k=1}^{m} b_{jk} I_{jk,\,n} + \left(1 - \frac{1}{2m}\right) \sum_{j,\,k=1}^{m} b_{jk} \gamma_k J_{j,\,n} + C. \qquad (31)$$

Equations (30) for the integrals can be found from (20). We multiply both members by $x_j x_k d\Omega_x$ and integrate over Ω_x. Then, $I_{jk,\,n+1}$ appears in the left member of the equation, and the expression takes the form:

$$I_{jk,\,n+1} = \int\limits_{\Omega_x} x_j x_k \Big[\int\limits_{\Omega_\xi} \varphi(\xi, \mathbf{x})\, p_n(\xi)\, d\Omega_\xi\Big] d\Omega_x =$$

$$= \int\limits_{\Omega_x} x_j x_k \Big[\int\limits_{\Omega_\xi} \prod_{i=1}^{m} \frac{\psi(v_i)}{\alpha_i}\, p_n(\xi)\, d\Omega_\xi\Big] d\Omega_x. \qquad (32)$$

We now reverse the order of integration, and change from the variables $x_1, x_2, \ldots, x_m$ to the new integrand variables $v_1, v_2, \ldots, v_m$. Since $dx_i = -\alpha_i dv_i$, and the change in sign of the differential compensates for the changes in the signs of the limits of integration, we then find, by letting $d\Omega_v = dv_1 \ldots dv_m$, that

$$I_{jk,\,n+1} = \int\limits_{\Omega_\xi} p_n(\xi) \Big[\int\limits_{\Omega_v} \sum_{i=1}^{m} \psi(v_i)\, (\gamma_j - \alpha_j v_j + \sum_{\nu=1}^{m} A_{j\nu} \xi_\nu + B_j)\, (\gamma_k - \alpha_k v_k + \sum_{\nu=1}^{m} A_{k\nu} \xi_\nu + B_k)\, d\Omega_v\Big] d\Omega_\xi = \int\limits_{\Omega_\xi} p_n(\xi)\, L_{jk}\, d\Omega_\xi. \quad (33)$$

We now consider the interior integral L_{jk} included within the square brackets. By expanding the parentheses in it, we obtain

$$L_{jk} = \int\limits_{-\infty}^{+\infty} \cdots \int\limits_{-\infty}^{+\infty} \Big[\prod_{i=1}^{m} \psi(v_i)\Big] [\alpha_k \alpha_j v_k v_j + v_j (-\alpha_j \gamma_k - \alpha_j \sum_{\nu=1}^{m} A_{k\nu} \xi_\nu - \alpha_j B_k) +$$

$$+ v_k (-\alpha_k \gamma_j - \alpha_k \sum_{\nu=1}^{m} A_{j\nu} \xi_\nu - \alpha_k B_j) + \qquad (34)$$

$$+ (\gamma_j \gamma_k + \gamma_k B_j + \gamma_j B_k + B_k B_j) + (\gamma_j + \gamma_k) \sum_{\nu=1}^{m} (A_{k\nu} + A_{j\nu})\, \xi_\nu + (B_j + B_k) \sum_{\nu=1}^{m} (A_{k\nu} + A_{j\nu})\, \xi_\nu + \sum_{\mu,\,\nu=1}^{m} A_{k\nu} A_{j\mu}\, \xi_\mu \xi_\nu]\, dv_1, \ldots, dv_m.$$

Now, we take into account that

$$\int\limits_{-\infty}^{+\infty} \psi(v_i)\, dv_i = 1, \qquad \int\limits_{-\infty}^{+\infty} v_i\, \psi(v_i)\, dv_i = 0, \qquad (35)$$

and denote the dispersion of the noise at the output by

$$\sigma^2 = \int\limits_{-\infty}^{+\infty} v_i^2\, \psi(v_i)\, dv_i. \qquad (36)$$

By taking (35) and (36) into account, we may rewrite (34) in the form

$$L_{jk} = \delta_{jk} \alpha_k^2 \sigma^2 + (\gamma_j \gamma_k + \gamma_j B_k + \gamma_k B_j + B_k B_j) + \sum_{\nu=1}^{m} [(\gamma_j + B_j) A_{k\nu} + (\gamma_k + B_k) A_{j\nu}]\, \xi_\nu + \sum_{\mu,\,\nu=1}^{m} A_{k\nu} A_{j\mu}\, \xi_\mu \xi_\nu. \qquad (37)$$

By substituting (37) in (33), we obtain

$$I_{jk,\,n+1} = \delta_{jk} \alpha_k^2 \sigma^2 + (\gamma_j \gamma_k + \gamma_j B_k + \gamma_k B_j + B_j B_k) + \sum_{\nu=1}^{m} [(\gamma_j + B_j) A_{k\nu} + (\gamma_k + B_k) A_{j\nu}]\, J_{\nu,\,n} + \sum_{\mu,\,\nu=1}^{m} A_{k\nu} A_{j\mu}\, I_{\mu\nu,\,n}. \qquad (38)$$

It is possible to write $m(m+1)/2$ such equations for determining $I_{jk,\,n+1}$ from $I_{\mu\nu,\,n}$. The $\underline{m}$ quantities $J_{\nu,\,n}$ ($\nu = 1, \ldots, m$) also appear in these equations. These latter quantities can be found from (20) in an analogous way. Indeed, by multiplying this expression by $x_{j,\,n+1} d\Omega_x$ and integrating over Ω_x, we arrive at the formula

$$J_{j,\,n+1} = \int\limits_{\Omega_x} x_j \Big[\int\limits_{\Omega_\xi} \varphi(\xi, \mathbf{x})\, p_n(\xi)\, d\Omega_\xi\Big] d\Omega_x =$$

$$= \int\limits_{\Omega_x} x_j \Big[\int\limits_{\Omega_\xi} \prod_{i=1}^{m} \frac{\psi(v_i)}{\alpha_i}\, p_n(\xi)\, d\Omega_\xi\Big] d\Omega_x = \qquad (39)$$

$$= \int\limits_{\Omega_\xi} p_n(\xi) \Big[\int\limits_{\Omega_x} x_j \prod_{i=1}^{m} \frac{\psi(v_i)}{\alpha_i}\, d\Omega_x\Big] d\Omega_\xi = \int\limits_{\Omega_\xi} p_n(\xi)\, L_j\, d\Omega_\xi.$$

With this,

$$L_j = \int\limits_{\Omega_x} x_j \prod_{i=1}^{m} \frac{\psi(v_i)}{\alpha_i}\, d\Omega_x = \int\limits_{-\infty}^{\infty} \cdots \int\limits_{-\infty}^{\infty} \prod_{i=1}^{m} \psi(v_i)\, (\gamma_j - \alpha_j v_j + \sum_{\nu=1}^{m} A_{j\nu} \xi_\nu + B_j)\, dv_1 \ldots dv_m = \gamma_j + \sum_{\nu=1}^{m} A_{j\nu} \xi_\nu + B_j. \qquad (40)$$

By substituting (40) in (39), we find that

$$J_{j,\,n+1}=\int\limits_{\Omega_\xi} p_n(\xi)\,(\gamma_j+\sum_{\nu=1}^{m}A_{j\nu}\xi_\nu+$$

$$+B_j)\,d\Omega_\xi=(\gamma_j+B_j)+\sum_{\nu=1}^{m}A_{j\nu}J_{\nu,\,n}. \qquad (41)$$

Using (41), we can determine $J_{j,\,n+1}$ from the $J_{\nu,\,n}$, and then substitute the result in (38). The presence of the noises v_i is completely unreflected in (41). For $v_i = 0$, the distribution densities reduce to unit pulse functions, but (41) remain unchanged by this. Therefore, the necessary and sufficient conditions for convergence for the sequence $J_{\nu,n}$ as $n \to \infty$ remain the same inequalities (19). The sequence of second moments $I_{jk,\,n}$ of the distribution also converges for $v_i \neq 0$.

In fact, the presence of the noise v_i in (38) is reflected by the additive terms $\delta_{jk}\,\alpha_k^2\,\sigma^2$. For $\sigma^2 = 0$ (absence of noises v_i), conditions (19) are necessary and sufficient for convergence of the sequence $I_{jk,n}$. It is obvious that the presence of the additional terms $\delta_{jk}\,\alpha_k^2\sigma^2$ only changes the steady-state value, but has no effect on the fact of convergence, since the transformation matrix of the $I_{jk,\,n}$ [cf. (38)] depends only on the A_{jk}. Therefore, inequalities (19), when random noises v_i are present, also guarantee convergence of the first and second moments and, consequently, convergence of the sequence $M[y_n]$ [cf. (31)].

We set

$$I_{jk}=\lim_{n\to\infty}I_{jk,\,n};\quad J_j=\lim_{n\to\infty}J_{j,\,n};$$

$$\eta=\lim_{n\to\infty}M\,[y_n]. \qquad (42)$$

It follows, from (31), (38), and (41), that the quantities I_{jk}, J_j, and η are defined by (43), (44), and (45):

$$I_{jk}=\delta_{jk}\,\alpha_k^2\sigma^2+(\gamma_j\gamma_k+\gamma_jB_k+\gamma_kB_j+B_jB_k)+$$

$$+\sum_{\nu=1}^{m}[(\gamma_j+B_j)\,A_{k\nu}+(\gamma_k+B_k)\,A_{j\nu}]\,J_\nu+$$

$$+\sum_{\mu,\,\nu=1}^{m}A_{k\nu}A_{j\mu}I_{\mu,\,\nu}\quad (j,\,k=1,\,\ldots,\,m). \qquad (43)$$

$$J_j=(\gamma_j+B_j)+\sum_{\nu=1}^{m}A_{j\nu}J_\nu\ (j=1,\,\ldots,\,m). \qquad (44)$$

$$\eta=\sum_{j,\,k=1}^{m}b_{jk}\,I_{jk}+\left(1-\frac{1}{2m}\right)\sum_{j,\,k=1}^{m}b_{jk}\,\gamma_k\,J_j+C. \qquad (45)$$

Thus, the problem of determining the mathematical expectation η of the quantity y in the steady-state mode is solved. A consequence of (43), (44), and (45) is that the error is defined only by the dispersion σ^2 of the noise, and does not depend on the form of the function ψ (v). This property is a consequence of the quadratic characteristic of the object. The mathematical expectation of the deviations from the minimum (in the given case, $y_{\min} = 0$) in the steady state may be considered as a certain measure of the error in this mode. As for the duration of the transient response, its mathematical expectation may also serve as its measure. This criterion was introduced in [4].

However, another measure turns out to be simpler – not the mathematical expectation of the duration of the transient response, but the duration of the transient response for the mathematical expectation, which is not the same thing. Consider the dependence of $M[y_n]$ on n [cf. (31)]. This is a transient response in some equivalent discrete system which may be studied by the ordinary methods, for example by frequency methods, integral methods, etc. In the simple cases (cf., below), one can obtain an expression for the duration of the transient response in such equivalent systems.

If the vector γ is not fixed, but has some probability distribution $W(\gamma)$, we may then, by denoting $d\Omega_\gamma = d\gamma_1 \ldots d\gamma_m$, average the values of η over Ω_γ in accordance with the formula

$$\eta_{av}=\int\limits_{\Omega_\gamma}\eta W(\gamma)\,d\Omega_\gamma. \qquad (46)$$

It may be more advantageous for computational purposes to use (45), where the maximum expected values of the γ_i are substituted.

Example of a Simplest System (m = 1)

We illustrate the use of the formulas obtained by the example of a simple system with one input variable. We set

$$\alpha_1=\alpha,\ \alpha_{01}=\alpha_0,\ x_1=x,\ \xi_1=\xi,\ \gamma_1=$$
$$=\gamma,\ b_{11}=b,\ B_1=B,\ A_{11}=A.$$

In this case, (19) for search stability takes the form $|A| < 1$ or, in accordance with (13),

$$|A|=|1-4\alpha\alpha_0b+\alpha\gamma b|<1. \qquad (47)$$

It is clear from this that the speed γ must not go beyond certain limiting values, i.e., $\gamma_1 \leq \gamma \leq \gamma_2$, where $(\gamma_1, \gamma_2) > 0$.

Equation (45) takes the form

$$\eta=bI_{11}+\frac{b\gamma}{2}J_1+b\left(\alpha_0^2-\gamma\frac{\alpha_0}{2}+\frac{\gamma^2}{8}\right). \qquad (48)$$

The integrals I_{11} and J_1 are determined from (43) and (44), which are rewritten in the form

$$I_{11}=\alpha^2\sigma^2+(\gamma+B)^2+2A\,(\gamma+B)+A^2I_{11}, \qquad (49)$$

$$J_1=\gamma+B+AJ_1. \qquad (50)$$

Here, in accordance with the second of Eqs. (13),

$$B=-\alpha b\gamma\frac{1}{2}\left(2\alpha-\frac{\gamma}{2}\right)=\alpha b\gamma\left(\frac{\gamma}{4}-\alpha_0\right). \qquad (51)$$

From these expressions, we find that

$$J_1=\frac{\gamma+B}{1-A},\ I_{11}=\frac{\alpha^2\sigma^2+(\gamma+B)^2}{1-A^2}+2A\,\frac{(\gamma+B)^2}{(1-A)(1-A^2)} \qquad (52)$$

The transient response is determined by (31), (38), and (41), which take the following form:

$$\eta_n = bI_{11,n} + b\left(\alpha_0^2 - \frac{\gamma\alpha_0}{2} + \frac{\gamma^2}{8}\right) + \frac{b\gamma}{2} J_{1,n},$$
$$I_{11,n+1} = \alpha^2\sigma^2 + (\gamma + B)^2 + 2A(\gamma + B) J_{1,n} + A^2 I_{11,n}.$$
$$J_{1,n+1} = \gamma + B + AJ_{1,n}. \tag{53}$$

We set

$$A_0 = \alpha_0 \sqrt{\frac{b}{\sigma}}, \quad \delta = \gamma \sqrt{\frac{b}{\sigma}}, \quad k = \alpha\alpha_0 b, \quad \varepsilon = \frac{\eta}{\sigma}. \tag{54}$$

Then, after substitution of the values of I_{11} and J_1 from (49) and (50), (48) assumes the form

$$\varepsilon = \left(A_0 - \frac{\delta}{4}\right)^2 + \left(\frac{\delta}{k}\right)^2 \frac{1}{\left(4 - \frac{\delta}{A_0}\right)^2} +$$
$$+ \left(\frac{k}{A_0}\right)^2 \frac{1}{1 - \left(1 - 4k + \frac{k\delta}{A_0}\right)^2}. \tag{55}$$

We rewrite stability condition (47) in the form

$$\left|1 - 4k + k\frac{\delta}{A_0}\right| < 1.$$

$$\text{Если } j = 1 - 4k + k\frac{\delta}{A_0}, \text{ то } k\left(4 - \frac{\delta}{A_0}\right) = \tag{56}$$
$$= 1 - j = q.$$

If $j = 1 - 4k + k\frac{\delta}{A_0}$, then $k(4 - \frac{\delta}{A_0}) = 1 - j = q$.

In a stable system, $-1 < j < 1$ and $0 < q < 2$. The boundary of stability is reached for

$$K_{bo} = \frac{2}{4 - \delta/A_0} \tag{57}$$

The other boundary is obtained from the condition that $k > 0$, i.e.,

$$4 - \frac{\delta}{A_0} > 0. \tag{58}$$

Thus, the region of stability has the form shown in Fig. 2.

As an example, let us set $\delta = 0.2$. For this value, and by giving A_0, we find from (55) the minimal value $\epsilon_{\min}$ as a function of k. Let it be attained for $k = k_{opt}$ (Fig. 3). If we trace the curve $\epsilon_{\min} = \epsilon_{\min}(A_0)$ (Fig. 4a) and the curve $k_{opt} = k_{opt}(A_0)$ (Fig. 4b), we can find the minimum possible value of the steady-state error $\epsilon_{\min\min}$ and the values of the parameters A_0 and k which correspond to it. It is clear from Fig. 4 that $\epsilon_{\min\min} \approx 0.3$, $A_0 = 0.4$, and $k = 0.15$.

The optimal parameter values depend on the fact that for very large steps the error increases due to the significant deviations from the minimum; however, for very small steps the system can not compensate the effect of the "drift" γ of the characteristics, thanks to which the error again increases. One easily convinces oneself that for $\gamma = 0$, the optimal values of α and α_0 are infinitesimally small and, in the limit, the error ϵ tends to zero.

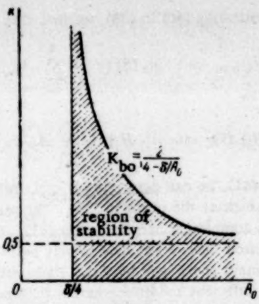

Fig. 2.

We now find the duration of the transient response where, for simplicity, we limit ourselves to the case when $\gamma = 0$. Then from (51) and (53), we find that $B = 0$ and

$$\eta_n = bI_{11,n} + b\alpha_0^2, I_{11,n+1} = \alpha^2\sigma^2 + A^2 I_{11,n}, A = 1 - 4k. \tag{59}$$

The steady-state values turn out to be

$$I_{11} = \frac{\alpha^2\sigma^2}{8k(1 - 2k)}, \quad \eta = \frac{b\alpha^2\sigma^2}{8k(1 - 2k)} + b\alpha_0^2. \tag{60}$$

Since

$$I_{11,n} = \alpha^2\sigma^2 + A^2 I_{11,n-1} = \alpha^2\sigma^2 + A^2[\alpha^2\sigma^2 + A^2 I_{11,n-2}] = \cdots$$
$$\cdots = \alpha^2\sigma^2[1 + A^2 + \cdots + A^{2(n-1)}] + A^{2n} I_{11,0} =$$
$$= \alpha^2\sigma^2 \frac{1 - A^{2n}}{1 - A^2} + A^{2n} I_{11,0} = I_{11}(1 - A^{2n}) + A^{2n} I_{11,0}, \tag{61}$$

the difference

$$\theta_n = \eta_n - \eta = b(I_{11,n} - I_{11}) = bA^{2n}(I_{11,0} - I_{11}). \tag{62}$$

It may be that at the initial moment $I_{11,0} < I_{11}$, if the initial value of x is, for example, at the origin of coordinates. However, if we assume that the system is significantly distant from the steady-state position at the initial moment of time, we can assume that $I_{11,0} - I_{11} > 0$. Then, the quantity θ_n tends to zero with increasing n, while remaining positive. We now find the discrete time n_0 after whose expiration the following relationship is valid:

$$\frac{\theta_n}{\lambda} \leqslant 1, \tag{63}$$

where the constant $\lambda \ll 1$ is some admissable threashold.

It follows from (60), (62), and (63), that

$$n_0 = \frac{1}{2} \frac{\ln \lambda (I_{11} + \alpha_0^2) - \ln (I_{11,0} - I_{11})}{\ln A} \tag{64}$$

The quantity n_0 serves as a measure of the duration of the transient response in the system.

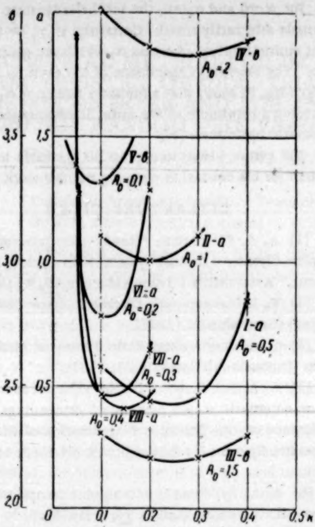

Fig. 3.

Example of a System with Two Variables (m = 2)

Let the object's equation have the form:

$$y = x_1^2 + 2\beta x_1 x_2 + x_2^2. \tag{65}$$

For $|\beta| < 1$, the unique minimum of the function y is found at the origin of coordinates. This case corresponds to m = 2, $b_{11} = b_{22} = 1$, and $b_{12} = \beta$ in the general formulas. We further set $\gamma_1 = 0$, $\alpha_1 = \alpha_2 = \alpha$, $\alpha_{01} = \alpha_{02} = \alpha_0$, $\alpha_1\alpha_{01} = \alpha_2\alpha_{02} = k$. Then, from (13), we find that

$$A_{11} = A_{22} = 1 - 4k, \quad A_{12} = A_{21} = -4\beta k. \tag{66}$$

Equation (45) takes the form:

$$\eta = I_{11} + 2\beta I_{12} + I_{22} + \alpha_0^2. \tag{67}$$

and I_{11}, I_{12}, and I_{22} are found from (43), which can be written in the following forms:

$$\begin{gathered} I_{11} 8k(1-2k) + 8\beta k(1-4k) I_{12} - 16\beta^2 k^2 I_{22} = \alpha^2\sigma^2, \\ I_{11} 4\beta k(1-4k) + 8k(1-2k-2\beta^2 k) I_{12} + I_{22} 4\beta k(1-4k) = 0 \\ -16\beta^2 k^2 I_{11} + 8\beta k(1-4k) I_{12} + I_{22} 8k(1-2k) = \alpha^2\sigma^2. \end{gathered} \tag{68}$$

In these equations, the quantities I_{11} and I_{22} enter in identical fashion, as was to be expected. We set

$$8\beta k(1-4k) = D, \quad 8k(1-2k-2\beta^2 k^2) = E. \tag{69}$$

Then, solving (68), we find that

$$I_{11} = I_{22} = \frac{\alpha^2\sigma^2 E}{E^2 - D^2}, \quad I_{12} = \frac{\alpha^2\sigma^2 D}{D^2 - E^2} \tag{70}$$

and, as follows from (67),

$$\eta = \frac{2\alpha^2\sigma^2(E - \beta D)}{E^2 - D^2} + \alpha_0^2. \tag{71}$$

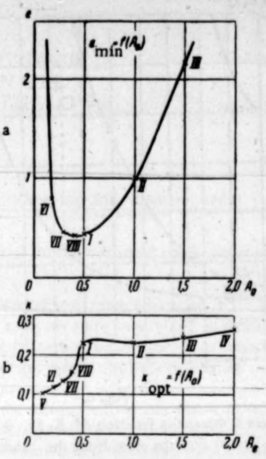

Fig. 4.

We now introduce the relative error from the random noise (for this, we assume that $\alpha_0\alpha = k$)

$$\frac{\eta - \alpha_0^2}{\left(\frac{\sigma}{\alpha_0}\right)^2} = \frac{2k^2(E - \beta D)}{E^2 - D^2} = \theta(k, \beta). \tag{72}$$

By substituting the values of E and D from (69), we find that

$$\theta(k, \beta) = \frac{k(1-2k)}{4} \times$$

$$\times \frac{1-\beta^2}{(1-2k)^2 - 4\beta^2 k(1-2k) + 4\beta^4 k^2 - \beta^2(1-4k)^2}. \tag{73}$$

We find the stability conditions from the characteristic equation $|A - E\lambda| = 0$, or

$$\begin{vmatrix} A_{11} - \lambda & A_{12} \\ A_{21} & A_{22} - \lambda \end{vmatrix} = 0. \tag{74}$$

By substituting the values of A_{ij} here, we arrive at the equation

$$(1 - 4k - \lambda)^2 - 16\beta^2 k^2 = 0, \tag{75}$$

whose roots are

$$\lambda_{1,2} = (1 - 4k) \pm 4\beta k. \tag{76}$$

The search is stable if $|\lambda_{1,2}| < 1$. It follows from this that k must be found within the limits

$$0 < k < \frac{1}{2(1 + |\beta|)}. \tag{77}$$

For a given k, the quantity β may vary within the limits

$$|\beta| < \frac{1}{2k} - 1. \tag{78}$$

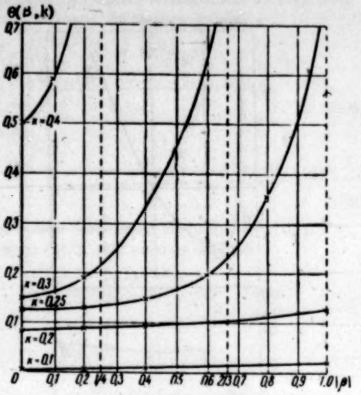

Fig. 5.

Figure 5 shows the function $\theta(\beta, k)$. It is clear from the graphs that the error from the random noise, generally speaking, increases with increasing $|\beta|$. Indeed, for $\beta = 0$ the lines y = const on the (x_1, x_2) plane are concentric circles. With increasing $|\beta|$, they become ellipses whose axes are turned by 45° with respect to the coordinate axes. The greater $|\beta|$ is, the more "elongated" these ellipses become, which worsens the conditions for minimum search and increases the steady-state error from the random noise.

For $\alpha \to 0$ and $\alpha_0 \to 0$, the total steady-state error can be made arbitrarily small. Certainly, if $\gamma_1 \neq 0$, there exist optimal values of α and α_0 which are greater than zero. The essential dependence of the error on α_0 and α (or k) (Fig. 5) shows that automatic tuning of α_0 and α, providing a minimum of the error, is advantageous in automatic optimizers [5].

The author wishes to express his gratitude to B. M. Levitan for his counsel in carrying out this work.

A STATISTICAL METHOD FOR DETERMINING DYNAMIC CHARACTERISTICS OF INDUSTRIAL OBJECTS IN THE PRESENCE OF NOISE AND FOR ANALYZING INFRALOW-FREQUENCY RANDOM PROCESSES

Yu. P. Leonov and L. N. Lipatov
(Moscow)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 2, pp. 180-190, February, 1960)
Original article submitted August 3, 1959

The paper deals with a computer for the computation of estimates of certain statistical characteristics of stationary random functions and of linear objects' characteristics.

In the experimental investigation of the dynamic characteristics of controlled industrial objects by the method of determining an object's reaction to standard stimuli, the presence of "noise" limits, to a significant extent, the accuracy of the estimates of the high-frequency characteristics.

The investigated object itself is frequently a source of "noise." In a number of cases (for example, in the chemical industry), the "noise" level is so high, and the requirements on the technological regime so rigid, that the investigation of the dynamics of such an object by means of sufficiently large standard stimuli becomes impossible.

Today, one of the methods of investigating the dynamics of industrial objects under their actual working conditions is a statistical method, based on the correlation analysis of realizations of the input and output quantities, with the condition that these quantities, as well as the investigated object's dynamic characteristics, are stationary. The basic difficulty in analyzing industrial systems by statistical methods is that these methods require a large expenditure of labor in carrying out the computational work, in particular, in computing correlation functions or spectral densities.

With the aim of decreasing the volume of computational work, special instruments for statistical analysis were developed, both in the USSR and abroad. The instruments developed can be divided into two groups on the basis of their method of recording results:

a) recording on magnetic tape,
b) recording on paper.

There are a number of special features in the technical characteristics of instruments of the first and the second type. Instruments that record on magnetic tape are superior to instruments that record on paper as regards speed of processing statistical data; but under commutation conditions, or in the presence of magnetic fields, they are surpassed by the latter in reliability and in simplicity of use. Moreover, instruments that record on magnetic tape are designed, as a rule, for the processing of comparatively high-frequency random processes. From this point of view, it might sometimes be more convenient, in investigating the dynamics of industrial objects, to use records obtained on ruled (graph) paper.

Computers of such type, developed in the USSR and the Amsler company, were constructed on mechanical principles. Multiplication and integration in these instruments are implemented mechanically with elements which complicate preparation and increase the instrument's cost. Moreover, the existing instruments which record on paper are designed for narrowly circumscribed goals, i.e., for the computing of correlation functions, while the problem of investigating the dynamics of industrial objects requires a more complete statistical analysis.

Below, we describe an instrument for the statistical investigation of the dynamic characteristics of objects in the presence of noise, and for the analysis of infralow-frequency random processes. Considered also are the possibilities of using such an instrument for estimating statistical characteristics, weight-function parameters and for the determination of objects' frequency characteristics by statistical methods.

Instrument Capabilities and Their Uses

The instrument permits an operation of the following form to be applied to the functions $x(t)$ and $y(t)$:

$$R_{yx}(\tau, T) = \frac{1}{T}\int_0^T x(t)\,y(t-\tau)\,dt. \qquad (1)$$

1. Computing Estimates of Correlation Functions and Dispersions

Expression (1) is an estimate of the cross-correlation function of the random processes $X(t)$ and $Y(t)$. Thus, the instrument allows one to obtain estimates of cross-correlation functions. This is an unbiased estimate which converges in the mean to the true correlation function as $T \to \infty$.

If one sets $X(t) = Y(t)$, then (1) gives an estimate of the autocorrelation function of the process $X(t)$ and, in particular, for $\tau = 0$ we obtain an estimate of the dispersion.

2. Computing Coefficients of Fourier Series

If it is necessary to compute the coefficients of the Fourier series for an arbitrary function $x(t)$, then one should choose, in (1), $y(t) = \cos \omega_k t$ and $\tau = 0$. For this, a realization of $x(t)$ in the given interval $(0,T)$ is written on the graph paper. The realization is reproduced in the form of a voltage on potentiometer brushes, supplied from a sine-wave generator which produced voltages of the form $\sin(2\pi k/T)$ $(k = 1,2, \ldots)$.

3. Computing Estimates of Spectral–Density Functions

If $x(t)$ is a realization of the stationary random process $X(t)$, then the value of the spectral density at the point ω_k is computed on the basis of (1)

$$M[a_k^2] = \frac{2}{T}\int_0^T R_{xx}(\tau)\cos\omega_k\tau\, d\tau + 0\left(\frac{1}{T^2}\right) \quad (2)$$

$$a_k = \frac{2}{T}\int_0^T x(t)\cos\omega_k t\, dt. \quad (3)$$

If the interval $(0,T)$ is sufficiently large, then

$$M[a_k^2] = \frac{\pi}{T}G_{xx}(\omega_k) + 0\left(\frac{1}{T^2}\right), \quad (4)$$

where $G_{xx}(\omega_k)$ is the spectral density of the random process $X(t)$.

The value of the dispersion $M[a_k^2]$ is computed approximately, starting from a finite number of realizations of the process $X(t)$.

4. Determination of Frequency Characteristics by Statistical Methods

Even with a significant noise level, statistical methods permit one to find an estimate of the frequency characteristics of an object at whose input a harmonic oscillation of known frequency and amplitude is applied. Such a method is based on the following relationships.

Let there be three signals:

$$f_1(t) = D\cos\omega t,$$

$$f_2(t) = B\sin(\omega t + \theta) + n(t)$$

and

$$f_3(t) = D\sin\omega t,$$

where $f_1(t)$ is the signal at the object's input, $f_2(t)$ is the signal at the object's output which includes the reaction $B\sin(\omega t + \theta)$ to stimulus $f_1(t)$ and the "noise" $n(t)$, with the condition that $M[n(t)] = 0$.

It is then easily verified that

$$R_{3,2}(0) = \lim_{T\to\infty}\frac{1}{T}\int_0^T f_3(t)\, f_2(t)\, dt = \frac{1}{2}BD\cos\theta, \quad (5)$$

$$R_{1,2}(0) = \lim_{T\to\infty}\frac{1}{T}\int_0^T f_1(t)\, f_2(t)\, dt = \frac{1}{2}BD\sin\theta. \quad (6)$$

On the basis of (5) and (6) we get

$$A = \frac{2}{D^2}\sqrt{R_{1,2}^2(0) + R_{3,2}^2(0)},\ \theta = \arctan\frac{R_{1,2}(0)}{R_{3,2}(0)}, \quad (7)$$

where $A = B/D$ is the value of the amplitude characteristic at frequency ω, and θ is the value of the phase characteristic at the same frequency.

It is easily seen that $R_{3,2}(0)$ and $R_{1,2}(0)$ are estimates of the correlation functions for $\tau = 0$. These estimates are increasingly accurate, the larger the time of integration T.

It is essential to mention that the computation of the integrals must be carried out for the function $f_2(t)$ for $t \geq t_1$, where t_1 is the time after which the natural motions of the system will, for all practical purposes, have ceased.

The instrument described in this paper permits one to execute the enumerated mathematical operations on the estimates of frequency characteristics. A scheme for taking off frequency characteristics by the statistical method is shown in Fig. 1.

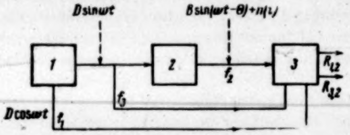

Fig. 1. 1 is a sine and cosine generator; 2 is the object; 3 is the computer.

The signal from the servosystem, which continuously reads the realization $f_2(t)$ of the random process under investigation, is applied to potentiometers which are supplied from the sine-cosine generator. The quantities thus obtained, $f_2(t)\sin\omega t$ and $f_2(t)\cos\omega t$, are applied to integrating motors. The indications of the counters on the motors' shafts correspond to the quantities $R_{3,2}(0)$ and $R_{1,2}(0)$.

5. Estimating the Parameters of Linear Objects' Weight Functions

Sometimes, to simplify a problem, one takes a rough general form of an object's transfer function; it is then necessary to determine its coefficients. As previously, we assume that there is "noise" in the object, and, consequently, we can only determine estimates of the desired parameters on the basis of recordings of the signals at the input and output of the object being investigated.

We shall consider here a method of estimating the moments of the object's weight function by means of the instrument described, for the case of objects with monotonic transient responses* (the reactions of such objects to unit disturbances are monotonic functions of time).

Industrial objects with monotonic transient responses occur quite frequently. In order to describe, in the first approximation, the weight function of such an object, one need estimate only several parameters.

---

*The method considered here can also be extended to the case of nonmonotonic transient responses.

Let $k(t)$ be the object's weight function. By the zeroth-order moment of the function $k(t)$ we mean the number

$$\alpha_0 = \int_{-\infty}^{+\infty} k(t)\,dt. \tag{8}$$

Since $\alpha_0 = \Phi(j\omega)|_{\omega=0}$, where $\Phi(j\omega)$ is the object's frequency characteristic, α_0 is then the static gain.

By the nth-order moment we mean the number

$$\alpha_n = \int_{-\infty}^{+\infty} t^n k(t)\,dt \qquad (n = 0, 1, \ldots). \tag{9}$$

For objects with monotonic transient responses, the weight function is completely determined, under sufficiently general conditions, by giving its moments. We note that for such objects the weight function obviously possesses the properties of a probability-density function, and the frequency characteristic possesses the properties of a characteristic function. For a complete analogy, we should introduce the normalized weight function

$$\bar{k}(t) = \frac{1}{\alpha_0} k(t) \tag{10}$$

and, correspondingly,

$$\bar{\alpha}_n = \int_{-\infty}^{+\infty} t^n \bar{k}(t)\,dt \qquad (n = 0, 1, 2, \ldots). \tag{11}$$

Then, the analogs of the mathematical expectation and the dispersion will be the quantities

$$\bar{\alpha}_1 = \frac{\alpha_1}{\alpha_0} \tag{12}$$

and

$$\bar{\alpha}_{20} = \frac{\alpha_2}{\alpha_0} - \left(\frac{\alpha_1}{\alpha_0}\right)^2 = \bar{\alpha}_2 - (\bar{\alpha}_1)^2. \tag{13}$$

The quantities α_0, $\bar{\alpha}_1$ and $\bar{\alpha}_{20}$ turn out to be very useful in the investigation of objects, and these quantities are frequently sufficient for the description, in a first approximation, of an object's functioning. These quantities have the following physical meanings: α_0 is the object's static gain; $\bar{\alpha}_1$ is the average lag of the transient response; $\bar{\alpha}_{20}$ characterizes the distortion of the input signal.

If the object possesses a pure lag, and does not distort the form of its input signals, its weight function then obviously has the form:

$$k(t) = \delta(t - T), \tag{14}$$

where T is the lag and $\delta(t)$ is a Dirac delta function.

Then, on the basis of (8), (11), and (13), we obtain $\alpha_0 = 1$, $\alpha_1 = \bar{\alpha}_1 = T$, and $\bar{\alpha}_{20} = 0$.

For an object with the weight function

$$k(t) = \frac{1}{T_1} e^{-(t-T)\frac{1}{T_1}} \tag{15}$$

we have

$$\alpha_0 = 1, \bar{\alpha}_1 = T + T_1 \text{ and } \bar{\alpha}_{20} = T^2 + 2TT_1 + 2T_1^2. \tag{16}$$

This weight function corresponds to an object consisting of a series connection of a pure delay link and an aperiodic link. We note that, on the basis of (16), we can easily compute the time constant T_1 and the true lag T of the object as functions of the average lag $\bar{\alpha}_1$ and of $\bar{\alpha}_{20}$.

Now, let $k(t)$ be the weight function of an object consisting of two series-connected links with weight functions $k_1(t)$ and $k_2(t)$.

Then,

$$k(t) = \int_{-\infty}^{+\infty} k_1(t - \tau) k_2(\tau)\,d\tau, \tag{17}$$

and for the transfer functions

$$\Phi(s) = \Phi_1(s)\,\Phi_2(s), \tag{18}$$

where

$$\Phi_i(s) = \int_{-\infty}^{+\infty} e^{-st} k_i(t)\,dt \qquad (i = 1, 2),$$

we have

$$\Phi(s) = \int_{-\infty}^{+\infty} \left[1 - st + \frac{s^2t^2}{2!} - \ldots +\right] k(t)\,dt = \alpha_0 - \alpha_1 s + \frac{\alpha_2 s^2}{2!} - \ldots + . \tag{19}$$

On the basis of (18) and (19) we have, by equating coefficients of like powers of s,

$$\begin{aligned} \alpha_0 &= \gamma_0\beta_0, \\ \alpha_1 &= \gamma_0\beta_1 + \gamma_1\beta_0, \\ \alpha_2 &= \gamma_0\beta_2 + 2\gamma_1\beta_1 + \gamma_2\beta_0, \end{aligned} \tag{20}$$

from which it follows that

$$\begin{aligned} \bar{\alpha}_1 &= \bar{\gamma} = \bar{\beta}_1, \\ \bar{\alpha}_{20} &= \bar{\gamma}_{20} + \bar{\beta}_{20}, \end{aligned} \tag{21}$$

where γ_n and β_n are the moments of the functions $k_1(t)$ and $k_2(t)$, and $\bar{\gamma}_n$ and $\bar{\beta}_n$ are the moments of the normalized functions $\bar{k}_1(t)$ and $\bar{k}_2(t)$ [Cf. (10)].

We now consider the expression

$$R_{yx}(t) = \int_0^T k(t)\,R_{yy}(t - \tau)\,d\tau. \tag{22}$$

We assume here that T in (22) is chosen sufficiently large. By analogy with (20), we can write

$$\begin{aligned} a_0 &= \alpha_0 b_0, \\ a_1 &= b_0\alpha_1 + b_1\alpha_0, \\ a_2 &= b_0\alpha_2 + 2b_1\alpha_1 + b_2\alpha_2, \end{aligned} \tag{23}$$

where

$$a_n = \int\limits_{-\infty}^{+\infty} \tau^n R_{yx}(\tau)\, d\tau \tag{24}$$

and

$$b_n = \int\limits_{-\infty}^{+\infty} \tau^n R_{yy}(\tau)\, d\tau = 2\int\limits_{0}^{\infty} \tau^n R_{yy}(\tau)\, d\tau \; (n = 0, 2, 4, \ldots). \tag{25}$$

Since $R_{yy}(\tau)$ is an even function, we have

$$a_1 = b_0\alpha_1,$$

$$a_3 = b_0\alpha_2 + b_2\alpha_0. \tag{26}$$

Thus, the problem of estimating the α_n reduces to estimating the moments a_n and b_n of the corresponding correlation functions, and to the solution of the system of algebraic equations (26).

The instrument considered below allows the moments a_n and b_n to be estimated. We consider the estimate of the a_n.

On the basis of (24), we can write, starting from the record of a realization on the interval $(t-T_2, t)$,

$$a_n^* = \frac{1}{T_2}\int\limits_{-b}^{a} \tau^n\, d\tau \int\limits_{t-T_2}^{t} x(u)\, y(u-\tau)\, du. \tag{27}$$

The inaccuracy of the estimate in (27) is related to two circumstances: first, the infinite limits in (24) are replaced by finite ones in (27) and, secondly, instead of the cross-correlation function $R_{yx}(\tau)$, we used its estimate, obtained by an averaging operation on the finite interval $(t-T_2, t)$.

It is necessary to bear in mind that the moment of time $\underline{t}$ in (27), at which one can begin averaging to obtain the estimate of the correlation function, must be chosen subject to the condition that $t_0 \geq T$, where T is the object's "memory" (duration of the transient response). With this, t = 0 is taken as the moment when the system begins to operate.

By reversing the order of integration in (27), we get

$$a_n^* = \frac{1}{T_2}\int\limits_{t-T_2}^{t} x(u)\, du \int\limits_{-b}^{a} (\tau)^n y(u-\tau)\, d\tau =$$

$$= \int\limits_{t-T_2}^{t} \Big[x(u)\int\limits_{0}^{a} (\tau)^n y(u-\tau)\, d\tau +$$

$$+ y(u)\int\limits_{0}^{b} (-\tau)^n x(u-\tau)\, d\tau\Big]\, du. \tag{28}$$

An estimate in the form of (28) can be computed in the following way. The realization y(t), written on one strip of paper, is read off in the form of a voltage and applied to a model, where one has chosen a system with finite memory $\underline{a}$ [with weight function $(\tau)^n$]. The voltage at the model's output is applied to a potentiometer whose moving contact is moved in accordance with the law x(t). The voltage at the potentiometer's output is applied to an integrating motor. The number of rotation of the motor gives the first term in (28); the second term is computed analogously.

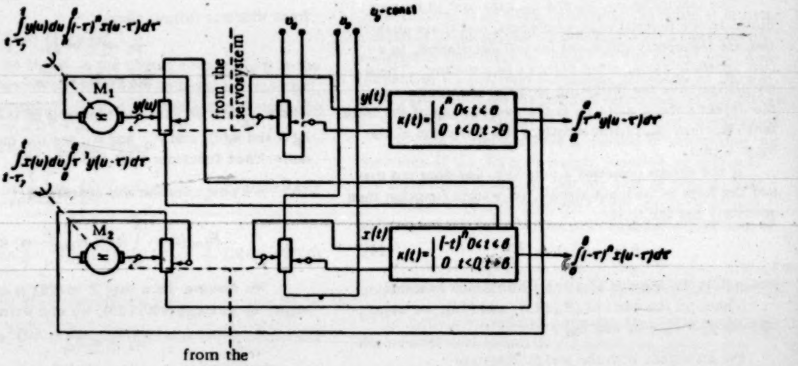
The functional block diagram for the instrument which computes these estimates is shown in Fig. 2. For estimating the moments of the correlation function in (28), it is necessary to set

$$x(t) = y(t),$$

and then

$$b_n^* = \frac{2}{T_2}\int\limits_{t-T_2}^{t} y(u)\, du \int\limits_{0}^{a} \tau^n y(u-\tau)\, d\tau \; (n = 0, 2, 4, \ldots).$$

The conditions for choosing $\underline{a}$, $\underline{b}$, and $\underline{T_2}$ such that the estimates of the moments a_n and b_n will be sufficient-



$\int_{t-T_2}^{t} y(u)du \int_0^b (-\tau)^n x(u-\tau)d\tau$

from the servosystem

Fig. 2.

ly accurate are easily obtained if the functions $R_{xy}(t)$ and $R_{xx}(\tau)$ are known [1]. A more detailed discussion of the questions involved in the choice of a, b, and T_2 may be found in [5].

Description of the Instrument

The instrument's functional-block schematic is shown in Fig. 3, and its outside view is shown in Fig. 4. The instrument is constructed physically of two blocks. In the first block are mounted the servosystem (reading), the tape-handling mechanism, and the multiplication potentiometer.

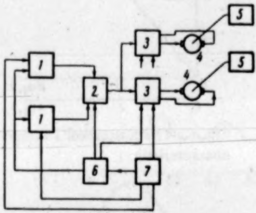

Fig. 3. 1 is a reading device (servosystem); 2 is a multiplier; 3 is a power amplifier; 4 is an integrating motor, 5 is a rotation counter; 6 is a stabilized power supply and 7 is a control panel.

The operation of the servosystem is based on the principle of tracing by a photohead along the edge of a curve drawn on the graph paper. (By the edge of a curve we mean the boundary between the black and white regions.) The photohead consists of a photoimpedance, which is the sensitive element, and a small light bulb.

The photoimpedance is placed on the front side, and the light bulb on the internal side, of the graph-paper strip. The photoimpedance is connected in one of the arms of the servosystem's bridge circuit. The bridge circuit is supplied from a transformer.

Depending on whether the illuminated area of the photoimpedance is increased or decreased, its impedance will decrease or increase, causing a signal of the proper phase to be applied to the input of the phase-sensitive amplifier, made up of twin triodes in a bridge circuit.

The servosystem is executed on the basis of programing device RU5-01 (02). The block schematic of the servosystem's mock-up was changed, permitting the instrument's dynamic characteristics to be increased, i.e., the servosystem's processing speed was increased from 12 to 100 mm/sec.

Depending on the phase of the input signal to a reversible two-phase induction motor, whose control winding is connected in the amplifier's cathode circuit and which is turned in the proper direction, the carriage on which the photohead is mounted will move so as to decrease the imbalance in the bridge circuit.

At the moment when the program's edge covers that portion of the light-sensitive layer of the photoimpedance for which the bridge circuit is balanced, the error signal will equal zero.

Synchronous motors serve as the tape-handling mechanism of the instrument. A realization is carried separately on two reels of graph paper. Reading is implemented separately by the two reading servosystems. Such a kinematic scheme allows the lag τ to be established comparatively simply and within broad limits. The

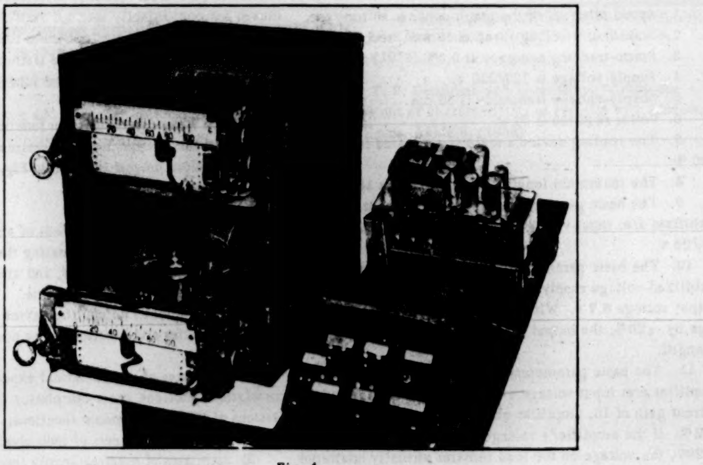

Fig. 4

speeds of the tape-handling drives are synchronized. Multiplication is affected by potentiometers, of which there are two pairs. The moving contacts of the paired potentiometers are rigidly connected to each other.

The resistance ratio of the multiplication potentiometers was designed to be 1:20, for the purpose of avoiding the distortions of their characteristics caused by the loading of one potentiometer by the other. The potentiometers are made up of bridge circuits for the compensation of the voltages corresponding to the mathematical expectations of the random functions.

In this block, the mechanism for reversing the tape-handling drives is also mounted. The second block contains:

1) two ferroresonant voltage stabilizers with two half-period rectifiers and filters;

2) two semiconductor stabilized-voltage sources based on Zener pedestal diodes, used for supplying the multiplication potentiometers;

3) two semiconductor phase-sensitive power amplifiers for controlling the integrating motors, whose inputs are the multiplication potentiometers' output circuits;

4) two integrating motors with rotation counters;

5) the control panel.

The control panel is used for starting, reversing, and stopping the instrument. Instrument stopping is also effected by limit switches on the tape-handling mechanisms. When the limit switches operate, the tape-handling mechanism and integrating motors, whose windings are shorted, are disconnected. The limit switches operate when an index from the pencil on the graph paper hits the transducer of the limit switch. Execution of the various computational tasks on the instrument is implemented by various combinations of its elements.

Technical Characteristics

1 Speed of travel of the graph paper is 15 mm/sec.

2. Maximum tracking speed is 10 mm/sec.

3. Static-tracking accuracy is 0.5%.

4. Supply voltage is 127/220 v.

5. Supply-voltage frequency is 50 cps.

6. Power required is 30 w.

7. The reading device's scale is graduated from 0 to 100 %.

8. The maximum length of graph paper is 16 m.

9. The basic parameters of the ferroresonant voltage stabilizer are: input voltage 12 v, and output voltage 22/25 v.

10. The basic parameters of the semiconductor stabilized-voltage supply are: input voltage 22 v, and output voltage 8.7 v. With variations of the input voltage by ±20%, the output voltage remains virtually unchanged.

11. The basic parameters of the phase-sensitive power amplifier are: input voltage ± 6.7 v, output voltage ± 16 v, current gain of 10, amplifier characteristic linear to within 2%. If the amplifier's voltage supply varies from -10 to 20%, the voltage on the load remains virtually unaltered.

Experimental Characteristics

Figure 5 shows the curve for the number $\underline{n}$ of rotations of the integrating motor during 30 seconds as a function of the voltages u_2 and u_1 at the inputs of the amplifier and motor respectively.

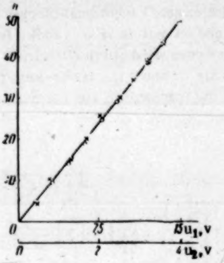

Fig. 5. The instrument's integral characteristic.

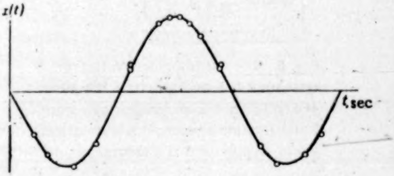

Fig. 6

Figure 6 shows the results of applying operator (1) to the function $\sin(\omega t + \theta)$, it being known that the form of this curve is invariant (as $T \to \infty$) with respect to transformation (1). Consequently, sinusoidal (or cosinusoidal) curves are conveniently used for verifying the instrument's accuracy. The small circles denote the ordinates of the curve computed by means of the instrument. As is clear, the deviation of the experimental function from the computed one does not exceed 4%.

Figure 7 shows a correlation function computed with the help of the instrument. The realization of the corresponding random process is shown in Fig. 8.

Conclusions

This work considered methods of analyzing low-frequency random processes, estimating the parameters of objects in the presence of noise, and also described an instrument for solving such problems.

The instrument's computing device permits the following quantities and functions to be computed automatically:

1) estimates of mathematical expectations, autocorrelation functions, cross-correlation functions and dispersions of stationary random functions;

2) Fourier coefficients of individual realizations;

3) estimates of spectral-density functions;

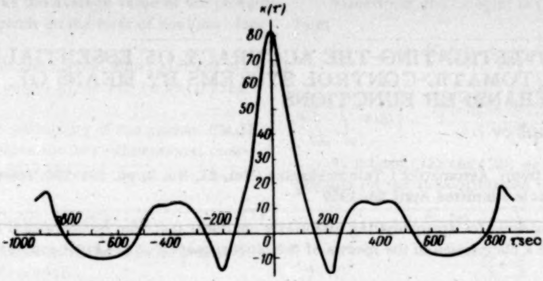

Fig. 7

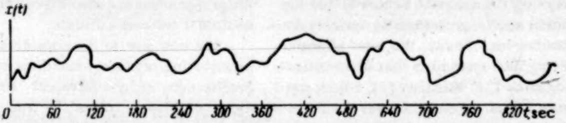

Fig. 8

4) estimates of systems' frequency characteristics;

5) estimates of weight-function moments.

The instrument developed is very simple to use, and is very reliable. These two qualities make it particularly convenient for use in the analysis of industrial objects, and also nicely distinguish it from electronic computing devices with complex circuitry and low reliability.

Among the superior features of this instrument is its capability of using realizations written on paper, since widely used industrial apparatus permits recording on paper tape.

Among the disadvantages of the instrument is the large amount of time necessary for an analysis.

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 2, pp. 191-200, February, 1960)
Original article submitted April 29, 1959

A method is considered for approximating essentially nonlinear functions by equivalent frequency characteristics on the basis of a comparison of the spectra of the random process at the input and at the output of the nonlinear element.

One of the complicated problems in automatic-control theory is that of analyzing the dynamic accuracy and the forced motions of closed nonlinear automatic systems acted on by random disturbances. Today, the most effective method for investigating such systems is that of statistical linearization, developed by I. E. Kazakov [1], which starts from the representation of inertialess nonlinear elements by constant equivalent coefficients. This coefficient is most simply defined by one or another of two assumptions and, with this, two values are obtained for the coefficient.

Definition of the coefficient by the condition that the dispersions at the output of the true nonlinear element and of the equivalent linear one be equal leads to the expression

$$k_1^{(1)} = \frac{\sigma_y}{\sigma_x}, \tag{1}$$

where σ_x is the mean-square deviation of the random function at the input of the nonlinear element and σ_y is the mean-square deviation at its output.

The definition of the coefficient starting from the requirement that the mean-square difference between the true and the approximating random functions be a minimum leads to an expression of the form

$$k_1^{(2)} = \frac{R_{yx}(\tau v)}{\sigma_x^2}, \tag{2}$$

where $R_{yx}(\tau)$ is the cross-correlation function of the random processes at the nonlinear element's input and output.

In both cases, the nonlinear element's transfer factor by average value is defined as the ratio of the mathematical expectations at the output and input of this element:

$$k_0 = \frac{m_y}{m_x}, \tag{3}$$

where m_x and m_y are the mathematical expectations of the random processes at the nonlinear element's input and output respectively.

Approximation by the coefficients in (1) and (2) gives good results with the condition that a narrow-band filter stands beyond the nonlinear element. These coefficients are conveniently used only in the analysis of the operational accuracy of simple automatic-control systems which do not contain complicated filters in their structure since, in this case, the representation of the true spectral content of the random process in the nonlinear system is lost. This latter circumstance also makes the synthesis of optimal nonlinear systems difficult.

We turn now to the consideration of a method of approximating nonlinear functions by equivalent frequency coefficients, or by equivalent "transfer" functions, which more completely mirror the true outlines of the random process's passage through the nonlinearity.

This method allows one to compute, with as great an accuracy as desired, the dispersion of any coordinate of a nonlinear system, and opens up a path for the synthesis of optimal filters.

An equivalent frequency-transfer factor for a nonlinear element is defined as the square root of the ratio of the spectral densities of the random process at the input and output:

$$K(\omega, \sigma_x, m_x) = \sqrt{\frac{S_{\text{out}}(\omega)}{S_{\text{in}}(\omega)}}, \tag{4}$$

where $S_{\text{in}}(\omega)$ is the spectral density of the random process at the nonlinear element's input, and $S_{\text{out}}(\omega)$ is that at its output.

Naturally, $K(\omega, \sigma_x, m_x)$ is also a function of σ_x and m_x, and depends on the type of nonlinear characteristic.

For the determination of the frequency characteristic, it is necessary to know the spectral density of the process at the output. We assume that we know the two-dimensional-distribution law and the correlation function of the random process at the input of the nonlinear element, where the distribution law is a normal one.

For a stationary random process, the correlation function (the autocorrelation function) is defined by the expression

$$R_x(\tau) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} x_1 - m\ )(x_2 - m_x) W_2(x_1\ x_2, \tau)\, dx_1, dx_2,$$

where $W_2(x_1, x_2, \tau)$ is the random process's two-dimensional probability density.

We now consider the nonlinear functional dependency

$$y = f(x). \tag{6}$$

The autocorrelation function $R_y(\tau)$ at the nonlinear element's output will be the average value of the product $y(t)y(t+\tau)$, which depends on the form of nonlinear function (6).

If the values of the input signal equal $x(t)$ and $x(t+\tau)$, then the values of the output signal will be $f[x(t)]$ and $f[x(t+\tau)]$.

Consequently, the probability of the product $f[x(t)]\, f[x(t+\tau)]$ will determine the two-dimensional probability density $W_2(x_1, x_2, \tau)$.

The mean value

$$M\{f[x(t)]\, f[x(t+\tau)]\} \tag{7}$$

is the autocorrelation function of the random process at the nonlinear element's output.

Expression (7) can be written in the alternative form

$$R_y(\tau) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} f(x_1)\, f(x_2)\, W_2(x_1, x_2, \tau)\, dx_1\, dx_2, \tag{8}$$

where

$$x_1 = x(t), \quad x_2 = x(t+\tau).$$

In (8), the random process is taken to have zero mean value.

For the computation of the integral in (8), we approximate the nonlinear function of (6) by rectilinear segments and, for $W_2(x_1, x_2, \tau)$, we use Cramer's expansion by terms of orthogonal Hermite polynomials [2].

The Cramer expansion has the form:

$$\frac{1}{\sqrt{1-\rho^2}} \exp\left[-\frac{\rho^2 x_1^2 + \rho^2 x_2^2 - 2\rho x_1 x_2}{2(1-\rho^2)}\right] = \sum_{\nu=0}^{\infty} \frac{H_\nu(x_1)\, H_\nu(x_2)}{\nu!}\rho^\nu, \tag{9}$$

where $\rho = \frac{R(\tau)}{R(0)}$ is the normalized autocorrelation function, and $H_\nu(x)$ ($\nu = 1, 2, 3, \ldots$) are orthogonal Hermite polynomials.

For the two-dimensional normal probability-density function, we get

$$\frac{1}{2\pi\sqrt{1-\rho^2}} \exp\left[-\frac{\rho^2 x_1^2 + \rho^2 x_2^2 - 2\rho x_1 x_2}{2(1-\rho^2)}\right] \times \exp\left[-\frac{x_1^2 + x_2^2}{2}\right] = \exp\left[-\frac{x_1^2 + x_2^2}{2}\right] \sum_{\nu=0}^{\infty} \frac{H_\nu(x_1)\, H_\nu(x_2)}{2\pi\nu!}\rho^\nu \tag{10}$$

or

$$\frac{1}{2\pi\sqrt{1-\rho^2}} \exp\left[-\frac{x_1^2 + x_2^2 - 2\rho x_1 x_2}{2(1-\rho^2)}\right] = \exp\left[-\frac{x_1^2 + x_2^2}{2}\right] \sum_{\nu=0}^{\infty} \frac{H_\nu(x_1)\, H_\nu(x_2)}{2\pi\nu!}\rho^\nu. \tag{11}$$

We now normalize the random variable $\underline{x}$ with respect to the mean square value σ, i.e., we set $\xi_1 = x_1/\sigma_1$ and $\xi_2 = x_2/\sigma_2$.

In the sequel, we can take $\sigma_1 = \sigma_2 = \sigma$, since the random process is stationary.

Sometimes, the integral in (8) can be written in the form

$$R_y(\tau) = \frac{1}{2\pi\sqrt{1-\rho^2}} \times \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \exp\left[-\frac{\xi_1^2 + \xi_2^2 - 2\rho\xi_1\xi_2}{2(1-\rho^2)}\right] f(\sigma\xi_1)\, f(\sigma\xi_2)\, d\xi_1 d\xi_2. \tag{12}$$

By joining (11) and (12), we obtain the following expression for the autocorrelation function:

$$R_y(\tau) = \frac{1}{2\pi\nu!} \sum_{\nu=0}^{\infty} \rho^\nu \times \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} f(\sigma\xi_1)\, f(\sigma\xi_2)\, e^{-\frac{\xi_1^2+\xi_2^2}{2}} H_\nu(\xi_1)\, H_\nu(\xi_2)\, d\xi_1\, d\xi_2. \tag{13}$$

The double integral in (13) decomposes into the product of two simple ones. Then (13) may be given in the form:

$$R_y(\tau) = \sum_{\nu=0}^{\infty} a_\nu^2 \rho^\nu, \tag{14}$$

where

$$a_\nu = \frac{1}{\sqrt{2\pi\nu!}} \int_{-\infty}^{\infty} f(\sigma\xi)\, H_\nu(\xi)\, e^{-\frac{\xi^2}{2}}\, d\xi. \tag{15}$$

The orthogonal Hermite polynomials are defined by the relationship

$$\left(\frac{d}{d\xi}\right)^\nu e^{-\frac{\xi^2}{2}} = (-1)^\nu H_\nu e^{-\frac{\xi^2}{2}} \tag{16}$$

and equal, for various values of ν, respectively:.

$$\begin{gathered} H_0(\xi) = 1, \; H_1(\xi) = \xi, \; H_2(\xi) = \xi^2 - 1, \\ H_3(\xi) = \xi^3 - 3\xi, \; H_4(\xi) = \xi^4 - 6\xi^2 + 3, \\ H_5(\xi) = \xi^5 - 10\xi^3 - 15\xi. \end{gathered} \tag{17}$$

Thus, the autocorrelation function at the nonlinear element's output can be determined by computing the series in (14). This series is absolutely convergent, since $\rho(\tau)$ is a bounded function, and the coefficients a_ν decrease at the rate $1/\nu$:.

If the nonlinear device's characteristic is an antisymmetric function, then (14) contains only odd terms of the expansion

$$R_y(\tau) = a_1^2\rho + a_3^2\rho^3 + a_5^2\rho^5 + \cdots \tag{18}$$

If this function is odd, but not symmetric, then all the terms of the series are retained. With this, the coefficient a_0^2 equals the square of the mean value at the output which results from the lack of symmetry.

In this case, the autocorrelation function for the centered random process will be defined by

$$R_y^0(\tau) = \sum_{\nu=1}^{\infty} a_\nu^2 \rho^\nu. \tag{19}$$

From a known autocorrelation function, we obtain the spectral density by a Fourier transformation.

We may now turn to the definition of the equivalent frequency transfer factor. For the determination of this coefficient, it turns out that it suffices to know the a_ν and the spectral densities of the powers of the autocorrelation function at the nonlinear element's input.

Then, by the definition of (4), $K(\omega, \sigma_x, m_x)$ will have the form:

$$K(\omega, \sigma_x \; m_x) = \frac{1}{\sigma} \sqrt{\sum_{\nu=1}^{\infty} a_\nu^2 b_\nu}, \qquad (20)$$

where

$$b_\nu = \frac{S^\nu(\omega)}{S_{\text{in}}(\omega)}, \quad S^\nu(\omega) \div \rho^\nu(\tau).$$

For example, for correlation functions and spectral densities of the form

$$\rho_x(\tau) = e^{-\beta|\tau|}, \quad S_x(\omega) = \frac{2\beta}{\omega^2 + \beta^2} \qquad (21)$$

the coefficients b_ν equal:

$$\begin{aligned} b_1 &= 1, \\ b_2 &= 2\frac{\omega^2 + \beta^2}{\omega^2 + 4\beta^2} \\ b_3 &= 3\cdot\frac{\omega^2 + \beta^2}{\omega^2 + 9\beta^2}, \\ b_4 &= 4\frac{\omega^2 + \beta^2}{\omega^2 + 16\beta^2}, \\ b_5 &= 5\frac{\omega^2 + \beta^2}{\omega^2 + 25\beta^2}, \\ &\ldots\ldots\ldots\ldots \end{aligned} \qquad (22)$$

In this case, the transfer coefficient equals

$$K(\omega, \sigma_x, m_x) =$$

$$= \frac{1}{\sigma_x}\sqrt{a_1^2 + 2a_2^2\frac{\omega^2 + \beta^2}{\omega^2 + 4\beta^2} + 3a_3^2\frac{\omega^2 + \beta^2}{\omega^2 + 9\beta^2} + \cdots} \qquad (23)$$

In accordance with (14), the coefficients a_ν^2 are proportional to the dispersions, and may be computed for the standard essential nonlinearities.

In the given case, the transfer factor by mean value is defined by the expression

$$k_0(m_x, \sigma_x) = \frac{km_x - a_0}{m_x}, \qquad (24)$$

where k is the slope of the nonlinear characteristic at the working point.

We now consider (20) in more detail. If we assume that the spectral densities at the nonlinear element's input and output have the same form, then the coefficients $b_\nu = 1$. As a result, we get the transfer coefficient

$$K(\sigma_x, m_x) = \frac{1}{\sigma_x}\sqrt{\sum_{\nu=1}^{\infty} a_\nu^2} \equiv k_1^{(1)}, \qquad (25)$$

which corresponds to equivalent transfer factor (1), computed by the first approximation method, since

$$\sum_{\nu=1}^{\infty} a_\nu^2 = \sigma_y^2.$$

If we take only the first term of the series, we obtain the transfer factor

$$K(\sigma_x, m_x) = \frac{a_1}{\sigma_x} \equiv k_1^{(2)}, \qquad (26)$$

which corresponds to the equivalent coefficient in (2), computed by the second approximation method.

If we neglect all the coefficients a_ν except a_1, this means physically that we are not taking into account the components of the random process due to the nonlinear transformation.

Thus, (25) and (26) serve as the mathematical bases for the two methods of statistical linearization of nonlinear functions.

We now turn to the consideration of the equivalent "transfer" function for a nonlinear element. Taking into consideration that the equivalent frequency-transfer factor is taken as the ratio of spectral densities, which are even functions of frequency, we present it in the form of a product of complex conjugate factors:

$$K^*(j\omega, \sigma_x, m_x)K(j\omega, \sigma_x, m_x) = K^2(\omega, \sigma_x, m_x). \qquad (27)$$

By choosing the zeroes and poles in the upper half of the complex plane, we obtain the following expression for the equivalent "transfer" function:

$$K(j\omega, \sigma_x, m_x) = k_{\text{st}}\frac{(T_1 j\omega + 1)(T_3 j\omega + 1)\ldots}{(T_2 j\omega + 1)(T_4 j\omega + 1)\ldots}, \qquad (28)$$

where the value of

$$k_{\text{st}} = \frac{1}{\sigma_x}\sqrt{a_1^2 + \frac{1}{2}a_2^2 + \frac{1}{3}a_3^2 + \cdots} \qquad (29)$$

is found from (23) for $\omega = 0$; T_1, T_2, T_3,... are time constants, and are functions of the coefficients a_ν, and of the form of the spectral density at the input, for which $T_1 > T_2$, $T_3 > T_4$, etc.

The coefficient in (29) has a value lying between the values of the coefficients in (25) and (26), and can give as accurate a value as desired for the computation of the dispersion in a nonlinear system.

However, this fact holds in the case when, at the input of the nonlinear element, there acts a random process with a spectral density in the form of "white" noise, or with a frequency band which exceeds the pass band of the linear filter which follows the nonlinearity. In all other cases, it is desirable, in analyzing dynamic accuracy, to use the equivalent "transfer" function of (28).

Since (20), (28), and (29) have been obtained in the form of series, it suffices for practical computations to limit oneself to five, and sometimes even three, terms of the expansion.

It is obvious that, both for the computation of equivalent transfer factors and for the determination of the equivalent "transfer" function, it is necessary to know the coefficients a_ν, defined by the integral in (15). These coefficients are functions of the dispersion of the input random process, and depend on the form of the nonlinear function.

The computational formulas for the a_ν may be given for any nonlinear characteristic.

Let us consider the methodology of computing the a_ν. In (15) the nonlinear function $f(\sigma\,\xi)$ enters, complicating the computation of the integral, so that we approximate this function by rectilinear segments. Then, the integral of (15) may be easily computed by using tables of the incomplete gamma function and of the χ^2 probability function [3].

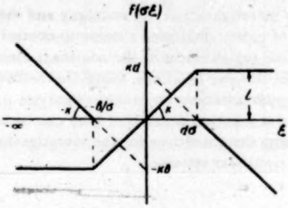

Fig. 1.

We illustrate this methodology by an example. We take a nonlinearity of the limitation type, as shown in Fig. 1, and write the general expression for the a_ν, which has the form:

$$a_\nu = \frac{k\sigma}{\sqrt{2\pi\nu!}} \int_{0^\bullet}^{\infty} \xi H_\nu(\xi)\, e^{-\frac{\xi^2}{2}}\, d\xi +$$

$$+ \frac{k}{\sqrt{2\pi\nu!}} \int_{\frac{d}{\sigma}}^{\infty} (d - \sigma\xi) H_\nu(\xi)\, e^{-\frac{\xi^2}{2}}\, d\xi +$$

$$+ \frac{k\sigma}{\sqrt{2\pi\nu!}} \int_{-\infty}^{\nu} \xi H_\nu(\xi)\, e^{-\frac{\xi^2}{2}} d\xi +$$

$$+ \frac{k}{\sqrt{2\pi\nu!}} \int_{-\infty}^{-\frac{b}{\sigma}} (-b - \sigma\xi)\, H_\nu(\xi)\, e^{-\frac{\xi^2}{2}}\, d\xi. \qquad (30)$$

In the integrands of (30) there appear powers of the variable which depend on the order of the polynomials in (16).

These integrals may be reduced to the tabulated ones:

$$\int_0^{\chi} \xi^n e^{-\frac{\xi^2}{2}}\, d\xi = \sqrt{2}^{\,n-1}\left(\frac{n-1}{2}\right)!\,[1 - P(\chi^2,\ n+1)] \qquad (31)$$

or

$$\frac{1}{2^{\frac{n-2}{2}}\,\Gamma\left(\frac{n}{2}\right)} \int_{\chi}^{\infty} \xi^{n-1} e^{-\frac{\xi^2}{2}}\, d\xi = P(\chi^2,\ n). \qquad (32)$$

The function $P(\chi^2, n)$ is a function of two arguments for which tables have been computed (Cf. [2]).

In the given case, the quantity χ is defined as

$$\chi = \frac{d}{\sigma}, \qquad (33)$$

where

$$d = h \pm m_x.$$

For the nonlinear characteristic shown in Fig. 1,

$$\chi_1 = \frac{h - m_x}{\sigma_x} = \frac{d}{\sigma_x},$$

$$\chi_2 = \frac{-h - m_x}{\sigma_x} = -\frac{b}{\sigma_x}.$$

Then,

$$a_0 = L\left\{\frac{1}{2}\left[\left|\frac{h-m}{h}\right| P(\chi_1^2,\ 1) - \frac{h+m}{h} P(\chi_2^2,\ 1)\right] + \right.$$
$$\left. + \frac{1}{\sqrt{2\pi}}\frac{\sigma}{h}\left[-P(\chi_1^2,\ 2) + P(\chi_2^2,\ 2)\right]\right\},$$

$$a_1 = L\left\{\frac{\sigma}{h}\left[1 - \frac{1}{2}\left(P(\chi_1^2,\ 3) + P(\chi_2^2,\ 3)\right)\right] + \right. \qquad (34)$$
$$+ \frac{1}{\sqrt{2\pi}}\frac{m}{h}\left[P(\chi_2^2,\ 2) - P(\chi_1^2,\ 2)\right] +$$
$$\left. + \frac{1}{\sqrt{2\pi}}\left[P(\chi_1^2,\ 2) + P(\chi_2^2,\ 2)\right]\right\}$$

etc.

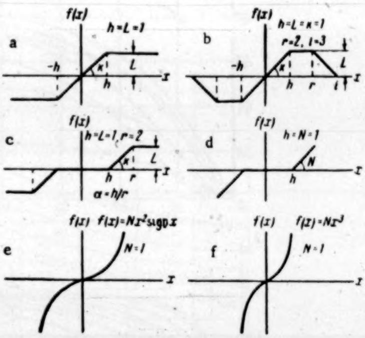

Fig. 2.

Using (34), set up for the nonlinear characteristics shown in Fig. 2, we have calculated and constructed the graphs for the normalized coefficients $a_{n\nu}$ which are given in the Appendix in Figs. 3-28. The parameter m on the graphs has the scale of the quantity x/σ.

In computing the coefficients a_ν from these graphs, it is necessary to take the following relationships into account:

1) for nonlinearities of the limitation type (Fig. 2,a and b),

$$a_\nu = a_{n\nu} L$$

2) for dead zones with limitations (Fig. 2, c),

$$a_\nu = a_{n\nu}\frac{L}{1-\alpha}, \qquad \alpha = \frac{h}{r},$$

3) for dead zones, cubic parabolas and antisymmetric quadratic parabolas (Fig. 2,d,e and f),

$$a_\nu = a_{n\nu} N$$

Example. In conclusion, we give the example of the determination of the equivalent "transfer" function for a nonlinearity of the cubic-parabola type of Fig. 2,f.

Let.

$$N=1, \quad S_{\text{in}}(\omega)=\frac{2\beta}{\omega^2+\beta^2}, \quad \sigma_x=1{,}5, \quad \beta=10, \tag{35}$$

$$K(j\omega,\sigma_x,m_x)=\frac{1}{\sigma_x}\sqrt{a_1^2+\frac{a_3^2}{3}}\;\frac{\sqrt{\dfrac{a_1^2+3a_3^2}{3\beta^2(3a_1^2+a_3^2)}}\,j\omega+1}{\dfrac{1}{3\beta}\,j\omega+1}$$

or

$$K(s,\sigma_x,m_x)=k_{\text{st}}\,\frac{T_1s+1}{T_2s+1}, \qquad s=j\omega,$$

where

$$K_{\text{st}}=\frac{1}{\sigma_x}\sqrt{a_1^2+\frac{a_3^2}{3}}=2{,}25\sqrt{11},$$

$$T_1=\sqrt{\frac{a_1^2+3a_3^2}{3\beta^2(3a_1^2+a_3^2)}}=0{,}1\sqrt{\frac{3}{11}}.$$

$$T_2=\frac{1}{3\beta}=\frac{1}{30}.$$

Then,

$$K(s,\sigma_x,m_x)=7{,}5\,\frac{0{,}0524s+1}{0.0333\,s+1}. \tag{36}$$

The investigation of the accuracy and the forced motions of closed nonlinear automatic-control systems leads to the replacement of the nonlinear elements by equivalent transfer functions, using the method of successive approximations for graphicoanalytic methods. The transfer function considered here can be used for determining the conditions for the investigation of stability of nonlinear systems.

PROCESSES OF FINITE DURATION IN PULSE-WIDTH SYSTEMS

I. V. Pyshkin

(Moscow)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 2, pp. 201-208, February, 1960)
Original article submitted July 18, 1959

Equations are derived for pulse-width systems which determine the form of the transient responses which terminate in a finite time. For second-order systems, methods of realizing such processes are given. It is suggested that the complicated nonlinearities necessary for the realization of such processes be replaced by linear elements. Results of experiments on a model are given, confirming the possibility of such replacements.

Today, much attention is being given to those optimal processes which terminate in a finite and, moreover, a minimal interval of time. In particular, such types of processes may be realized in relay and in pulse systems.

The duration of such a transient response is determined by the order of the differential equation of the system's continuous portion [1, 2]. Finite-duration processes in pulse-amplitude systems with amplitude limitations were considered in [3, 4].

The present work is devoted to the investigation of finite-duration processes in pulse-width systems, where the pulse height is given, and the duration is limited by the repetition interval.

In order that the transient response terminate at some point of discrete time, t = *l* T, it is necessary that, at this moment, the error quantity and its first (n-1) derivatives, inclusive, equal zero, where n is the order of the differential equation describing the system's continuous portion. These conditions may be satisfied by the proper choice of the n durations of the pulses which act on the system up to the moment of time t = *l* T($l \geq n$). Thus, with a limited external stimulus, the transient response can terminate after n cycles of the pulsed (sampled-data) element, just as in sampled-data systems with amplitude modulation. We shall call such a process an n-cycle one. The problem of investigating a transient response of finite duration reduces to the determination of the form of this process and of its realization. In this work we derive the equations which define the indicators of such a process and, for a system described by a second-order equation, we present methods of realizing it. Experiments on a type MN-7 analog computer confirmed the results obtained, and showed that the complicated nonlinearities necessary for realizing finite-duration processes may be replaced by simple amplifiers.

Conditions for Finite Duration

We shall consider a control system which is comprised of a continuous portion and a pulse (sampled-data) element which carried out pulse-width modulation (Fig. 1) Let the continuous portion, which contains an integrating link, be described by a differential equation of the form

$$a_n z^{(n)}(t) + a_{n-1} z^{(n-1)}(t) + \cdots + a_1 z'(t) = y(t), \quad (1)$$

where z(t) is the system's output quantity and y(t) is the pulse element's output quantity. The operation of this latter element is described by the expression

$$y(t) = \begin{cases} k_p \operatorname{sign} \sigma(kT) \\ \quad \text{for } kT < t < kT + T\Omega[\sigma(kT)], \\ 0 \text{ for } kT + T\Omega[\sigma(kT)] < t < kT + T, \end{cases} \quad (2)$$

where σ(t) is the controlling stimulus and

$$\Omega(\sigma) = \begin{cases} \frac{1}{\varkappa}|\sigma| \text{ for } & |\sigma| < \varkappa, \\ 1 \quad \text{for} & |\sigma| > \varkappa. \end{cases} \quad (3)$$

It is clear from (2) and (3) that the pulse element is characterized by three parameters: the repetition interval T, the gain k_p and the sensitivity κ.

At the output of the comparator we shall have the quantity

$$x(t) = F(t) - z(t), \quad (4)$$

where F(t) is the external stimulus.

In the ordinary system, the controlling signal σ(t) equals this difference, i.e., σ(t) = x(t). We assume the external stimulus to be a step function.

In order that an n-cycle process occur in the system for a step-function stimulus of height B, it is necessary that the input quantity to the pulse element σ(t) at the discrete moments of time, 0, T, 2T, .., (n-1)T assume definite values σ(0), σ(T), ..., σ(nT-T) such that, at

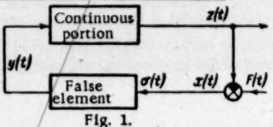

Fig. 1.

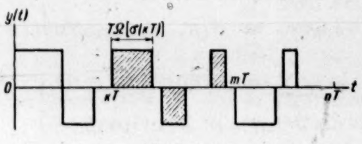

Fig. 2.

time t = nT, the system's output quantity $z(t)$ take the value β and its derivatives, up to and including the (n-1)-th, vanish. Thus, the input quantity y(t) of the continuous portion is a sequence of n rectangular pulses (Fig. 2) whose durations are determined from the conditions for a finite duration of the process:

$$z(nT) = \beta, \quad z^{(j)}(nT) = 0 \quad (j = 1, 2, \ldots, n-1). \tag{5}$$

We now express the $z^{(j)}(mT)$ (j = 0,1,2,...,n-1) in terms $z^{(j)}(kT)$ (j = 0,1,2,..,n-1), where m and k are arbitrary numbers, with n ≥ m > k ≥ 0. It is obvious that the quantities $z^{(j)}(mT)$ can be found as the reaction of the continuous portion to the sequence of rectangular pulses shown hatched on Fig. 2, with initial conditions $z^{(j)}(kT)$ (j = 0,1,2,...,n-1).

If we apply the Lapace transform [5] to (1) with the initial conditions given above, and solve the expression thus obtained with respect to the transform of the output quantity, i.e., with respect to Z(p), we find that

$$Z(p) = \sum_{i=0}^{n-1} A_i(p) z^{(i)}(kT) + K(p) Y_{km}(p),$$

where

$$A_i(p) = \frac{a_{i+1} + a_{i+2}p + \cdots + a_n p^{n-i-1}}{a_1 p + \cdots + a_n p^n},$$

$$K(p) = \frac{1}{a_1 p + \cdots + a_n p^n},$$

and $Y_{km}(p)$ is the transform of the hatched portion of the sequence of rectangular pulses (Fig. 2),

$$Y_{km}(p) = k_p \sum_{i=k}^{m-1} \operatorname{sign}[\sigma(iT)] e^{-pT(i-k)} \frac{1 - e^{-pT\Omega[\sigma(iT)]}}{p}.$$

Using the well-known rules [5] for finding the transforms of the derivatives, we get

$$L\{z^{(j)}(t)\} = \sum_{i=0}^{n-1} B_{ji}(p) z^{(i)}(kT) + \\ + k_p p^j K(p) \sum_{i=k}^{m-1} \operatorname{sign}[\sigma(iT)] e^{-pT(i-k)} \frac{1 - p^{-pT\Omega[\sigma(iT)]}}{p}, \tag{6}$$

where

$$B_{ji}(p) = \begin{cases} p^j \dfrac{a_{i+1} + a_{i+2}p + \cdots + a_n p^{n-i-1}}{a_1 p + \cdots + a_n p^n} & \text{for } j \leqslant i, \\ -p^{j-i-1} \dfrac{a_1 p + \cdots + a_i p^i}{a_1 p + \cdots + a_n p^n} & \text{for } j > i. \end{cases} \tag{7}$$

If we go from (6) to the time-domain function for t = =(m-k)T, we obtain the relationship connecting the quantity $z(t)$ and its derivatives at time t = mT with the quantity $z(t)$ and its derivatives at time t = kT.

$$z^{(j)}(mT) = \sum_{i=0}^{n-1} L^{-1}\{B_{ji}(p)\}_{t=(m-k)T} z^{(i)}(kT) + \\ + k_p \sum_{i=k}^{m-1} \operatorname{sign}[\sigma(iT)] \{h^{(j)}(mT - iT) - \\ - h^{(j)}(mT - iT - T\Omega[\sigma(iT)])\}, \tag{8}$$

where $h^{(j)}(t)$ is the jth derivative of the transient-response function of the system's continuous portion.

This last expression is necessary for us in our investigation of second-order systems. Here, we shall make use of it in order to express analytically the conditions for finite duration of transient response (5) for a system of any order. By setting m = n and k = 0 in (8), and by taking into account that $z^{(j)}(0) = 0$ (j = 0,1,2,..,n-1), we find that

$$k_p \sum_{i=0}^{n-1} \operatorname{sign}\sigma(iT) \{h(nT - iT) - \\ - h(nT - iT - T\Omega[\sigma(iT)])\} = \beta, \\ \sum_{i=0}^{n-1} \operatorname{sign}\sigma(iT) \{h^{(j)}(nT - iT) - \\ - h^{(j)}(nT - iT - T\Omega[\sigma(iT)])\} = 0 \\ (j = 1, 2, \ldots, n-1). \tag{9}$$

In order for an n-cycle process to be realized, the controlling stimuli $\sigma(t)$ must assume, at times 0,T,2T,..., (n-1)T, the values defined by (9). These equations are transcendental so that, just as in the case of relay systems, it is impossible, in the general case, to solve them for the $\sigma(iT)$ (i = 0,1,2,..,n-1) or to state a general method for realizing such a process. We therefore limit ourselves in the sequel to the consideration of special cases, specifically, to second-order systems.

Second-Order Systems

Let the continuous portion be described by the differential equation

$$T_1 z''(t) + z'(t) = ky(t).$$

By comparing this expression with (1), we note that

$$n = 2, \quad a_2 = \frac{T_1}{k}, \quad a_1 = \frac{1}{k}, \quad K(p) = \frac{k}{p(T_1 p + 1)},$$

from whence

$$h(t) = L^{-1}\left\{\frac{1}{p} K(p)\right\} = L^{-1}\left\{\frac{k}{p^2(T_1 p + 1)}\right\} = \\ = k\left[t - T_1\left(1 - e^{-\frac{t}{T_1}}\right)\right], \tag{10}$$

$$h'(t) = k\left(1 - e^{-\frac{t}{T_1}}\right). \tag{11}$$

If we take the inverse Laplace transform [5] of (7), we find that

$$L^{-1}\{B_{00}(p)\} = L^{-1}\left\{\frac{\frac{1}{k} + \frac{T_1}{k} p}{\frac{1}{k} p + \frac{T_1}{k} p^2}\right\} = 1[t], \tag{12}$$

$$L^{-1}\{B_{01}(p)\} = L^{-1}\left\{\frac{\frac{T_1}{k}}{\frac{1}{k} p + \frac{T_1}{k} p^2}\right\} = T_1\left(1 - e^{-\frac{t}{T_1}}\right), \tag{13}$$

$$L^{-1}\{B_{10}(p)\} = L^{-1}\{0\} = 0, \tag{14}$$

$$L^{-1}\{B_{11}(p)\} = L^{-1}\left\{p \frac{\frac{T_1}{k}}{\frac{1}{k} p + \frac{T_1}{k} p^2}\right\} = e^{-\frac{t}{T_1}}. \tag{15}$$

If we substitute (10) and (11) in (9) for n = 2, and carry out some elementary transformations, we can write the conditions for finite duration in the following form:

$$\operatorname{sign}\sigma(T)\left(e^{\frac{T}{T_1}\Omega[\sigma(T)]}-1\right)+ \\ +\operatorname{sign}\sigma(0)\left(e^{\frac{T}{T_1}\Omega[\sigma(0)]}-1\right)e^{-\frac{T}{T_1}}=0 \tag{16}$$

and, by virtue of (16),

$$x(0)=\beta=kk_pT\operatorname{sign}\sigma(T)\,\Omega[\sigma(T)]+ \\ +kk_pT\operatorname{sign}\sigma(0)\,\Omega[\sigma(0)]. \tag{17}$$

In accordance with (3), the parenthesized terms in (16) will be greater than zero and, in order that the left member of (16) equal zero, it is necessary that the quantities σ(T) and σ(0) have opposite signs. With this taken into account, we solve (16) for Ω[σ(T)] and substitute the expression thus obtained in (17). The result is

$$x(0)=N_0[\sigma(0)]=kk_pT\operatorname{sign}\sigma(0)\Big\{\Omega[\sigma(0)]- \\ -\frac{T_1}{T}\ln\left(e^{-\frac{T}{T_1}+\frac{T}{T_1}\Omega[\sigma(T)]}-e^{-\frac{T}{T_1}}+1\right)\Big\}, \tag{18}$$

Where the function Ω[σ(0)] is defined by (3). The inverse relationship, i.e.,

$$\sigma(0)=N_0^{-1}[x(0)], \tag{19}$$

is the relationship sought between the error x(t) and the input function σ(t) of the pulse element at time t = 0.

At time t = T, the relationship between x(T) and σ(T) has a different form. To find it, we use (8) for k=1 and m = n = 2, in which we substitute (10)-(15)for t = (m-k)T = T. If we substitute the values thus obtained for z(2T) and z'(2T), expressed in terms of z(T) and z'(T), in conditions (5) for finite duration, and solve the equations obtained with respect to z(T) and z'(T), we get

$$z(T)=\beta-kk_pT\operatorname{sign}\sigma(T)\times \\ \times\left\{\Omega[\sigma(T)]-\frac{T_1}{T}\left(e^{\frac{T}{T_1}\Omega[\sigma(T)]}-1\right)\right\}=\beta-N_1[\sigma(T)], \tag{20}$$

$$z'(T)=-kk_p\operatorname{sign}\sigma(T)\left(e^{\frac{T}{T_1}\Omega[\sigma(T)]}-1\right)= \\ =-N_2[\sigma(T)]. \tag{21}$$

By noting that, for β = const, x(T) = β -z(T) and x' (T) = -z'(T), we find from these expressions that x(T)= N₁ [σ (T)], x'(T) = N₂[σ(T)], or

$$\sigma(T)=N_1^{-1}[x(T)], \tag{22}$$

$$\sigma(T)=N_2^{-1}[x'(T)]. \tag{23}$$

Relationships (22) and (23) define the relationship between the values of the controlling function and the error, or the velocity of the error, at time t = T. It follows from (19), (22), and (23) that the output quantity of the controlling device can be given by the following two methods:

$$\sigma(t)=\begin{cases}N_0^{-1}[x(0)] & \text{for } t=0,\\ N_1^{-1}[x(T)] & \text{for } t=T\end{cases} \tag{24}$$

and

$$\sigma(t)=\begin{cases}N_0^{-1}[x(0)] & \text{for } t=0,\\ N_2^{-1}[x'(T)]=-N_2^{-1}[z'(T)] & \text{for } t=T.\end{cases} \tag{25}$$

In the intervals between the cycle times (the discrete time moments), σ (t) can assume arbitrary values.

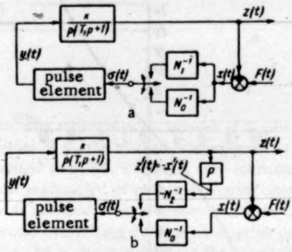

Fig. 3.

In accordance with (24) or (25), the controlling device is comprised of two nonlinear elements and a relay, which switches the error signal from one nonlinear element to the other (Fig. 3, and b). Realization (24) (Fig. 3, a) is worse than realization (25) (Fig. 3, b) since, if the external stimulus varies, not by jumps but arbitrarily, then at time t = T the comparator's output quantity in the first case will not correspond to a two-cycle process, and the system will not process in two cycles that stimulus which was measured for t = 0. In the second case (25) (Fig. 3,b), at cycle time t = T, control is effected by the velocity of the system's output quantity, and on this the variations of the external stimulus have no influence.

Example. As a numerical example, we consider a system in which the continuous portion is described by the differential equation

$$Z''+Z'=y(t),$$

i.e., T_1 = 1 sec, k = 1 and the pulse element has the following parameters: k_p = 20v, κ = 20v and T = 1 sec.

To this system, we apply the second variant of the realization of a finite-duration process. By substituting the parameter values given above for the continuous portion and the pulse element in Expressions (18) and (21), and by taking (3) into account, we find that

$$x(0)=N_0[\sigma(0)]= \\ =\begin{cases}\sigma(0)-20\operatorname{sign}\sigma(0)\ln\left(0{,}368\,e^{\frac{|\sigma(0)|}{20}}+0{,}632\right)\\ \qquad\qquad\text{for } |\sigma(0)|<20,\\ 10{,}3\operatorname{sign}\sigma(0) \qquad \text{for } |\sigma(0)|>20,\end{cases}$$

$$-Z'(T)=N_2[\sigma(T)]= \\ =\begin{cases}20\operatorname{sign}\sigma(T)\left(e^{\frac{|\sigma(T)|}{20}}-1\right) & \text{for } |\sigma(T)|<20,\\ 34{,}4\operatorname{sign}\sigma(T) & \text{for } |\sigma(T)|>20.\end{cases}$$

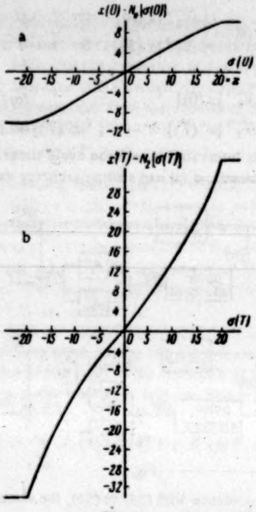

Fig. 4.

The graphs of the relationships $x(0) = N_0[\sigma(0)]$ and $-Z'(T) = N_2[\sigma(T)]$ are given on Fig. 4, a and b. For the realization of a two-cycle process with nonlinearities inverse to these, it is necessary to use control by the scheme shown in Fig, 3,b in the system.

It turned out, with empirical investigation on a model, that these nonlinearities can be replaced by amplifiers which roughly approximate them. It is clear with this that the saturation zone can be ignored, since the pulse element itself, according to (3), possesses saturation for values of the input signal $\sigma(t)$ which correspond to the onset of saturation in the nonlinearities N_0 and N_2. Thus, in the given example, the nonlinearities $N_0^{-1}[x(t)]$ and $N_2^{-1}[-Z'(t)]$, shown in Fig. 3,b can be replaced by amplifiers with gains approximately equal to 2.5 and 0.6 respectively.

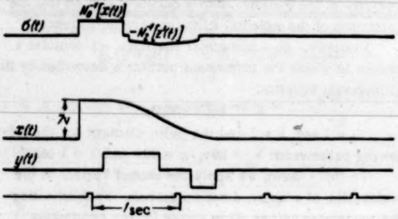

Fig. 5a.

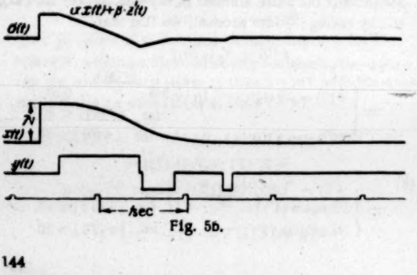

Fig. 5b.

Figure 5,a shows the oscillogram of the transient response of a finite-duration process in the system for a stimulus $F(t) = \beta \cdot 1[t] = 7v$, from which it is clear that the transient response terminates after two cycles of the pulse element, while the ordinary process continues for approximately six cycles. By using the standard linear-correction methods, for example, the introduction of derivative control, one can significantly improve the transient response, but this improved response will last longer than two cycles (Fig. 5,b).

In conclusion, we make several remarks about the behavior of such systems for large amplitudes of the external stimuli. From the oscillograms shown in Fig. 6,a and b, it is clear that, for $\beta = 15v$, the duration of the finite-duration transient response (Fig. 6,a) is comparable with the duration of the response in the system for which the relationship between stimulus magnitude and error velocity was selected in the very best way (Fig. 6,b). Thus, the method presented above for the realization of a two-cycle process becomes of little effect when the stimuli are large.

Equation (18) gives the relationship between the quantity which the system can process within two cycles, and the relative duration of the first corresponding pulse $\Omega[\sigma(0)]$, which cannot be greater than unity. Thus, the maximum amplitude of the external stimulus which the system can process in two cycles is determined by (18) for $\Omega[\sigma(0)=1$, i.e.,

$$x_{0\ \max} = kk_p T\left[1 - \frac{T_1}{T}\ln\left(2 - e^{-\frac{T}{T_1}}\right)\right]. \tag{26}$$

In our numerical example, $x_{0\ \max} = 10.3$. For $F(t) = \beta > x_{0\max}$, the system processes $x_{0\max}$ during the first two cycles and, during the next two cycles, the quantity $\beta - x_{0\ \max}$. If this latter quantity is less than x_0 max, the process terminates after four cycles, otherwise it continues for even longer. Figure 7,a shows the approximate form of such a transient response. As is clear from this figure, the response consists of a series of two-cycle processes. In this case, even the introduction of a simple combination of the quantity and its derivatives can result it an improved transient response. This, however, occurs only for $\beta > x_{0\max}$.

It follows from (26) that the magnitude of $x_{0\max}$ is proportional to the repetition period T. If $\beta > x_{0\ \max}$, then, to obtain an even shorter finite-duration process, it is necessary that the first pulse not terminate at time t = T, but continue even longer, i.e., the system must operate as if the repetition period were 2T, not T. The approximate form of such a process is shown on Fig. 7,b. The dashed lines on Fig. 7,a and b show the variations of the

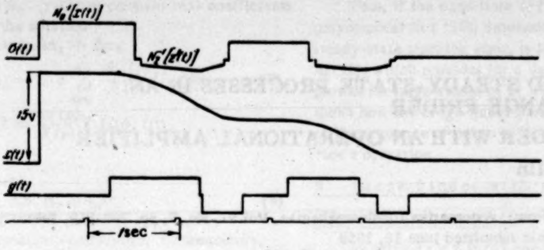

Fig. 6a.

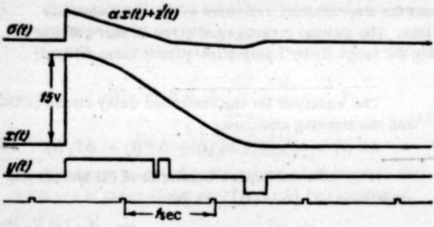

Fig. 6b.

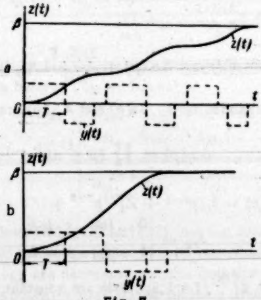

Fig. 7.

quantity y(t). The total duration of the first and second, and also the third and fourth, pulses can be determined from the same expressions as in the case when $\beta < x_{0\,\max}$ if, in them, one substitutes 2T instead of T. For even greater values of β, the system must operate as if the repetition period were 3T, 4T, etc., as β increases.

For the realization of such still shorter transient responses, it is necessary that the controlling device incorporate several controlling devices, similar to those shown on Fig. 3, a and b, but designed for the repetition periods T, 2T, 3T, 4T, etc. as a function of the maximum possible value of the external stimulus. The switching of one or another of the controlling devices into the system must be implemented as a function of the magnitude of the initial error x(0), which equals the external stimulating step β, and may be implemented by means of some supplementary device.

TRANSIENT AND STEADY-STATE PROCESSES IN AN AUTOMATIC RANGE FINDER

II. RANGE FINDER WITH AN OPERATIONAL AMPLIFIER

F. M. Kilin

(Leningrad)

(Translated from: Avtomatika i Telemekhanika, Vol.21, No. 2, pp. 209-219, February, 1960)
Original article submitted June 16, 1959

The dynamic properties of a range finder with an operational amplifier, including an integrating and an inertial link, are considered. In the general case, the investigation of the processes in a range finder with an operational amplifier, if with this one takes into account the step-function variations of the time-separator parameters, leads to cumbersom mathematical computations. The general investigation given in part I of this work [1] and the equations therein obtained for estimating the range finder's properties permit these difficulties to be avoided.

1. Properties of the Range Finder with an Operational Amplifier When It Is Investigated as a Continuous Automatic-Control System

An estimate of the effect of noise on a range finder of the simplest construction, not containing any operational amplifier, was given in [2]. In the present work, we start from the general-range-finder theory presented in [1]. Application of this theory to practically important concrete designs permits their dynamic properties to be estimated comparatively simply. We shall not treat the passage of random signals through the range finder in this paper.

In [1] we found the conditions under which the investigation of the processes in the range finder can be reduced to the investigation of processes in the continuous system described by (I.38)*. We shall assume here that these conditions are met†. We take a definite structure for the operational amplifier, for example, one for which (I.38) take the following form.

The equations for the time separator and the operational amplifier are

$$
\begin{gathered}
(D + a_{11}) U_1(t) = \frac{2K_0 E_s}{\tau_{10} T} \Delta\alpha(t), \\
a_{21} U_1(t) + (D + a_{22}) U_2(t) = 0, \qquad (1) \\
a_{31} U_1(t) + a_{32} U_2(t) + (D + a_{33}) U_3(t) = 0, \\
\dots\dots\dots\dots\dots\dots\dots\dots \\
\sum_{m=1}^{r-1} a_{rm} U_m(t) + (D + a_{rr}) U_r(t) = 0.
\end{gathered}
$$

The parameter a_{11} appertains to the time separator, and is expressed in terms of the time constants τ_{10} and τ_{11} by

$$a_{11} = \frac{\frac{\alpha}{\tau_{10}} + \frac{T-\alpha}{\tau_{11}}}{T}. \qquad (2)$$

The equations for the controlled delay circuit (CDC) and the tracking error are

$$\Delta\vartheta(t) = \sigma U_r(t), \quad \Delta\alpha(t) + \Delta\vartheta(t) = \Delta\vartheta_1(t). \qquad (3)$$

If we take the Lapace transforms of (1) and (3) and solve them for $L\{\Delta\alpha(t)\}$, we get

$$L\{\Delta\alpha(t)\} = \frac{\Delta a(p)}{X(p)} L\{\Delta\vartheta_1(t)\} - \sigma \sum_{k=1}^{r} \frac{A_{rk}(p) U_k(0)}{X(p)}, \qquad (4)$$

where

$$X(p) = \Delta a(p) + \frac{2\sigma K_0 E_s}{\tau_{10} T} A_{r1}(p). \qquad (5)$$

In expanded form, $\Delta a(p)$ and $A_{rk}(p)$ are given by

$$
\begin{gathered}
\Delta a(p) = \prod_{k=1} (p + a_{kk}), \\
A_{rk}(p) = \delta_{rk} p^{r-1} + Z_1^{(rk)} p^{r-2} + \dots + Z_{r-1}^{(rk)}, \qquad (6) \\
\delta_{rk} = \begin{cases} 0 & \text{for} \quad r \neq k, \\ 1 & \text{for} \quad r = k, \end{cases}
\end{gathered}
$$

where the $Z_j^{(rk)}$ $(j = 1, 2, \dots, r-1)$ are constant real coefficients.

The form of the operator function $X(p)$, defined by (5), depends on the structure of the element A_{r1}. In its expanded form, the expression for $A_{r1}(p)$ is given as

$$
A_{r1}(p) = (-1)^{r+1} \begin{vmatrix} a_{21}, & p + a_{22}, & 0, \dots, 0 \\ a_{31}, & a_{32}, & p + a_{33}, \dots, 0 \\ \dots & \dots & \dots \\ a_{r1}, & a_{r2}, & a_{r3}, \dots, a_{r,\,r-1} \end{vmatrix} =
$$

$$= Z_1 p^{r-2} + Z_2 p^{r-3} + \dots + Z_{r-1}, \qquad (7)$$

---

*The Roman numeral I in parentheses means that the formula numeration refers to part I of the given work.

† Cf. [1], section 9 and (I.44).

where the Z_j ($j = 1,2,\ldots,r-1$) are constant real coefficients.

We introduce the notation

$$\Delta\alpha = \Delta\alpha_1 + \Delta\alpha_2,$$

$$L\{\Delta\alpha_1(t)\} = -\sigma\sum_{k=1}^{r}\frac{A_{rk}(p)}{X(p)}U_k(0), \tag{8}$$

$$L\{\Delta\alpha_2(t)\} = \frac{\Delta a(p)}{X(p)}L\{\Delta\vartheta_1(t)\}.$$

We assume that

$$\Delta\vartheta_1(t) = \eta_s t^s, \tag{9}$$

where the η_s are constant coefficients. Consequently,

$$L\{\Delta\alpha_2(t)\} = s!\,\frac{\eta_s\Delta a(p)}{p^{s+1}X(p)}. \tag{10}$$

If the range finder is a stable system, then, for the steady-state mode, we obtain

$$\Delta\alpha_1 = 0,$$

$$\Delta\alpha_2(t) = s!\;\eta_s\sum_{k=0}^{s}\frac{G_k}{(s-k)!}t^{s-k},$$

$$G_k = \frac{1}{k!}\left[\frac{d^k}{dp^k}\frac{\Delta a(p)}{X(p)}\right]_{p=0}. \tag{11}$$

For large values of t, the greatest influence on the accuracy of range-finder operation will be manifested by the term

$$\Delta\alpha_{20}(t) = \eta_s G_0 t^s,\ G_0 = \frac{\prod\limits_{k=1}^{r} a_{kk}}{\prod\limits_{k=1}^{r} a_{kk} + \frac{2\sigma K_0 E_s}{\tau_{10}T}A_{r1}(0)}. \tag{12}$$

On the basis of (7), we have

$$A_{r1}(0) = (-1)^{r+1}\begin{vmatrix} a_{21}, & a_{22}, & 0, & \ldots, & 0 \\ a_{31}, & a_{32}, & a_{33}, & \ldots, & 0 \\ . & . & . & . & . \\ a_{r1}, & a_{r2}, & a_{r3}, & \ldots, & a_{r,\,r-1} \end{vmatrix} \tag{13}$$

It follows from (12) and (13) that the steady-state accuracy of the range finder will be increased if the coefficients a_{kk} are decreased and the quantity $A_{r1}(0)$ is increased. According to (13), the increase of $A_{r1}(0)$ can be achieved by means of the operational amplifier parameters a_{jk} for which $j \neq k$.

To see more graphically how the coefficients a_{kk} ($k = 1,2,\ldots,r$) affect tracking accuracy, we consider the case when the following equalities hold

$$a_{ii} = 0 \quad (i = r-\rho+1,\ r-\rho+2,\ \ldots,\ r). \tag{14}$$

For this case, in the steady state, we get

$$\Delta\alpha_2(t) = s!\;\eta_s\sum_{k=0}^{\nu}\frac{G_{\nu k}}{(\nu-k)!}t^{\nu-k},\quad \nu = s-\rho. \tag{15}$$

The coefficients $G_{\nu k}$ are found from the formulas

$$G_{\nu k} = \frac{1}{k!}\left[\frac{d^k}{dp^k}\frac{\Delta a_\rho(p)}{X(p)}\right]_{p=0},\ \Delta a_\rho(p) = \prod_{k=1}^{r-\rho}(p + a_{kk}). \qquad 16)$$

Thus, if the conditions of (14) hold, the degree of the polynominal in t (15), determining the magnitude of the steady-state tracking error, is lower by ρ units than that in (11), which provides for a decrease in the rate of error growth for large values of t. Formula (12) graphically shows how the range-finder parameters and the parameters of the sequence of pulses affect the accuracy of the device's operation.

2. Range Finder with a Simple-Integration Operational Amplifier

By setting $r = 2$ in (1) and (3), we obtain the equations for the range finder with the simplest operational amplifier:

$$\begin{gathered}(D + a_{11})U_1(t) = \frac{2K_0E_s}{\tau_{10}T}\Delta\alpha(t),\\ a_{21}U_1(t) + (D + a_{22})U_2(t) = 0,\end{gathered} \tag{17}$$

$$\Delta\vartheta(t) = \sigma U_2(t), \qquad \Delta\alpha(t) + \Delta\vartheta(t) = \Delta\vartheta_1(t).$$

We shall be interested only in the component $\Delta\alpha_2$. We assume that the translation of the return pulses from the object is described by the function

$$\Delta\vartheta_1(t) = \begin{cases}0 & \text{for } t \leqslant 0,\\ \eta_0 + \eta_1 t & \text{for } t > 0,\end{cases} \tag{18}$$

where η_0 and η_1 are constants.

By solving (17) with (18) taken into account, we obtain the expression for $\Delta\alpha_2(t)$:

$$\Delta\alpha_2(t) = \eta_0\left[G_0 + \sum_{k=1}^{2}S_k e^{\mu_k t}\right] + \tag{19}$$

$$+\ \eta_1\left[G_0 t + G_1 + \sum_{k=1}^{2}\frac{S_k}{\mu_k}e^{\mu_k t}\right].$$

The coefficients G_k and S_k are found, respectively, from the formulas

$$G_0 = \frac{a_{11}a_{22}}{X_2},\ G_1 = -\frac{2\sigma K_0E_s a_{21}(a_{11} + a_{22})}{\tau_{10}TX_2^2}, \tag{20}$$

$$S_k = \frac{\Delta a(\mu_k)}{\mu_k X'(\mu_k)} \quad (k = 1, 2),$$

where

$$X'(\mu_k) = \left\{\frac{d}{dp}X(p)\right\}_{k=\mu_k}. \tag{21}$$

Here,

$$\begin{gathered}X(p) = p^2 + X_1p + X_2,\quad X_1 = a_{11} + a_{22},\\ X_2 = a_{11}a_{22} - \frac{2\sigma K_0E_s}{\tau_{10}T}a_{21}.\end{gathered} \tag{22}$$

The parameters μ_1 and μ_2 are the roots of the characteristic equation

$$X(\mu) = 0.$$

If the range finder is a stable system, then, for the steady state, (19) takes the simple form:

$$\Delta\alpha_2(t) = G_0[\eta_0 + \eta_1 t] + \eta_1 G_1. \tag{23}$$

The function $\Delta \vartheta_1(t)$ is related to the function $R(t) = R_0 = R_1 t$ which describes the motion of the object with respect to the radar set. This relationship is expressed by

$$\Delta\vartheta_1(t) = \frac{2R(t)}{c},$$

where c is the velocity of propagation of electromagnetic waves.

Consequently, (23) can be rewritten in the form:

$$\Delta\alpha_2(t) = \frac{2G_0}{c}[R_0 + R_1 t] + \frac{2R_1 G_1}{c}. \tag{24}$$

The value of $\Delta\alpha_2$ corresponds to an error in the radius

$$\Delta R(t) = \frac{c\Delta\alpha_2(t)}{2} = G_0[R_0 + R_1 t] + R_1 G_1. \tag{25}$$

If there are very limited possibilities for decreasing the rate of error growth in the range-finder with a simple amplifier, such limitations do not exist in the given scheme. It follows from (19), (20), and (24) that, if a_{22} tends to zero, one can attain an arbitarily small value for the quantity $2G_0R_1/c$ which characterizes the rate of growth of the error. For $a_{22} = 0$, when the operational amplifier becomes a straight integrator, the following relationships hold:

$$X_2 = -\frac{2\sigma K_0 E_3 a_{21}}{\tau_{10}T}, \quad G_0 = 0, \quad G_1 = \frac{a_{11}}{X_2},$$

i.e., for the steady state, (24) in the given case takes the form:

$$\Delta\alpha_2 = -\frac{R_1 a_{11}\tau_{10}T}{\sigma K_0 E_3 a_{21} c}. \tag{26}$$

To guarantee stability of operation, one must give a positive value to the parameter X_2, i.e., $X_2 > 0$ or $a_{21} > 0$.

According to (26), when $a_{22} = 0$ the tracking error in the steady state is proportional to a_{11}, the parameter of the time separator. The value of this parameter is chosen in accordance with the conditions which guarantee reliable operation of the time separator. As shown by (2), to decrease parameter a_{11} it is necessary to increase both time constants τ_{22} and τ_{11}, which is not always possible. Thus, even if the translations of the return pulses follow (18), the range finder now under consideration has essential disadvantages. In it, the tracking accuracy is limited by the possibilities of decreasing parameter a_{11} of the time separator.

Parameter a_{11} also imposes limitations on the character of the range finder's transient response. In fact, for s = 2, $a_{22} = 0$ and a given value of a_{11}, there remains at our disposal just the one variable parameter a_{21}, which is related to X_2 by the equation

$$X_2 = -\frac{2\sigma K_0 E_3}{\tau_{10}T} a_{21}. \tag{27}$$

In view of the fact that the device is described by a second-order differential equation, it is necessary to have at least two variable parameters. The presence of only one of them entails this, that for $X_2 > a_{11}^2/4$, the roots of the characteristic equation assume complex values, and the tracking system goes into a mode of damped oscillation. With this, the lower the value of a_{11}, the lower the values of X_2 for which this transition occurs. From this point of view, it is well to have a large value of a_{11}, which may be obtained by decreasing the time constants τ_{22} and τ_{11} (and not increasing them, as was required above).

To decrease the steady-state error, it is required to give a large value to the quantity X_2. However, for large values of X_2, the oscillatory process will be characterized by an inadmissibly large overshoot. This is shown by the example, given in the Appendix, of the given range-finder scheme.

Structure of an Operational Amplifier Providing Changes in the Range-Finder's Dynamic Properties

It was previously shown that an increase of the parameter X_2 leads to an oscillatory transient response with a large overshoot. This imposes a limitation on the choice of values for X_2. It also limits the possibilities of decreasing the tracking error in the transient and steady states. We now show that such limitations, and to a large degree, also appear when an operational amplifier with multiple integration is connected in the range finder; due to these limitations, the effectiveness of employing such an amplifier in similar devices is significantly decreased. We now write the characteristic equation of (5) in expanded form. By setting $a_{ii} = 0$ (i = 2,3,..,r) in (5), we get

$$\Delta a(p) = p^{r-1}(p + a_{11}), \tag{28}$$

$$X(p) = p^r + X_1 p^{r-1} + \dots + X_{r-1}p + X_r = 0. \tag{29}$$

The coefficients X_k are found from the formulas

$$X_1 = a_{11},$$

$$X_k = \frac{2\sigma K_0 E_3}{\tau_{10}T} Z_{k-1} \quad (k = 2, 3, \dots, r). \tag{30}$$

In their turn, the quantities $Z_1, Z_2, \dots, Z_r$ are determined from (6) in terms of the operational amplifier's parameters a_{jk} (j = 2,3,...,r; k = 1,2,...,j).

In the case under consideration, the operational-amplifier implements an s-fold integration. With this, the quantity s is related to r by the equation s = r-1.

The character of the transient response depends on the roots of characteristic equation (29). If it is possible to vary, within wide limits, all the coefficients X_k of (29), this will thereby provide the necessary conditions for changing the character of the tracking system's transient response. These possibilities are easily established, on the basis of (30).

Since the coefficients $X_2, X_3, \dots, X_r$ depend on the operational amplfier's parameters, they admit variations within quite broad limits. This can not be said, however, of coefficient $X_1 = a_{11}$, the magnitude of which is determined by the parameter a_{11} of the time separator. As has already been stated, the possibilities of varying this parameter are limited.

On the other hand, the coefficients X_k may be expressed as follows:

$$X_1 = \sum_{k=1}^{r} M_k,$$

$$X_2 = M_1 \sum_{k=2}^{r} M_k + M_2 \sum_{k=3}^{r} M_k + \cdots + M_{r-1} M_r, \tag{31}$$

$$\cdots\cdots\cdots\cdots\cdots\cdots$$

$$X_r = M_1 M_2 \ldots M_r.$$

Here,

$$M_k = -\mu_k \quad (k = 1, 2, \ldots, r) \tag{32}$$

Consequently,

$$a_{11} = \sum_{k=1}^{r} M_k = \sum \operatorname{Re} M_k. \tag{33}$$

Thus, if it is necessary to improve the transient response by increasing the real parts of the roots μ_k then, according to (33), it is necessary to increase the value of parameter a_{11}. In the case of multiple roots,

$$M = M_1 = M_2 = \cdots = M_r$$

Formula (33) takes the simplier form: $a_{11} = rM$, or $a_{11} = (s+1)M$, i.e., it is required to provide a greater value for the parameter a_{11}, the greater the multiplicity s of integration in the operational amplifier and the greater the necessary magnitude of the quantity M.

The basic disadvantage of the scheme under consideration is that it is not possible in practice to provide the variation in the time separator's parameter a_{11} which is required for improving the transient response in the automatic range finder. We now show that this disadvantage is eliminated if we use a different operational-amplifier scheme, for example, one for which the processes are described by the equations:

$$\begin{gathered}
(D + a_{11}) U_1(t) = \frac{2K_0 E_s}{\tau_{10} T} \Delta\alpha(t), \\
a_{21} U_1(t) + (D + a_{22}) U_2(t) = 0, \\
a_{31} U_1(t) + a_{32} U_2(t) + (D + a_{33}) U_3(t), \\
\cdots\cdots\cdots\cdots\cdots\cdots \\
\sum_{k=1}^{r-1} a_{rk} U_k(t) + (D + a_{rr}) U_r(t) = 0, \\
\sum_{k=1}^{r} a_{r+1,k} U_k(t) + U_{r+1}(t) = 0.
\end{gathered} \tag{34}$$

Equations (34) can be obtained from (1) by adding

$$U_{r+1} = -\sum_{k=1}^{r} a_{r+1,k} U_k,$$

which expresses the simple amplification of the signals U_k with gains proportional to the coefficients $a_{r+1,k}$, with summation of the results. For (34) we find

$$\begin{gathered}
\Delta a(D) = \prod_{k=1}^{r} (D + a_{kk}), \; A_{r+1,1}(D) = \\
= Z_0' D^{r-1} + Z_1' D^{r-2} + \cdots + Z_{r-2}' D + Z_{r-1}'.
\end{gathered} \tag{35}$$

The equations for the controlled delay circuit and the tracking error when the operational amplifier described by (34) is connected in the device are written in the form

$$\Delta\vartheta(t) = \sigma U_{r+1}(t), \; \Delta\alpha(t) + \Delta\vartheta(t) = \Delta\vartheta_1(t). \tag{36}$$

Taking the Laplace transforms of (34) and (36), and solving them for $L\{\Delta\alpha(t)\}$, we obtain

$$\begin{gathered}
L\{\Delta\alpha_1(t)\} = -\sigma \sum_{k=1}^{r} \frac{A_{r+1,k}(p)}{X(p)} U_k(0), \\
L\{\Delta\alpha_2(t)\} = \frac{\Delta a(p)}{X(p)} L\{\Delta\vartheta_1(t)\}, \\
\Delta\alpha_1 + \Delta\alpha_2 = \Delta\alpha.
\end{gathered} \tag{37}$$

For $a_{ii} = 0$ $(i = 2, 3, \ldots, r)$, we have

$$\begin{gathered}
\Delta a(p) = p^{r-1}(p + a_{11}), \\
X(p) = p^r + X_1 p^{r-1} + X_2 p^{r-2} + \cdots + X_r, \\
X_1 = a_{11} + \frac{2\sigma K_0 E_s}{\tau_{10} T} Z_0', \\
X_k = \frac{2\sigma K_0 E_c}{\tau_{10} T} Z_{k-1}' \quad (k = 2, 3, \ldots, r).
\end{gathered} \tag{38}$$

Here, all the coefficients $X_1, X_2, \ldots, X_r$ depend on the operational amplifier's parameters. Consequently, it is not required to vary the parameter a_{11} in changing from one mode of operation to another, since this transition may be effected by a corresponding change of the operational amplifier's parameters. When an operational amplifier of the type described by (34) is used, the parameter a_{11} is not profitably increased, as was required in the examples given earlier, but, conversely, should be decreased, since the steady-state error is the lower, the smaller the value of a_{11}.

4. Automatic Range Finder with Double Integration Operational Amplifier

In using an operational amplifier with a double integration, the processes of which are described by (34), the automatic range finder's equations are written in the form

$$\begin{gathered}
(D + a_{11}) U_1(t) = \frac{2K_0 E_s}{\tau_{10} T} \Delta\alpha(t), \\
a_{21} U_1(t) + (D + a_{22}) U_2(t) = 0, \\
a_{31} U_1(t) + a_{32} U_2(t) + (D + a_{33}) U_3(t) = 0, \\
a_{41} U_1(t) + a_{42} U_2(t) + a_{43} U_3(t) + U_4(t) = 0, \\
\Delta\vartheta(t) = \sigma U_4(t), \\
\Delta\alpha(t) + \Delta\vartheta(t) = \Delta\vartheta_1(t).
\end{gathered} \tag{39}$$

We shall be interested below only in the component $\Delta\alpha_2$. Taking the Laplace transform of (39), we get

$$L\{\Delta\alpha_2(t)\} = \frac{\Delta a(p)}{X(p)} L\{\Delta\vartheta_1(t)\}. \quad (40)$$

Here, $\Delta a(p) = (p + a_{11})(p + a_{22})(p + a_{33})$,

$$X(p) = p^3 + X_1p^2 + X_2p + X_3,$$

$$X_1 = a_{11} + a_{22} + a_{33} + \varepsilon Z'_0,$$

$$X_2 = a_{11}(a_{22} + a_{33}) + a_{22}a_{33} + \varepsilon Z'_1, \quad (41)$$

$$X_3 = a_{11}a_{22}a_{33} + \varepsilon Z'_2,$$

$$\varepsilon = \frac{2\alpha_0K_0E_c}{\tau_{10}T}.$$

The coefficients Z'_0, Z'_1 and Z'_2 are found from the equations

$$Z'_0 = -a_{41},$$

$$Z_1 = a_{21}a_{42} + a_{31}a_{43} - a_{41}(a_{22} + a_{33}), \quad (42)$$

$$Z'_2 = a_{31}a_{22}a_{43} + a_{21}(a_{33}a_{42} - a_{32}a_{43}) - a_{41}a_{22}a_{33}.$$

We set

$$\Delta\vartheta_1(t) = W_1t + \frac{1}{2}W_2t^2, \ R(t) = R_1t + \frac{1}{2}R_2t^2 \quad (43)$$

or

$$\Delta\vartheta_1(t) = \frac{2R(t)}{c} = \frac{2R_1}{c}t + \frac{R_2}{c}t^2, \quad (44)$$

where c is the velocity of propagation of electromagnetic waves. The function R(t) describes the translation of the object with respect to the radar set.

Going to the time-domain function corresponding to (40) while taking (44) into account, we find, for the steady state,

$$\Delta\alpha_2(t) = \frac{2R_1}{c}f_1(t) + \frac{R_2}{c}f_2(t),$$

$$f_1(t) = G_{10}t + G_{11}, \quad (45)$$

$$f_2(t) = \frac{G_{20}}{2!}t^2 + \frac{G_{21}}{1!}t + G_{22}, \quad (t > t_0),$$

where t_0 is the quantity defining the duration of the transient response.

The coefficients G_{1k} and G_{2k} are found from the formulas

$$G_{ik} = \frac{1}{k!}\left\{\frac{d^k}{dp^k}\frac{\Delta a(p)}{X(p)}\right\}_{p=0} \quad (i = 1, 2). \quad (46)$$

If we set $a_{22} = a_{33} = 0$, we obtain

$$f_1(t) = 0, \ f_2 = \frac{2a_{11}}{X_2}. \quad (47)$$

The most favorable conditions for increasing tracking accuracy occur when $a_{22} = a_{33} = 0$, when the operational amplifier acts simply as a double integrator.

Appendix

Example 1. To determine the transient response and the magnitude of the steady-state tracking error for the following automatic range-finder data: pulse-repetition frequency F = 500 $\sec^{-1}$, duration of the return pulses from the object $\alpha = 2 \cdot 10^{-6}$ sec, length of the tracking pulses $\alpha_0 = 3 \cdot 10^{-6}$ sec, $K_0E_3 = 60$v, $\tau_{10} = 2 \cdot 10^{-4}$ sec, $\tau_{11} = \infty$, the operational amplifier is an integrator, i.e., $a_{22} = 0$. The object moves relative to the radar set with a constant velocity of $R_1 = 300$m/sec.

In correspondence with (2), we find that

$$a_{11} = \frac{\alpha}{T\tau_{10}} = 5 \sec.^{-1}, \ T = \frac{1}{F} = 0{,}002 \text{ sec}$$

The computational results are given in the first table:

The table fives the steady-state values of $\Delta\alpha_2$ and ΔR. In addition, we have computed the values of the roots μ_1 and μ_2, from which one may derive a representation of the character of the transient response in the tracking system. The table also gives the values of the quantities

$$\rho_1T = |\operatorname{Re}\mu_1T|, \quad \rho_2T = |\operatorname{Re}\mu_2T|,$$

$$\varphi T = |\operatorname{Im}\mu_1T| = |\operatorname{Im}\mu_2T|, \quad (48)$$

from which one may judge if (I.44) hold, as they do in the example under consideration.

As we can see, for $a_{11} = 5 \sec^{-1}$, there ensues a damped oscillatory mode when $X_2 > 6.25 \sec^{-2}$. Figure 1 shows a graph of the transient response for the case when $X_2 = 16.12 \sec^{-2}$ and $X_2 = 45.73 \sec^{-2}$. The first case corresponds to the roots $\mu_{1,2} = 2.5 \pm i\pi$, the second to the roots $\mu_{1,2} = 2.5 \pm i2\pi$.

For $X_2 = 16.12 \sec^{-2}$, the overshoot reaches approximately 24%; as the result of this, the maximum error reaches 105m and, in the steady-state, 93m. For $X_2 = 45.73 \sec^{-2}$, the overshoot reaches a significant size - about 69%. Transient responses with such overshoots are inadmissible.

We note in conclusion that the tracking error must not exceed $|\Delta\alpha| < \alpha_0$. If $|\Delta\alpha| \geq \alpha_0$, the return pulses from the object fall beyond the limits of the tracking pulses, and normal operation of the range finder is disrupted. From this point of view, the mode of operation with $X_2 = 2.25 \sec^{-2}$ can not actually exist.

Example 2. To determine the transient response and the steady-state tracking error of an automatic range finder with one integrator for the following data: F = 500 $\sec^{-1}$, $\alpha = 2 \cdot 10^{-6}$ sec, $\alpha_0 = 3 \cdot 10^{-6}$ sec, $\tau_{10} = 10^{-4}$ sec, $\tau_{11} = \infty$; $R_1 = 300$m/sec.

This example differs from the previous one in that the time constant τ_{10} has half the value it previously did. Determining the value of the parameter a_{11}, we find that

$$a_{11} = \frac{F\alpha}{\tau_{10}} = 10 \sec^{-1},$$

the increased value of a_{11} creating more favorable conditions for improving the transient response. Figure 1 shows the graph of the transient response for $X_2 = 50 \sec^{-2}$ For this value of X_2, the overshoot is about 7%, i.e., is significantly less than in the case with $X_2 = 45.73 \sec^{-2}$, considered in Example 1.

X_2, sec $^{-2}$	μ_1, sec $^{-1}$	μ_2, sec $^{-1}$	ρ_1T	ρ_2T	φT	$\Delta\alpha_2$, sec	ΔR, м
2,25	−0,5	−4,5	0,001	0,009	0	$4 \cdot 10^{-6}$	600
5,25	−1,5	−3,5	0,003	0,007	0	$1,9 \cdot 10^{-6}$	285
6,25	−2,5	−2,5	0,005	0,005	0	$1,6 \cdot 10^{-6}$	240
10,25	$-2,5+i2$	$-2,5-i2$	0,005	0,005	0,004	$0,98 \cdot 10^{-6}$	147
15,25	$-2,5+i3$	$-2,5-i3$	0,005	0,005	0,006	$0,66 \cdot 10^{-6}$	100

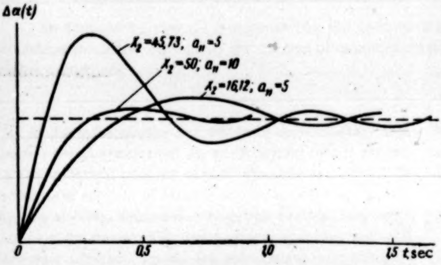

Fig. 1.

Example 3. To determine the parameters of the operational amplifier with a double integrator which provides equal values for all the roots of the characteristic equation, and to find the steady-state tracking error in the region $\Delta\alpha \lesssim 0.1\,\alpha$ as the object moves relative to the radar set with a constant acceleration of $\ddot{R}_2 = 3g = 30 \text{m/sec}^2$. The automatic range-finder data are: $F = 400 \text{sec}^{-1}$, $\alpha = 10^{-6}$-sec, $KE_3 = 60$v, $\sigma = 0.5 \cdot 10^{-6}$ sec/v. The computations are carried out for two cases: a) $\tau_{10} = 2 \cdot 10^{-4}$sec, $\tau_{11} = \infty$; b) $\tau_{10} = 2 \cdot 10^{-3}$sec, $\tau_{11} = \infty$.

The steady-state error is determined from the formula

$$\Delta\alpha = \Delta\alpha_2 = \frac{2R_2 a_{11}}{cX_3}. \tag{49}$$

The inequality $|\Delta\alpha| \geq 0.1\,\alpha$ will hold if

$$X_3 \geqslant X_{30} = \frac{2R_2 a_{11}}{0,1\,\alpha c} = \frac{2R_2 F}{0,1 c\tau_{10}}. \tag{50}$$

In finding the numerical value of X_{30} for cases "a" and "b", we get

$$X_{30} = \begin{cases} 4\,\dfrac{1}{\text{sec}^3} & \text{for} \quad \tau_{10} = 2 \cdot 10^{-4}\,\text{sec} \\ 0,4\,\dfrac{1}{\text{sec}^3} & \text{for} \quad \tau_{10} = 2 \cdot 10^{-3}\,\text{sec}. \end{cases}$$

We now determine the operational amplifier's parameters for the value $X_3 = 1.5X_{30}$. For this, we compute the value of ϵ in (41). By substituting numerical values, we get

$$\varepsilon = \begin{cases} 120\,\dfrac{1}{\text{sec}} & \text{for} \quad \tau_{10} = 2 \cdot 10^{-4}\,\text{sec} \\ 12\,\dfrac{1}{\text{sec}} & \text{for} \quad \tau_{10} = 2 \cdot 10^{-3}\,\text{sec}. \end{cases}$$

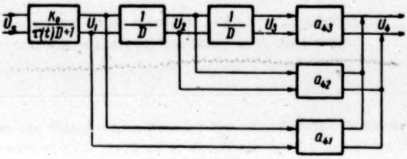

Fig. 2.

τ_{10}, sec	a_{41}	a_{42}	a_{43}
$2 \cdot 10^{-4}$	−0,03	0,08	−0,05
$2 \cdot 10^{-3}$	−0,20	0,18	−0,05

For the case of multiple roots, we have $\mu_1 = \mu_2 = \mu_3 = -M$. For this, the coefficients X_1, X_2, and X_3 are related to M by the equations

$$X_1 = 3M, \qquad X_2 = 3M^2, \qquad X_3 = M^3. \tag{51}$$

In the given example, the magnitude of M is found from

$$M = \sqrt[3]{15\,X_{30}} \approx \begin{cases} 1,82 \text{ sec}^{-1} & \text{for} \quad X_{30} = 4 \quad \text{sec}^{-3}, \\ 0,85 \text{ sec}^{-1} & \text{for} \quad X_{30} = 0,4 \text{ sec}^{-3}. \end{cases}$$

On the basis of (41) we have

$$\begin{gathered} a_{11} + a_{22} + a_{33} + \varepsilon Z_0' = 3M, \\ a_{11}(a_{22} + a_{33}) + a_{22}a_{33} + \varepsilon Z_1' = 3M^2, \\ a_{11}a_{22}a_{33} + \varepsilon Z_2' = M^3. \end{gathered} \tag{52}$$

By substituting $a_{22} = a_{33} = 0$ in Eqs. (42) and (52), and then substituting the values of Z'_0, Z'_1, and Z'_2 from (42) and (52), we get

$$\begin{gathered} a_{41} = \frac{a_{11} - 3M}{\varepsilon}, \quad a_{31}a_{43} + a_{21}a_{42} = \frac{3M^2}{\varepsilon}, \\ a_{21}a_{32}a_{43} = -\frac{1,5\,X_{30}}{\varepsilon}. \end{gathered} \tag{53}$$

We have at our disposal six variable parameters of the operational amplifier, these being related to M and X_{30} by the three equations of (53). Consequently, three of the six parameters can be given arbitrary values. For example, by setting $a_{21} = a_{32} = 1$, $a_{31} = 0$, we get

$$\begin{gathered} a_{41} = \frac{a_{11} - 3M}{\varepsilon}, \quad a_{42} = \frac{3M^2}{\varepsilon}, \\ a_{43} = -\frac{1,5\,X_{30}}{\varepsilon} = -\frac{1,5\,R_2}{0,1\sigma c K_0 E_3}. \end{gathered} \tag{54}$$

The structure of the time separator and the operational amplifier for the given case reduce to the scheme shown in Fig. 2. This scheme deserves attention, since its technological implementation is comparatively simple.

The results of the computations using (54) are given in the second table.

DETERMINATION OF THE SECOND-ORDER MOMENTS OF VARIOUS COORDINATES OF AUTOMATIC-CONTROL SYSTEMS BY THE USE OF ELECTRONIC ANALOG COMPUTERS*

L. A. Tel'ksnis

(Vil'nyus)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 2, pp. 220-223, February, 1960)

Original article submitted September 29, 1959

An engineering method is presented for the determination of second-order moments of various coordinates of automatic-control systems by the method of canonical representations of random functions, using electronic analog computers.

In the investigation and design of contemporary automatic-control systems (ACS), an important role is played by the statistical analysis of their dynamic accuracy. The taking into account of random factors is necessary in designing aircraft, automatic-navigation devices, ship-roll dampers, for determining radar-system accuracy and artillery-gear accuracy, for solving information-processing problems, for designing modern drilling equipment, coal-mining machines, automobile suspension systems, etc.

Analytical methods of determing second-order moments of various ACS variables [1-3], due to the large volume of complicated analytical computations and transformations they entail, can be used in engineering calculations only for solving the most elementary problems.

The method of physical simulation of random processes, using electronic analog computers for ACS statistical analysis [3] can be used only for the solution of a narrow class of stationary problems.

The methods of mathematical simulation of random processes, using electronic computers [2, 3], although they theoretically permit one to solve stationary and nonstationary problems of ACS statistical analysis, are very cumbersome to use in practice because of the large amount of complicated analytical computation and transformation which must be carried out in the preparation of the solution as well as in the solution process itself.

For the creation of a practical method of computing second-order moments of various ACS coordinates, it is advantageous to use the canonical representation of random functions [1, 6]

$$X(t) = \sum_{\nu=1}^{\infty} V_\nu x_\nu(t), \tag{1}$$

where the V_ν are the random, mutually uncorrelated coefficients of the canonical expansion, with dispersions D_ν, and the $x_\nu(t)$ are the canonical expansion's nonrandom coordinate functions.

Thanks to the introduction of the concept of normalized coordinate functions

$$x_\nu^*(t) = D_\nu^{\frac{1}{2}} x_\nu(t) \tag{2}$$

one can obtain expressions for the second-order moments of various ACS coordinates which are readily amenable to computation by uncomplicated special-purpose electronic computers. We now write these expressions:

a) for the output dispersion

$$D_y(t) = \sum_{\nu=1}^{\infty} y_\nu^{*2}(t); \tag{3}$$

b) for the output correlation (autocorrelation) function

$$K_y(t, \tau) = \sum_{\nu=1}^{\infty} y_\nu^*(t)\, y_\nu^*(\tau); \tag{4}$$

c) for the cross-correlation function of the input and output variables at a given moment of time

$$D_{xy}(t) = \sum_{\nu=1}^{\infty} x_\nu^*(t)\, y_\nu^*(t); \tag{5}$$

d) for the cross-correlation function of the input and output variables

$$K_{xy}(t, \tau) = \sum_{\nu=1}^{\infty} x_\nu^*(t)\, y_\nu^*(\tau). \tag{6}$$

Here, y_ν^* (t) is the solution of the differential equation

$$L(p, t)\, y_\nu^*(t) = M(p, t)\, x_\nu^*(t) \quad (\nu = 1, 2, \ldots), \tag{7}$$

and the expressions

$$L(p, t) = \sum_{i=0}^{n} a_i p^i, \quad M(p, t) = \sum_{j=0}^{m} b_j p^j,$$

$$p \equiv \frac{d}{dt}, \; m < n,$$

are the operators of the differential equation which describes the automatic-control system being investigated.

By using Relationships (3) - (6), one can construct a computer for the statistical analysis of an ACS which makes it possible to determine the second-order moments

*This paper was given at the All-Union Conference on Computational Mathematics and Computational Technology, at Moscow in 1959

† On the computation of normalized coordinate functions, Cf. [6].

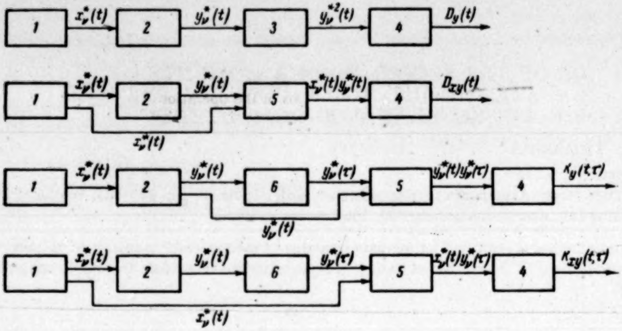

Fig. 1

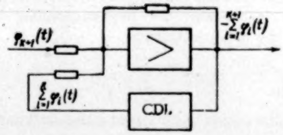

Fig. 2 Principal diagram of special adder.

of various coordinates of the ACS as it is acted on by random disturbances, basing the calculations solely on regular signals, namely, normalized coordinate functions.† Such a device is a special-purpose automatic electronic analog computer. Figure 1 shows the block diagram for a computer designed to determine second-order moments. It contains the following basic blocks: 1 is the block for the memory and for the program control of the computation, 2 is the electronic model of the ACS being investigated, 3 is a squaring device, 4 is a specialized adder, 5 is a multiplier, 6 is a device for introducing delays. The devices used in the computer for squaring, multiplying and introducing delays are standard functional blocks used in electronic simulation [4]. The memory and control block allows input of information (normalized coordinate functions $x_\nu^*(t)$ and the program for controlling the computation) which is written on magnetic tape. For solving (7), the electronic model of the investigated ACS is used. Summation of the series is implemented by means of a special adder (Fig. 2), which is a dc amplifier, operating as a scale amplifier, with additional feedback in the form of a controlled delay line (CDL).

It takes several minutes, on the average, to compute the output dispersion or the cross-correlation function of the ACS's input and output variables on such a machine. It takes some tens of minutes to determine the output autocorrelation function and the ACS's output variable.

Example. As an example, we consider the problem of determining the dispersion of the output coordinate ψ of an ACS during the transient response, when random disturbances act on it. The equations of the system, consisting of object plus controller, are written in the form:

$$\begin{aligned} \omega &= \dot{\psi}, \\ \omega &= a_1\omega - a_2\beta - a_3\delta + X(t) \\ \dot{\beta} &= \omega + a_4\beta + a_5\delta, \\ \dot{\delta} &= \frac{1}{T}\left[i(\psi + \mu\omega)\right] - \delta. \end{aligned} \tag{8}$$

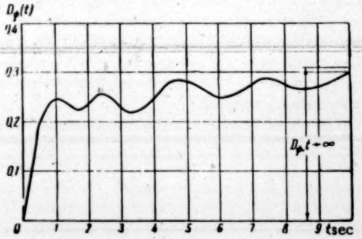

Fig. 3. Curve of the dispersion of the output coordinate ψ of the ACS described by differential equations (8).

Calculation of the dispersion $D_\psi(t)$ of the ACS's output coordinate ψ for $0 \le t \le T = 10$ sec, when the random disturbance $X(t)$ with correlation function $K_x(t,\tau) = \exp(-|t-\tau|)$ acts on it, was implemented in accordance with the block schematic (the first line thereof) shown on Fig. 1. With this, ten terms of the canonical representation of the random disturbance $X(t)$ [6] were taken into account. The time for the computation was 110 sec. Figure 3 gives the curve for the dispersion $D_\psi(t)$.

What has been presented here shows that the use of canonical representations of random disturbances, electronic models of the system being investigated, and additional uncomplicated electronic computing hardware make it possible to find, quite simply from the point of view of engineering practice, the second-order moments of various coordinates of a broad class of automatic-control systems.

FINITE AUTOMATA. I

M. A. Aizerman, L. A. Gusev, L. I. Rozonoér,
I. M. Smirnóva, and A. A. Tal'
(Moscow)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 2, pp. 224-236, February, 1960)
Original article submitted June 10, 1959

The views of the authors are presented on the basic content and problem areas of the theory of finite automata and on the interrelationships of this theory with the theory of relay-contact circuits; also considered are the possible ways of realizing finite automata.

INTRODUCTION

As soon as it became clear that the propositional calculus was adequate for the technical problems related to the investigations of many relay (switching) devices [1-3], the abstract concept of the "nonsequential switching circuit" was formulated. For many switching circuits, such an abstraction turned out to be natural, and the propositional calculus became the basic mathematical apparatus for analyzing and synthesizing within the limits of this abstraction. However, this abstraction turned out to be inadequate, even for many important switching circuits, since it gave, in principle, no possibility of considering circuit operation in time, and only by artificial methods can be used for solving certain problems in the theory of such circuits.

The desire to introduce time ("sequentiality") into consideration explicitly, and to find an adequate mathematical apparatus for the description of circuits operating through time went beyond the limits of application of solely algebraic, logical operations (the propositional calculus).

"Motion" in such devices was given by special formulas and tables (Cf., for example, [3-7]), by geometric forms (motion of a representative point along the vertices of multidimensional cubes, or along the nodes of some graph or another) (Cf., for example, 4,6-9]) and, finally, by integer recursive functions (Cf., for example, [9-14]). In these works, account was taken, to a greater or lesser degree, of the peculiar features of some concrete method or other of technically realizing logical operations (in particular, the specific features of relay contact technology), i.e., essentially, the soil was prepared for the introduction of new, broader abstractions. It gradually became understood that what was at issue was the isolating of a specific class of dynamic systems*, and that systems constructed of elements having, not two, but an arbitrary, though finite, number of possible states had to be encompassed by these new abstractions.

While, in ordinary dynamic systems, the space and time coordinates have continua for their domains, the basic idiosyncrasy of this special class of dynamic systems is that their time has a countable set for its domain, while their coordinates have finite sets for theirs.

As these abstractions were developed, various names were given to them: logical nets [10], generalized nerve nets [15, 16], finite automata [16], nonprimitive circuits [14], sequential machines [18, 19], robots [17] etc.

The authors prefer the name finite automata for these abstractions.

Certainly, not all switching devices (i.e., those exhibiting relay functioning) are encompassed by these abstractions. For example, the abstraction "finite automata" is not adequate for systems containing devices in which the coordinates are chosen from finite sets, while the time has a continuum for its domain, although these are relay devices. On the other hand, the abstraction "finite automata" corresponds organically to all relay contact circuits which are devoid of such devices. But with certain natural idealizations, many other important technical devices also correspond to it, for example, machine-stand automata, mass-production lines, various digital machines, automata for piecework production, certain abstract models of nervous systems (for example, the nerve nets of McCulloch and Pitts), etc.

2. Basic Definitions and Terminology

As was said earlier, a finite automaton is a special type of dynamic system. The first characteristic of this class of dynamic system is that, in describing its actions, only discrete moments of time are of importance, the intervals between these moments (which, in general, are of unequal duration) being called cycles of the finite automaton's operation. Let p be one of these moments ("the present moment"), and let $p-1, p-2, \ldots, 2, 1, 0$ be the series of preceding moments of time. In this notation, 0 corresponds to the initial moment of automaton operation. We assume that some conditions or other are given which unambiguously define the decomposition of the time axis into cycles†.

---

* In this sense, the older abstraction - the nonsequential relay contact circuit - corresponded to a static system.

In the general case, the dynamic systems under consideration are subject to external stimuli. In the sequel, these stimuli will be called inputs.

Definition. A finite automaton is a dynamic system which, at the discrete moments of time under consideration, satisfies the following conditions.

1. At each of these moments of time, the system can be in just one of a possible finite number k of states.

2. At these moments of time, the system's inputs are also restricted to be chosen from a finite number r of possible states.

3. At any of the moments of time considered, the state of the system is uniquely defined by the state of the system and the state of the input at the previous moment of time.

To distinguish one automaton state from another, we assign a different symbol to each of the k possible states. We denote these symbols by $\kappa_1, \kappa_2, \ldots, \kappa_k$. We call the set of these symbols, denoted by $\{\kappa\}$, the alphabet of the states. Analogously, we write the symbols $\rho_1, \rho_2, \ldots, \rho_r$ for the input states. They form the automaton's input alphabet $\{\rho\}$‡.

We denote by $\kappa(t)$ and $\rho(t)$ the symbols for the automaton state and, input respectively, at time t. Then, by virtue of point 3 in the definition of the finite its operation is described by the recursion formula

$$\varkappa(p) = F[\varkappa(p-1), \rho(p-1)], \tag{1}$$

where F is a single-valued function which puts a definite symbol from the state alphabet into correspondence with each pair of symbols, one of which is chosen from the state alphabet, the other from the input alphabet.

Thus, the abstraction introduced by the concept of "finite automata" singles out a class of systems whose processes are described, not by differential equations, nor yet by difference equations of general form, but by specific equations of the type given in (1). The theory of finite automata concerns the general properties of such a type of system. Therefore, from the point of view of this theory, all systems are identical whose descriptions, with the applicable idealizations, reduce to an equation of type (1) with the same function F in the right member. Moreover, automata described by equations of type (1) with different functions F in their right members can still turn out to be equivalent, in a definite sense, to one another (Cf. section 4 below).

In the actual systems subsumed under the heading of "finite automata," a change of state of an automaton can, in some cases, be taken directly as being the result of the system's operation. In other cases, the automaton has an "output," whose state is uniquely determined by the automaton's state, but is not identical with it**.

Of course, in a finite automaton, the number of possible output states may, but in general does not, coincide with k. Let the output have l ($l \leq k$) states. We write each of the possible output states by a symbol $\lambda\{\lambda_1, \lambda_2, \ldots, \lambda_l\}$, which we call the output alphabet. Then, to describe the operation of an automaton with outputs, (1) must be supplemented by the "instantaneous" relationship

$$\lambda(p) = \Phi[\varkappa(p)], \tag{2}$$

which puts a symbol from the output alphabet into correspondence with each symbol from the state alphabet.

Equation (1) can be given by Table 1, which we call the fundamental table of the finite automaton.

TABLE 1

	$\varkappa_1$	$\varkappa_2$	…	$\varkappa_k$
ρ_1	$\varkappa_3$	$\varkappa_5$	…	$\varkappa_3$
ρ_2	$\varkappa_1$	$\varkappa_k$	…	$\varkappa_6$
⋮	⋮	⋮		⋮
ρ_r	$\varkappa_4$	$\varkappa_5$	…	$\varkappa_3$

This table is set up in the following way: a cell of the table is defined by giving one symbol each from the $\{\rho\}$ and $\{\kappa\}$ alphabets; by taking these symbols to represent matters at time p-1, i.e., by considering them to represent $\rho(p-1)$ and $\kappa(p-1)$, we determine $\kappa(p)$ from (1); we assign the value of $\kappa(p)$ thus determined to this cell.

If the automaton has outputs, then (2) defines the table of correspondences between κ and λ (Table 2).

TABLE 2

$\varkappa$	$\varkappa_1$	$\varkappa_2$	$\varkappa_3$	$\varkappa_4$	$\varkappa_5$	…	$\varkappa_k$
λ	λ_2	λ_4	λ_1	λ_3	λ_l	…	λ_6

---

† It may be assumed, for example, that the continuous time axis is previously divided in some manner into cycles which depend neither on the automaton's operation nor on its external stimuli. In other cases, the moment when a new cycle begins can be taken as the moment when some change in the automaton's input occurs. Finally, the cycles may be defined in such manner that the beginning of a new cycle will also depend on the state of the automaton, or on its output (Cf. part II of the present paper, to be published in the next number of this journal).

‡ In particular, one can number the automata and input states. Then, the state and input alphabets would be comprised of sets of numbers, 1,2,...,k and 1,2,...,r. Such alphabets might be convenient in investigations of individual automata. They are inconvenient in those cases when automata are joined, one to another, since the same symbol here, say the number 3, would apply to states and inputs of different automata.

** For example, in an automaton used for sending alarm signals, the important thing is not its state at each moment, but only whether this state does or does not correspond to an alarm signal.

Together with the finite automaton's fundamental table (Table 1), we shall consider an infinite tape (Table 3), characterizing, for a given initial state and a given sequence of input symbols, the sequence of appearance of state symbols as determined by (1) (or, what amounts to the same thing, as determined by Table 1).

TABLE 3

t	0	1	2	3	4	...
ρ	ρ_1	ρ_3	ρ_5	ρ_r	ρ_2	...
κ	κ_4	κ_1	κ_k	κ_5	κ_1	...

On this tape, each moment of time t is put into correspondence with a ρ and a κ. We call it the state tape.

A triple of symbols, κ(p-1), ρ(p-1) and (p), such as shown on Table 3 by the heavy lines, and chosen for any p, is related internally by (1). We call such a triple a triad.

TABLE 4

t	1	2	3	4	5	...
ρ	ρ_1	ρ_3	ρ_5	ρ_r	ρ_2	...
λ	λ_2	λ_2	λ_5	λ_l	λ_2	...

In cases when the system is defined by (1) and (2) (or by Tables 1 and 2), we shall also consider the automaton's output tape (Table 4), in which each moment of time t is put into correspondence with a pair of symbols ρ and λ.

We take particular note of the case when the input state does not change with time - automata of such type are called autonomous. For an autonomous automaton, (1) has the form:

$$\kappa(p) = F[\kappa(p-1),\ \rho(0)], \qquad (3)$$

where $\rho(0)$ is a time-invariant symbol which can be considered as a parameter.

The operation of an autonomous automaton can be illustrated by a graph.

We place k points on a plane, assigning to each point one symbol corresponding to one of the automaton's possible states. Equation (3) then defines the sequence of changes of state, i.e., the directed transitions from point to point. These directions can be indicated by arrows. It is easily seen that, in general, several arrows can lead to the same point. From a given point, however, at most one, and possible no arrows may lead.

The set of k points, together with the arrows as just described, is called the graph of the autonomous finite automaton.

In a nonautonomous automaton, there can be r input states. Therefore, by fixing and by leaving thenceforth invariant the input state, one can organize r different autonomous automata from a given nonautonomous automaton, each of the autonomous automata having its own graph. The set of these r graphs completely characterizes the nonautonomous automaton. Figure 1 shows an example of such a set, comprised of three graphs; a state table (Table 5) corresponds to this automaton.

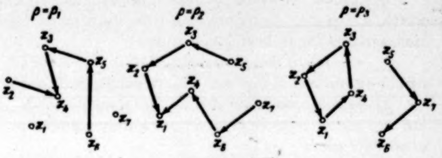

Fig. 1

TABLE 5

	κ_1	κ_2	κ_3	κ_4	κ_5	κ_6	κ_7
ρ_1	κ_1	κ_4	κ_4	κ_4	κ_3	κ_5	κ_7
ρ_2	κ_1	κ_1	κ_2	κ_1	κ_3	κ_4	κ_6
ρ_3	κ_4	κ_1	κ_2	κ_3	κ_7	κ_6	κ_6

3. The General Problems Arising in Connection with the Introduction of the Abstraction "Finite Automata"

Although the abstraction of "finite automata," as this term was introduced in section 2, is a far-reaching one, there arose with its introduction [i.e., with the isolating of the class of systems described by (1), or by (1) + (2)] a number of problems, equally important for all actual systems for which this concept is adequate.

One of these problems, that of the representation of events in finite automata, was solved (inefficiently, it is true) by Kleene's theorems [16] (Cf. also [19-21]).

This is not the sole problem, and a number of important problems in finite automata theory are today not only unsolved, but not even rigorously formulated. These problems arise principally in connection with the fact that both the state tape and the automaton's output tape are infinite. It is therefore meaningless to say that these tapes are "given." All that may be given are algorithms which permit, in a finite number of steps, choosing of the symbol from given alphabets which must be written in an arbitrary cell of the tape.

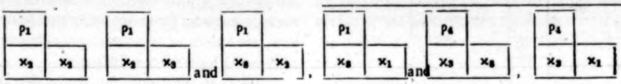
We denote by A_ρ and A_κ the algorithms corresponding to the upper (ρ) and lower (κ) rows of the state tape, and by A_ρ and A_λ the analogous algorithms for the output tape. From this point of view, a finite automaton, defined by (1) or by (1)+(2) (i.e., by Table 1 or Tables 1 and 2), is essentially an operator which establishes the relationships between algorithms A_ρ and A_κ, or between A_ρ and A_λ.

In connection with this, no scientific problems arise in the task of analysis, i.e., in the task of determining, for a given automaton, the algorithm A_κ (or A_λ) from A_ρ and conversely, and here one may only speak of developing more or less convenient ways of implementing the operations defined by the "finite automaton" operators.

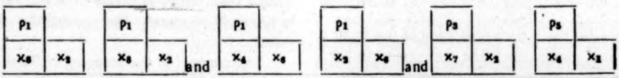
Matters are otherwise when the tape algorithms are given (i.e., A_ρ and A_κ, or A_ρ and A_λ) and it is required to synthesize the automaton (i.e., to construct (1)).

We first consider the case when it is required to synthesize the automaton from the given algorithms A_ρ and A_κ. It is clear that this problem cannot always be solved, since the tape defined by algorithms A_ρ and A_χ may contain triads which are mutually contradictory.

We call two triads contradictory if, in these triads, the symbols $\rho(p-1)$ and $\kappa(p-1)$ are identical, but the symbols for $\kappa(p)$ are different. For example, the pairs of triads



are contradictory, while the pairs of triads



are noncontradictory.

Each cell of Table I contains one symbol. Therefore, the existence of contradictory triads is incompatible with Table 1, i.e., it contradicts the single-valuedness of the function F in (1).

Thus arises the first problem: knowing the algorithms A_ρ and A_κ, to find an algorithm for recognizing their "noncontradictoriness," i.e., the absence of contradictory triads on the state tape.

This problem may be formulated precisely, as follows. We are given the recursive functions $\kappa(p)$ and $\rho(p)$, each of which can assume a finite number of values. It is required to construct a recursive functional $\Psi[\kappa(p), \rho(p)]$ (Cf. [23] Chap. 9) which equals unity on those functions $\kappa(p)$ and $\rho(p)$ for which there exists the function $F(u,v)$, defined on the finite set constituting the domain of u and v such that, for any p, the relationship $\kappa(p) = F[\kappa(p-1), \rho(p-1)]$ holds, and which equals zero otherwise. If, as may be assumed, the problem as formulated is algorithmically unsolvable, the necessity then arises of posing the more restricted tasks of determining a recursive functional Ψ on the functions $\kappa(p)$ and $\rho(p)$ which lie in a more restricted class than the class of all the recursive functions which assume the given number of values.

Although the automaton's state tape is infinite, the numbers r and k are finite, so that the total number of different triads on the tape is also finite. After the question of the "noncontradictoriness" of the algorithms is resolved, there arises a second problem: for given "noncontradictory" algorithms A_ρ and A_κ, to find an algorithm for seeking all the different triads contained on an infinite state tape. The solution of this problem would immediately permit one to fill in all or some of the cells of Table 1, and to define the automaton with an exactitude to within the cells which remained unfilled and could be filled in arbitrarily.

In the case when a finite number of state tapes is given, and it is required to find an automaton which reproduces all these tapes, no new problem arises, since the algorithm for observing contradictions and the algorithm for determining all the different triads may be applied to each tape in turn. New problems arise only when the number of state tapes is infinite.

The matter is significantly more complicated when it is required to synthesize an automaton from its output tape. Here the additional problem arises: knowing the algorithms A_ρ and A_λ, to determine k, i.e., the number of states which must be realized in the automaton, and to find the function Φ in (2), i.e., from the given output tape to construct a noncontradictory state tape.

It is precisely problems of this type which are most interesting in practice, since the requirements on the automaton to be synthesized are ordinarily given directly in "input-output" terms.

It is necessary to mention that the general problem of synthesizing finite automata from given operating conditions has thus far not been precisely formulated. The difficulty of a rigorous posing of this problem stams from the following. In the majority of questions arising in practice, the automaton must transform a given infinite class of input sequences into a required class of output sequences. Up to now, however, there has been developed no sufficiently general and convenient mathematical apparatus in terms of which an adequate description of these infinite classes of sequences could be given. In the present case, a description in terms of sets of tables [15] is unsatisfactory, since the original (verbal) given conditions of operation are posed in other ("logical") terms (closer to the language developed in [22]), while no algorithm has been established for making the transition from the language of sets of tables to the "logical" language.

All algorithmic problems of this nature vanish, and the synthesis problem becomes much easier, in the case when the automaton's tapes are finite.

4. Mappings of Finite Automata and Their Equivalence

In considering an automaton with outputs, we previously used the "instantaneous" relationship of (2).

This relationship can be considered as a rule for transforming state symbols to output symbols. An abstract device which realizes (2) is called a symbol transformer. There is, of course, an analogous symbol transformer at the automaton's input; it will transform the symbols of some external stimulus alphabet to symbols of the automaton's input alphabet.

We now assume that two automata are given: automaton A, operating with input alphabet $\{\alpha\}$ and with state alphabet $\{a\}$, and automaton B, with input alphabet $\{\beta\}$ and state alphabet $\{b\}$. We further assume that there are two symbol transformers: one of them (the input transformer) transforms the symbols $\{\alpha\}$ to $\{\beta\}$, and the second (output) transforms symbols $\{b\}$ to $\{a\}$.

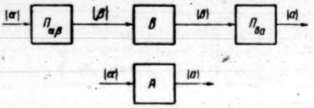


Fig. 2

We now consider the system consisting of the input symbol transformer, automaton B and the output symbol transformer (Fig. 2). This combined system has inputs from the alphabet $\{\alpha\}$ and outputs from the alphabet $\{a\}$, the same as automaton A††.

If we can choose input and output symbol transformers such that, for any sequence of input symbols from alphabet $\{\alpha\}$ and for any initial state of automaton, A, there would exist an initial state of automaton B such that there would appear, at the output of the combined system (automaton B and the two transformers), the same sequence of symbols from the alphabet $\{a\}$ as the sequence of state symbols in automaton A, then we shall say that automaton B is a mapping of automaton A (or that automaton A is mapped onto automaton B).

We symbolize this fact by:

$$A \subseteq B \quad \text{or} \quad B \supseteq A.$$

If simultaneously

$$A \subseteq B \quad \text{and} \quad A \supseteq B,$$

then the automata A and B will be said to be equivalent, and we symbolize this circumstance by $A \asymp B$.

We now give a precise definition of the concept of mapping.

The automaton A ($\{a\}$, $\{\alpha\}$) is mapped onto automaton B ($\{b\}$, $\{\beta\}$) (and automaton B is a mapping of automaton A) if, to each pair (a_i, α_j) of symbols from the alphabets $\{a\} = \{a_1, \ldots, a_k\}$ and $\{\alpha\} = \{\alpha_1, \ldots, \alpha_r\}$, one can set up a correspondence of such a pair ($\{b_i\}$, $\{\beta_j\}$) of sets of symbols from the alphabets $\{b\} = \{b_1, \ldots b_n\}$ and $\{\beta\} = \{\beta_1, \ldots, \beta_m\}$ such that, if

$$F_A(a_i, \alpha_j) = a_s, \tag{4}$$

then, for any symbols $b_{q_i} \in \{b_i\}$ and $\beta_{p_j} \in \{\beta_j\}$ the following condition holds

$$\tag{5}$$

Here, F_A and F_B are the functions in the left bers of equations of the type of (1) for automata A and B respectively.

Two equivalent automata do not differ practically from one another – their differences are external, consisting only in the methods chosen for coding the automata states and inputs. In spite of this, two equivalent automata can be described by completely different equations of type (1). Even the variables in these equations may be taken from different alphabets. Thus, for example, two automata with identical numbers of states and inputs, differing only by the notation of the states and the inputs, i.e., the alphabets from which the symbols are taken and the manner in which these are associated with states and inputs, are known to be equivalent, although the equations of type (1) for them are different.

If $A \subseteq B$, but $A \not\asymp B$, this means that there exists a symbol transformer by means of which automaton B can be "forced" to operate like automaton A, but not conversely.

The concept of the mapping of finite automata, and of their equivalence, is closely related to the topological peculiarities of their graphs.

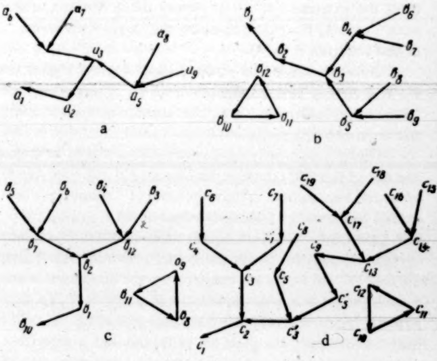

Fig. 3

As an example, we consider the graphs of the four autonomous finite automata, given in Fig. 3. The automata of Fig. 3, b, and c are equivalent, since they differ only by the nomenclature of the states. The automaton of Fig. 3a, is mapped onto each of the automata of Fig. 3, b, and c. This becomes clear by supposing that a transformer is placed at the output of the automaton of Fig. 3,b which places each symbol b_i ($i = 1,\ldots,8$) into correspondence with any of the a_i ($i = 1,\ldots,8$).

---

†† To be sure, such a combined system might not be a finite automaton, since its output symbol at time p might not be uniquely determined by its output and input symbols at time p-1. We shall assume that the combined system under consideration is a finite automaton.

All three of the automata thus far considered are mapped onto the automaton of Fig. 3,d. The output transformer which it is necessary to append to the automaton of Fig. 3,d for it to operate the same as the automaton of Fig. 3,b must place each of the symbols c_i into correspondence with b_i for $i = 1,2,6,7,8,9,10,11$, and 12. Symbols c_3 and c_3' are made to correspond with the same symbol b_3, symbols c_4 and c'_4 with b_4 and symbols c_5 and c''_5 with b_5. In addition, symbols $c_{13}, c_{14},\ldots,c_{20}$ are placed into correspondence with any of the symbols $b_1,\ldots,b_{12}$.

The problem now arises: knowing the fundamental tables of two automata, or their equations of type (1), to determine whether these automata are equivalent, or whether one of them is mapped onto the other ‡‡. In other words, it is required to find criteria for the mappings and equivalences of automata.

The concept of equivalence of automata, and of their mappings, allows one to introduce the concept of the abstract aggregating (assembly) of finite automata, i.e., of assembling a finite automaton from standard elementary automata.

5. Abstract Assembly of a Finite Automaton

We now consider a device with $\underline{s}$ input wires $u_1,\ldots,u_s$ and $\underline{n}$ generalized coordinates $x_1,\ldots,x_n$. At the times $0,1,2,3,\ldots,p$, each input and each coordinate may have only one of a finite number of values, which we shall symbolize by symbols from some alphabets. At any moment of time, each coordinate is determined uniquely by the values of all or some of the inputs and coordinates at the preceding moment of time.

The operation of such a device is described by the recursion relationships

$$x_i(p) = f_i[x_1(p-1),\ldots,x_n(p-1);$$

$$u_1(p-1),\ldots,u_s(p-1)]\ (i = 1,\ldots,n) \qquad (6)$$

or, in vector form,

$$x(p) = f[x(p-1),\ u(p-1)]. \qquad (7)$$

If an x_i can have χ_i different values ($i = 1,\ldots,n$), then the vector $x(p)$ can have $k = \prod_{i=1}^{n} \chi_i$ different values. We call the vector $\underline{x}$ the state of the device being considered, and we choose its $\underline{k}$ values from the symbols $\kappa_1,\ldots,\kappa_k$ of the alphabet $\{\kappa\}$. Analogously, the input vector $\underline{u}$, with $r = \prod_{j=1}^{s} \xi_j$ values (where ξ_j is the number of values of u_j) is called the input state, and we relate its values to the symbols $\rho_1,\ldots,\rho_r$ of the alphabet $\{\rho\}$. With this notation, (7) reduces to (1), which means that the device just described is a finite automaton.

Equations (6) can also be understood as another form of equation of the type (1). Different equations of type (6) can correspond to one and the same equation of type (1), but they all describe the processes in equivalent automata.

In the definition of a finite automaton, given in section 2, and in the equation of type (1) which corresponded to it, we had to do only with automata states and inputs. Now, in making the transition to equations of type (6), we introduced coordinates and input wires (input lines). We shall call the transition from (1) to the equivalent (6) a choice of structure for the finite automaton, and (6) will be called its abstract structure (AS). A technical device which, with the suitable idealizations, is described by equations of type (6), will be called a technical realization of the automaton's structure.

Let there now be given several systems of equations of type (6), each of which is the abstract structure of a corresponding automaton. Each of these systems of equations has its own coordinate and input-line alphabets.

We now introduce into the discussion symbol transformers, each with several input lines and one output. The symbols from the transformer's output alphabet appear at its output at the same instant that the symbols from their respective alphabets are applied to the input lines.

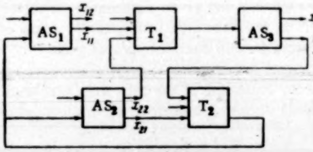

Fig. 4

We use transformers as means for the interconnection of AS (as, for example, on Fig. 4), choosing them in such manner that the corresponding AS alphabets and transformers are properly linked. We call such a set of AS, interconnected via symbol transformers, a net. The coordinates of the net are comprised of all the generalized coordinates x_i of all the AS, including those not applied to any transformer. The net's input lines are both the AS input lines on which no transformer acts, and the transformer input lines on which no AS coordinate acts.

In order to obtain the equations for a net, it is necessary to use the given equations for the transformers for eliminating from the systems of equations of type (6) the corresponding variables for the AS input lines, replacing them by the AS coordinates and the variables of the transformers' input lines. As the result, the net as a whole is also described by a system of recursion relationships of

---

‡‡ Certainly, what we have in mind here is not the trivial solution, obtained by the exhaustive trial of all meaningful correspondences of symbols.

$x(p-1)$				$u(p-1)$				$\kappa(p-1)$	$\rho(p-1)$	$\kappa(p)$	$x(p)$			
x_1	x_2	…	x_n	u_1	u_2	…	u_s				x_1	x_2	…	x_n

		…				…							…	
⋮	⋮	…	⋮	⋮	⋮	…	⋮	⋮	⋮	⋮	⋮	⋮	…	⋮

TABLE 6

type (6), i.e., the net itself is the abstract structure of some finite automaton.

From what has been said, it follows that a finite automaton can be constructed from other finite automata by joining them in a net. The question naturally arises as to the possibility of creating a set of automata, or even all meaningful automata, from a small collection of original automata – "elements." Such construction of automata we call abstract assembly. The technological value of this concept is obvious.

The introduction of the concept of abstract assembly leads immediately to the posing of the following problems: to construct algorithms which answer the question as to the possibility of constructing nets from a given set of AS and transformers, these nets being mappings (in the sense of section 4) of given automata, and to specify an algorithm for the efficient implementation of this construction.

A set of AS and transformers from which one can construct nets mapping any given automaton is called a complete set. The problem then immediately arises of determining criteria for the completeness of a set.

A complete set which is very important for technology is the set consisting of the following elements: a) a binary delay element, described by the following equation

$$x(p) = z(p-1)$$

where $\underline{x}$ and $\underline{z}$ are given in an alphabet which contains only two symbols (for example, 0 and 1); b) some set of logical elements which permits the realization of any logical function (this set may consist for example, of conjunction, disjunction and negation elements).

From this set, a net which is the mapping of any finite automaton can be constructed. Indeed, let a finite automaton be given by Eq. (1), i.e., let the function F and the alphabets $\{\kappa\}$ and $\{\rho\}$ be given.

We choose two numbers $\underline{n}$ and $\underline{s}$ such that the conditions $2^n \geq k$ and $2^s \geq \underline{r}$ are satisfied. We introduce the variables $x_1,\dots,x_n$ and $u_1,\dots,u_r$, where each of these variables assumes only the values 0 and 1.

We consider Table 6. On its left side are enumerated all possible combinations of all values of $x_1,\dots,x_n$, $u_1,\dots,u_s$, i.e., Table 6 has 2^{n+s} rows. Each different combination of variables $x_1,\dots,x_n$ is placed in correspondence with its own symbol from the alphabet $\{\kappa\}$. Since the number of these symbols is $\underline{k} \leq 2^n$, there may remain combinations $x_1,\dots,x_n$ for which the alphabet $\{\kappa\}$ cannot supply symbols different from other symbols already used. We assign arbitrary previously used symbols from $\{\kappa\}$ to these combinations $x_1,\dots,x_n$.

We proceed analogously with the combinations of variables $u_1,\dots,u_s$, designating them by symbols from $\{\rho\}$. We write the selected symbols from $\{\kappa\}$ and $\{\rho\}$ in the corresponding row of columns κ (p-1) and ρ(p-1) of Table 6.

Thus, to each set of variables $x_1,\dots,x_n$; $u_1,\dots u_s$ there corresponds a pair of symbols from the alphabets $\{\kappa\}$ and $\{\rho\}$. By taking these pairs of symbols as standing for κ(p-1) and ρ(p-1), we find κ(p) from (1), and write these values in the corresponding rows of column κ(p) of Table 6. We can then immediately fill up the right side of Table 6, since we have already related a definite combination of values $x_1,\dots,x_n$ with each symbol from $\{\ \}$ ***

The table thus constructed determined the value of all xi at time $\underline{p}$ from the given x_i and u_j at time p-1, i.e., it gives $\underline{n}$ logical recursion relationships of the type of (6):

$$x_i(p) = L_i[x_1(p-1),\dots,x_n(p-1);\ u_1(p-1),\dots,u_s(p-1)] \quad (i=1,\dots,n). \tag{8}$$

For any combination of values of the variables, the values of all the functions L_i are read off from Table 6.

It is easily seen that the obtained equations (8) are the abstract structure of an automaton which maps the original automaton which was given by an equation of type (1).

Each equation in (8) can be realized in the form of an elementary one-cycle lag, with equation

$$x_i(p) = z_i(p-1) \qquad (i = 1,\dots,n), \tag{9}$$

and a logical instantaneously acting transformer

$$z_i = L_i(x_1,\dots,x_n;\ u_1,\dots,u_s) \quad (i = 1,\dots,n), \tag{10}$$

which, in the given case, is also a transformer of the coordinate x_i and input u_j symbols to input z_k symbols of the lag of (9). In the given special case, all the symbols x_i, u_j, and z_k are chosen from the same alphabet, namely, $\{0, 1\}$. The entire set of equations (8) is a net composed of $\underline{n}$ lags of the form (9) and $\underline{n}$ transformers of the

---

*** If $k < 2^n$ and if several combinations, $x_1,\dots,x_n$ were related to one and the same symbol of $\{\kappa\}$, then we choose any one of them in any case when the corresponding symbol arises.

form (10). Since any logical transformer is realized from the set of logical elements given by us in the conditions of the problem, this shows that this set of logical elements, supplemented by a delay element, is a complete set of the elements necessary for constructing any automaton.

It can be shown analogously that a set of elements allowing any function of q-valued logic ($q > 2$) to be reproduced, and supplemented by a delay element of the form of (9), wherein the input and output assume values from a q-symbol alphabet, also comprises a complete set.

In this section we first used the concept of a delay element. This concept requires the following additional elucidation.

When any symbol from the input alphabet is applied to the input of delay element (9), the corresponding symbol from the output alphabet appears at its output after a one-cycle delay. It was stated, at the very beginning of this paper, that the cycles could be nonuniform, and that the division of the time axis into cycles was uniquely determined by some additional conditions. So long as we had to do with abstract structure and abstract assembly, i.e., essentially with the replacement of (1) by equations of the form (6), this circumstance was of no significance since in (1) and (6) the sequentiality (i.e., the character of the variation of the argument p) was considered as given. In using the complete sets, described above, for the technological realization of automata, it is assumed that the automata contain special devices – sequencing transducers which, in correspondence with given conditions, process the signals for cycle beginning and apply them to delay elements. This stimuli of the delay elements are not external in the sense in which the term "external stimuli" was used above; they are not encoded by symbols from $\{\rho\}$ in setting up (1), and are not germane to the stimuli u_j in (6). Therefore, even an autonomous automaton may contain these stimuli, which are essential only for the technological realization, and are not taken into consideration when one deals with abstract structure or abstract assembly.

A UNIVERSAL FUNCTION GENERATOR BASED ON THE PRINCIPLE OF QUADRATIC APPROXIMATIONS

A. A. Maslov and Yu. G. Purlov
(Moscow)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 2, pp. 237-244, February, 1960)
Original article submitted July 21, 1959

Methods are presented for quadratic approximations for functions given either analytically or graphically. Simple formulas and relationships are derived for finding the rule for argument partitioning. For obtaining a quadratic relationship, a variant of a diode element is considered.

The paper describes the circuit of a universal function generator using quadratic approximations and capable of being implemented in the form of an attachment to a type ÉMU-8 analog computer.

Universal diode-function generators [1-5] based on the principle of piecewise-linear approximations are widely used in modern electronic analog computers for reproducing various nonlinear functions.

When it is necessary to reproduce a function with a comparatively large range of variation of the absolute magnitude of the first derivative, function generators of this type require the use of a large number of diode elements, which complicates the circuit and increases the error. In addition, discontinuities in the value of the first derivative of the reproduced function are introduced which, in many cases, is highly undesirable.

The disadvantages just cited can, to a large extent, be removed if nonlinear functions are approximated by segments of curves, in particular, by segments of parabolas [6-8].

However, the use of quadratic approximations entails a significant increase in the amount of computational work necessary to determine the partitioning along the argument axis, which has resulted in work being carried out to develop simplified analytic and graphical methods of calculating functions, and a variant of a universal function generator, based on the principle of quadratic approximations, has been developed.

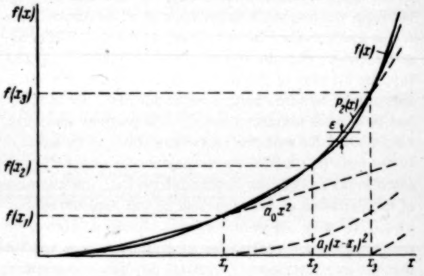

Fig. 1

Method of Piecewise-Quadratic Approximation of Nonlinear Functions

The problem of the piecewise-quadratic approximation of a nonlinear function f(x) amounts to the finding of a number of fixed argument values $x_1, x_2, x_3,$ which provides a second-order approximation polynomial with vertices $f(x_1), f(x_2), \ldots$

$$P_2(x) = a_0 + a_1 x + \sum_{i=1}^{n} b_i (x - x_i)^2,$$

where

$$b_i = \begin{cases} 0 & \text{for} \quad x \leqslant x_i, \\ B_i = \text{const} & \text{for} \quad x > x_i, \end{cases}$$

to the curve f(x) to be reproduced such that, on the entire interval of argument variation, the absolute error of the approximation function does not exceed some previously given value ϵ (Fig. 1).

With respect to the function f(x), it is assumed that it is single-valued and continuous on the given interval of argument variation, and that it has a continuous second derivative everywhere on that interval with the possible exception of a finite number of first-order discontinuities.

For quadratic interpolation, the remainder term in Newton's interpolation formula has the form [9, 10]:

$$R(x) = \frac{f'''(\xi)}{3!}(x - x_1)(x - x_2)(x - x_3),$$

where $f'''(\xi)$ is the value of the reproduced function's third derivative at some point ξ inside the interval (x_1, x_3). The modulus of the error R(x) has its maximum value when $f'''(\xi)$ and the expression $|(x-x_1)(x-x_2)(x-x_3)|$ simultaneously attain their maxima:

$$|R(x)|_{\max} = \frac{|f'''(\xi)|_{\max}}{3!}|(x - x_1)(x - x_2)(x - x_3)|_{\max}.$$

We introduce the new variable $u = (x-x_1)/(x_3-x_1)$ and let $k = (x_2-x_1)/(x_3-x_1)$ and $h = x_3-x_1$.

Then,

$$|R(u, k)|\max = \frac{|f'''(\xi)|\max}{3!}\,|u(u-1)(u-k)|\max h^3.$$

The function $u(u-1)(u-k)$, in the region of variable variation $0 \leq u \leq 1$, $0 \leq k \leq 1$, attains its greatest value, equal to 4/27, at the points ($u=1/3$, $k=1$) and ($u=2/3$, $k=0$).

Thus, for this worst case, we have

$$R(u\ \ k)\ \max = \frac{4h^3|f'''(\xi)|\max}{27\cdot 3!} = \frac{2h^3|f'''(\xi)|\max}{81}.$$

By assuming that $\max|R(u,k)| \leq \epsilon$, we obtain the expression for determining the length of the partition segment $h = x_3 - x_1$ in the form

$$h \approx 3{,}43\sqrt[3]{\frac{\varepsilon}{|f'''(\xi)|\max}}.$$

The worst case was taken in estimating the approximation error. In the general case, a more accurate consideration is very difficult. Experiment shows that, for a wide class of frequently arising functions, we may consider that

$$h = 4\sqrt[3]{\frac{\varepsilon}{|f'''(\xi)|_{\max}}}.$$

Example. It is required to reproduce the function $f(x) = x^3 \cdot 10^{-4}$ in the domain $0 \leq x \leq 100$. We find the law of argument partitioning when the approximation error is taken as $\epsilon = \pm\ 0.35$.

The third derivative of the given function equals the constant quantity $6 \cdot 10^{-4}$. Therefore, all the segments will be the same, and equal to

$$h_k \doteq 4\sqrt[3]{\frac{0{,}35\cdot 10^4}{6}} = 33{,}6.$$

The total number of partition segments is three.

If the function f(x) is given graphically, then the threefold graphical differentiation necessary for the computation of the value of $f'''(\xi)$ is very difficult, and entails large errors. In this case, a graphical method should be used to determine the law of argument partitioning. This method is based on the replacement of a quadratic approximation to the given function f(x) with error ϵ by a piecewise-linear approximation to the first derivative f'(x) with error ϵ'. The problem reduces to the finding of the relationship $\epsilon' = \varphi(\epsilon, x)$. Figure 2 shows one segment of the quadratic second-order approximation polynomial $P_2(x)$. For $x = x_1$, $x = x_2$ and $x = x_3$, the function f(x) to be reproduced and the polynomial $P_2(x)$ have the common points:

$$f(x_1) = P_2(x_1),$$
$$f(x_2) = P_2(x_2), \quad f(x_3) = P(x_3).$$

The greatest error of approximation occurs when $x = x'$ and $x = x''$. It is obvious that for this

$$f'(x') = P_2'(x'), \quad f'(x'') = P_2'(x'').$$

In Fig. 3 there has been constructed the derivative $f(x)$ of the given function, as well as the derivative $P'_2(x)$ of the approximating polynomial. The errors ϵ'_1, ϵ'_2, and ϵ'_3 occur respectively for $x = x_1$, $x = x_2$, and $x = x_3$.

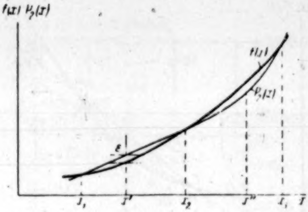

Fig. 2

From the approximation conditions, it follows moreover that

$$S_{ABC} = S_{CDE} = S_{DEF} = S_{FGK} = |\varepsilon|.$$

At the point $x = x'$, the angle between $f'(x)$ and $P'_2(x)$ on the left, α_-, is not greater than the angle on the right, α_+: $\alpha_+ = \alpha_- + \Delta\alpha$, where $\Delta\alpha \geq 0$.

By replacing the curve $f_2(x)$ by straight lines on the segments AC and CE we find, from the equality of the areas $S_{\Delta ABC} = S_{\Delta CDE} \approx |\epsilon|$, that $\epsilon'_1 \leq \epsilon'_2$.

Analogously, we can convince ourselves that $\epsilon'_3 \geq \epsilon'_2$.

We now consider F'(x) on the segment x', x''. Here there is a one-sided linear approximation. Therefore, [11],

$$\varepsilon'_2 \leqslant \frac{A_k(x'x'')^2}{8},$$

where A_k is the maximum value of the third derivative $f'''(x)$ in the interval $x'x''$.

By assuming that point x_2 divides segment $x'x''$ in the ratio l, we find that

$$\varepsilon'_1 \leqslant \frac{A_k(x'x'')^2}{8}l^2 \leqslant \varepsilon'_2 l^2,$$
$$\varepsilon'_2 \leqslant \frac{A_k(x'x'')^2}{8}(1-l)^2 \leqslant \varepsilon'_1(1-l)^2.$$

Thus,

$$\varepsilon = \frac{1}{2}S_{CFE} \approx \frac{1}{2}\left(S_{\Delta CEF} + S_{\Delta CER} + S_{\Delta EFO}\right) =$$
$$= \frac{x'x''}{2\cdot 2}\left[\varepsilon'_2 + l^3\varepsilon'_2 + (1-l)^3\varepsilon'_2\right] =$$
$$= \frac{x'x''}{4}\varepsilon'_2(3l^2 - 3l + 2).$$

From whence

$$\varepsilon'_2 = \frac{4\varepsilon}{x'x''(3l^2 - 3l + 2)}.$$

The expression in the denominator assumes its minimum value for $l = 1/2$. With this, $\epsilon'_2 \leq 16\,\epsilon/5a$, where $a = x'x''$. This last formula gives the connection between the given error ϵ and the tolerance margin ϵ' and size of a.

In reproducing various functions, the lengths of neighboring partition intervals differ little from one another. Therefore, by measuring the quantity a on a constructed segment, we find from the last formula what the tolerance will be for the following segment. Inside the tolerance band ϵ', constructed with respect to $f(x)$, we carry out a

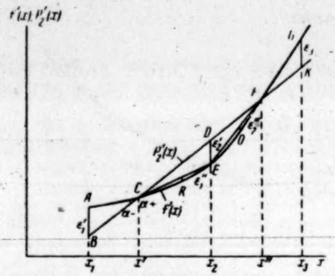

Fig. 3

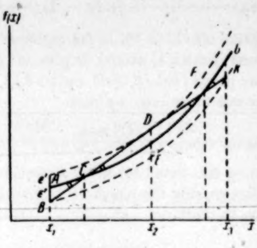

Fig. 4

two-sided linear approximation, as a result of which we find the size of the following partition interval.

It is easily shown that, with such a method of partitioning, the actual error will not be larger than the admissible approximation error ϵ. Indeed, let the admissible error ϵ' be computed from the previous segment. To determine the size of the partitioning segment, we construct the tolerance band with respect to f'(x) (Fig. 4). We then carry out a two-sided linear approximation.

Since ACB ≤ DCE, DFE≤ GFK, then $S_{\Delta ABC} \leq S_{\Delta CDE} \leq \epsilon$ and $S_{\Delta FGK} \leq S_{\Delta FDE} \leq \epsilon$, i.e., with this we obtain a certain underestimate of the length of the partition interval, which leads only to a decrease in the error of approximation of the nonlinear function f(x) to be reproduced.

As the second derivative f''(x) increases, the curvature of the function f(x) also increases and, consequently, the lengths of the segments of the argument partition decrease. So that the magnitude of the error, defined by the previous segment, not exceed the tolerance on the given interval, the partitioning should be carried out from large segments to small ones, i.e., on the side of an increasing second derivative f''(x).

For the finding of the first segment, we may recommend a simplified method of successive approximations, shown on Fig. 5 for the function $f(x) = x^3 \cdot 10^{-4}$, where the graphical construction of the first segment is given. Letting the magnitude of $a_1 = 20$v, we construct the tolerance margin $\epsilon'_1 = 16\ \epsilon/5a_1 = 0.16\,\epsilon$, and we then carry out a piecewise linear approximation. We obtain the quantity $a_2 > a_1 = 20$. We construct the new tolerance margin $\epsilon'_2 = 16\ \epsilon/5a_2$, and carry out a piecewise linear approximation which determines a_3. It is obvious that the optimal length of the segment will be $a_1 \leq a_3 \leq a \leq a_2$. As the interval length varies within these limits, the maximum actual error ϵ'_1 decreases from ϵ'_1 to ϵ'_2, varying along a certain curve AB which is close to being a straight line. At the same time, the admissible error varies along a hyperbola which passes through points C and D, which correspond to the maximum values of ϵ'_1 for $a_1 = 20$ and $a_2 = 24$. If we now replace the hyperbola by the straight line CD we find, on Fig. 5., the point 0 of intersection which, with an accuracy sufficient for a graphical method, gives the magnitude of the error ϵ' for the first and second intervals of the argument partitioning.

Circuit of the Quadratic Diode Element

For obtaining segments with quadratic dependencies in the present work, we used the diode element represented on Fig. 6, a [8]. To the diode are applied input vol-

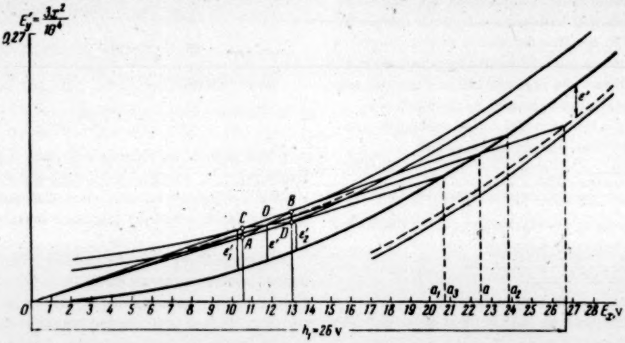

Fig. 5

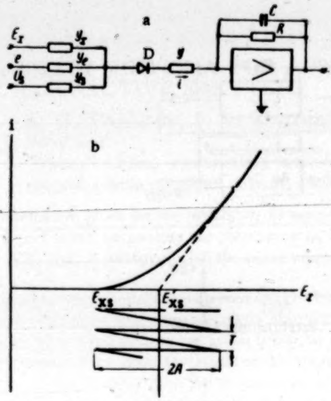

Fig.6

tage E_x, reference voltage e and high-frequency sawtooth voltage U_s. The diode element's transconductance characteristic is determined by the conductance Y.

If the high-frequency voltage U_s is not applied to the diode, the dependence of the current i on the input quantity E_x has the form shown on Fig. 6,b by the dotted line. For $E_x = E'_{xs} = eY_e/Y_x$, diode D is opened, and thereafter the current i increases proportionately to input voltage E_x.

If a sawtooth voltage of amplitude A is applied to the diode via Y_s, the diode will open for lower values of the input voltage:

$$E_x = E_{xs} = e\frac{Y_e}{Y_x} - A\frac{Y_s}{Y_x}.$$

By using the principle of superposition, we find the average value of the diode element's current:

$$i_{av} = \begin{cases} 0 & \text{for } E_x \leqslant E_{xs}, \\ \dfrac{Y}{YAY_0Y_s}(Y_xE_x - Y_ee + Y_s A)^2 & \text{for } E_x > E_{xs}. \end{cases}$$

Here,

$$E_{xs} = e\frac{Y_e}{Y_x} - A\frac{Y_s}{Y_x},$$

$$Y_0 = Y_x + Y_e + Y_s + Y.$$

For getting a sawtooth voltage, a generator circuit, shown on Fig. 7, was developed. A blocking generator was executed based on triode V_1, while pentode V_3 was used as a discharge tube. Charging condenser C_1 is connected in the anode circuit of V_3. During the blocking process, the condenser is charged up to the potential U_{max} close to the anode voltage. Tube V_1 is cut off and condenser C_1 discharges through tube V_3. Because of the current-stabilizing action of the pentode, the discharge of C_1 occurs linearly. As soon as the voltage becomes equal to $U_{C_1} = U_{unb.V_1}$, tube V_1 opens and the blocking process repeats. The generated voltage is applied to the grid of cathode follower V_2. Part of the output voltage is tapped off by the voltage divider formed by resistors R_2, R_3, and R_4, and is applied to the cathode of V_3. The magnitude of the positive feedback can be controlled by resistor R_3, thus varying, within very wide limits, the linearity of the output voltage.

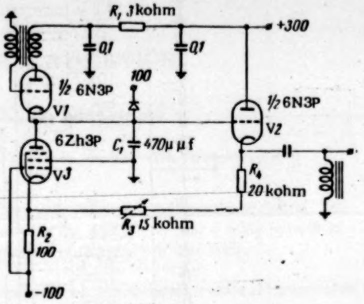

Fig 7

To stabilize the sawtooth amplitude, we use a reference voltage of +100v, limiting the growth of potential on capacitor C_1. The frequency of the generated voltage is determined by the capacitance of condenser C_1 and by the magnitude of the anode current of pentode V_3.

With the nominal values shown on Fig. 7, the circuit provides a generated sawtooth voltage of frequency 25 kcps and output voltage amplitude of 90v. With line-voltage variations of ± 10%, the sawtooth amplitude varies by ± 5%.

Complete Function-Generator Circuit and Its Technical Characteristics

Vacuum tube diodes type 6Kh2P were used as the function generator's diode elements. The transition to vacuum tubes resulted from the great difficulties which arose when germanium diodes were used, due to their low back impedance and their instability under various temperature conditions.

The functional schematic of the universal diode-function generator is given in Fig. 8. In it are included two operational amplifiers A_1 and A_2. Applied to the diode elements DE are a high-frequency sawtooth voltage and a reference voltage from a low-ohmic divider. The low-ohmic divider is executed in the form of individual sections, each of which consists of six wire resistances: r_1 = 60 ohm, r_2 = 120 ohm, r_3 = 240 ohm, r_4 = 420 ohm, r_5 = 840 ohm and r_6 = 1680 ohm. For setting up the law of argument partitioning, part of these resistances are short-circuited by means of a twelve-position switch with inserts in its panel. The total impedance of the low-ohmic dividers is always so chosen that a current of 16.7 ma flows through them. With this, the increment of the argument between the switching points of any neighboring diode elements is con-

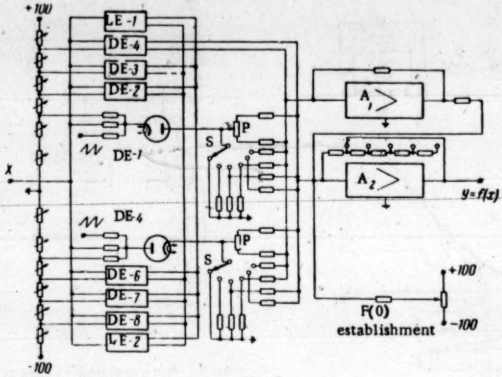

Fig. 8

trolled in the limits of 0 to 56v, varying by discrete steps of 1 volt.

In the function generator, there are eight quadratic diode elements, for which the switching voltage can be controlled, and two linear elements LE, made up of passive-resistor circuits, with switching voltages by zero. By applying the voltage after the diodes, either directly to A_2 or through sign-inverter A_1, we can obtain increments of the function's slopes in all four quadrants. The magnitude of these increments can be controlled discretely and smoothly by, respectively, switch S and potentiometer P (Fig. 8).

The function generator's complete circuit also contains an assembly for establishing the function's initial value.

SUMMARY

1. The function generator constructed in accordance with the principle of quadratic approximations has the following basic advantages in comparison with function generators, in which piecewise-linear approximations are used.

a) A significant reduction in the number of segments of the argument partitioning which are necessary to reproduce the function with the same error. This permits one to simplify the universal function-generator's circuit, to decrease markedly the number of vacuum tubes, to ease significantly the set-up of the functions and the adjustments of the generator.

b) The function generator provides smooth reproduction of functions, and eliminates discontinuities in the first derivative.

2. With this, the universal function generator constructed on the basis of the principle of quadratic approximation possesses the following disadvantages.

a) The device's pass band is determined by the sawtooth generator's frequency which, due to technical difficulties, can not be made higher than 30 to 50 kcps. Therefore, the function generator cannot have a larger band than 1 kcps.

b) The sawtooth voltage has a high-frequency component, so that the mounting block requires careful screening.

Despite these disadvantages, the circuit developed for the universal function generator can find practical employment in electronic models and in various computing devices.

RELIABILITY CRITERIA FOR AUTOMATIC RELAY DEVICES WITH RADIOACTIVE EMITTERS

A. G. Vasil'ev, I. S. Zhitomirskii and K. S. Klempner
(Khar'kov)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 2, pp. 245-253, February, 1960)
Original article submitted July 17, 1959

Criteria are given for the reliability of automatic relay devices with sources of radioactive emission. The relationship is given connecting the parameters of the relay devices with the probability that a relay remain in a given state and, in addition, with the mean number of "false" transfers of the relay in unit time.

Calculated relationships were given in [1] which allow one to choose the minimum necessary activity of emitters in relay devices from the given limits on the admissible number of standard deviations of the operating utilization of the detector from the threshold level. In the work just cited, one limited oneself, in dealing with the statistical characteristics of the process, to an approximate representation of the potential distribution at the integrator relay's output as a Poisson distribution, or as a Gaussian distribution close to a Poisson one. The recommendations based on these considerations turn out to be of practical utility in determining the parameters of ordinary industrial relay devices. However, in many relay devices in which high reliability or speed of action are required, the accuracy of the computations based on the methodology of [1] may turn out to be inadequate.

Moreover, in the methodology given, the reliability of a device's operation was given only by the probability of a relay's remaining in the proper states. For many devices, in addition to this criterion, it is of great practical value to use, as a reliability criterion, the mean number of "false" transfers to be expected in unit time.

In the present work we render more exact the limits of applicability of the first approximation of [1] for various values of relay parameters. Methods are given for the numerical calculation of reliability to any desired degree of accuracy. Reliability is defined in terms of the probability of "false" relay transfers. Methods are given for the computation of the mean number of "false" transfers in unit time to any desired degree of accuracy. Grapl are given for the determination of reliability from the probability of remaining in a "false" state, and the number of "false" transfers for various combinations of the parameters of relay devices.

As was shown in [2] and [3] the characteristic distribution function of the random variable

$$x = \frac{V}{V_0} \tag{1}$$

for a Poisson distribution of the frequency of the applied signal n(t) and reaction function Φ(t) of the device has the form:

$$\vartheta(\lambda) = \exp\left\{ \int_{-\infty}^{T} \left[e^{i\lambda\Phi(T-t)} - 1 \right] n(t)\, dt \right\}. \tag{2}$$

From (2) we immediately obtain the expression for the cumulants of the distribution

$$k_\mu = \int_{-\infty}^{T} \Phi^\mu (T-t)\, n(t)\, dt. \tag{3}$$

We shall consider devices in which an RC network is used an the integrator. Then, the reaction function will have the form:

$$\Phi(t) = e^{-\frac{t}{RC}}. \tag{4}$$

In (1), V is the potential at the RC network's output and V_0 is the increment of potential at the RC network's output at the moment when a pulse is applied. In the steady state, V_0 is a constant. During transient responses, V_0 remains practically constant if the pulse amplitude is very much greater than the size of V_0 over its entire range of variation during the transient response. This condition holds with sufficient accuracy in all relay devices which operate as velocity measurers with linear scales.

A direct use of (2) for calculating a probability density and a distribution function would lead to extremely cumbersome computations. We shall consider two series expansions for the desired probability density p(x) and the distribution function F(x), one of which is useful for large values of

$$\nu = nRC, \tag{5}$$

and the other for small values of ν.

It was shown, in [2, 3] that, as $\nu \to \infty$, the desired distribution tends to a normal one. For computing the correction to the normal distribution, Rice suggested the use of a series first introduced by Edgeworth (an expansion in terms of the derivatives of the normalized density of a normal distribution). For the probability density, this series has the form:

$$\begin{aligned} p(x) = \frac{1}{k_2^{1/2}} \Bigg[& \varphi\left(\frac{x-k_1}{k_2^{1/2}}\right) - \frac{1}{3!}\frac{k_3}{k_2^{3/2}}\varphi^{(3)}\left(\frac{x-k_1}{k_2^{1/2}}\right) + \\ & + \frac{1}{4!}\frac{k_4}{k_2^{2}}\varphi^{(4)}\left(\frac{x-k_1}{k_2^{1/2}}\right) + \\ & + \frac{10}{6!}\frac{k_3^2}{k_2^{3}}\varphi^{(6)}\left(\frac{x-k_1}{k_2^{1/2}}\right) - \frac{1}{5!}\frac{k_5}{k_2^{5/2}}\varphi^{(5)}\left(\frac{x-k_1}{k_2^{1/2}}\right) - \\ & - \frac{35}{7!}\frac{k_3k_4}{k_2^{7/2}}\varphi^{(7)}\left(\frac{x-k_1}{k_2^{1/2}}\right) - \frac{280}{9!}\frac{k_3^3}{k_2^{9/2}}\varphi^{(9)}\left(\frac{x-k_1}{k_2^{1/2}}\right) + \ldots \Bigg], \end{aligned} \tag{6}$$

and, for the distribution function,

$$F(x) = 0{,}5 + \Phi\left(\frac{x-k_1}{k_2^{1/2}}\right) - \frac{1}{3!}\frac{k_3}{k_2^{3/2}}\varphi^{(2)}\left(\frac{x-k_1}{k_2^{1/2}}\right) + \frac{1}{4!}\frac{k_4}{k_2^{2}}\varphi^{(3)}\left(\frac{x-k_1}{k_2^{1/2}}\right) + \frac{10}{6!}\frac{k_3^2}{k_2^3}\varphi^{(5)}\left(\frac{x-k_1}{k_2^{1/2}}\right) - \frac{1}{5!}\frac{k_5}{k_2^{5/2}}\varphi^{(4)}\left(\frac{x-k_1}{k_2^{1/2}}\right) - \frac{35}{7!}\frac{k_3k_4}{k_2^{7/2}}\varphi^{(6)}\left(\frac{x-k_1}{k_2^{1/2}}\right) - \frac{280}{9!}\frac{k_3^3}{k_2^{9/2}}\varphi^{(8)}\left(\frac{x-k_1}{k_2^{1/2}}\right) + \ldots \tag{7}$$

In using the Edgeworth series, the greatest difficulty is in computing the distribution cumulants in the case when n is not constant. If the velocity of counting does not depend on time, then

$$k_\mu = \int_{-\infty}^{T} e^{\frac{\mu(t-T)}{RC}} n(t)\,dt = \frac{nRC}{\mu} = \frac{\nu}{\mu} \tag{8}$$

and the solution is essentially simplified.

We shall consider such relay devices for which the relative fraction of the time spent in a stationary state is quite large. Then, any consideration of the reliability of the relay's operation can be reduced to a consideration of its reliability in the stationary states.* For this case, (6) and (7) are written in the form

$$p(x) = \frac{0{,}5}{\sqrt{\nu}}\Phi_1\left(\frac{z}{\sqrt{2}}\right) - \frac{0{,}0278}{\nu}\Phi_4\left(\frac{z}{\sqrt{2}}\right) + \frac{0{,}00520}{\nu^{3/2}}\Phi_5\left(\frac{z}{\sqrt{2}}\right) + \frac{0{,}00617}{\nu^{3/2}}\Phi_7\left(\frac{z}{\sqrt{2}}\right) - \frac{0{,}000834}{\nu^2}\Phi_6\left(\frac{z}{\sqrt{2}}\right) - \frac{9{,}87\cdot 10^{-5}}{\nu^2}\Phi_8\left(\frac{z}{\sqrt{2}}\right) - \frac{3{,}58\cdot 10^{-6}}{\nu^2}\Phi_{10}\left(\frac{z}{\sqrt{2}}\right) + \ldots, \tag{9}$$

$$F(x) = 0{,}5 + \Phi(z) - \frac{0{,}0278}{\sqrt{\nu}}\Phi_3\left(\frac{z}{\sqrt{2}}\right) + \frac{0{,}00522}{\nu}\Phi_4\left(\frac{z}{\sqrt{2}}\right) + \frac{0{,}000773}{\nu}\Phi_6\left(\frac{z}{\sqrt{2}}\right) - \frac{0{,}000832}{\nu^{3/2}}\Phi_5\left(\frac{z}{\sqrt{2}}\right) - \frac{1{,}15\cdot 10^{-4}}{\nu^{3/2}}\Phi_7\left(\frac{z}{\sqrt{2}}\right) - \frac{4{,}20\cdot 10^{-6}}{\nu^{3/2}}\Phi_9\left(\frac{z}{\sqrt{2}}\right) + \ldots, \tag{10}$$

where

$$\Phi(z) = \frac{1}{\sqrt{2\pi}}\int_0^z e^{-\frac{V^2}{2}}\,dV \tag{11}$$

is a normalized Laplace function, $\Phi_n(z/\sqrt{2})$ is a derivative of the error probability integral and

$$z = \frac{x-k_1}{k_2^{1/2}} \tag{12}$$

is the multiplicity of the standard deviation.

It is easily shown [1,4] that

$$x = n_0RC, \tag{13}$$

$$k_1 = nRC, \tag{14}$$

$$k_2^{1/2} = \sqrt{\frac{nRC}{2}}. \tag{15}$$

After substituting (13)-(15) in (12), we get

$$z = \frac{2RC(n_0-n)}{\sqrt{2RCn}}, \tag{16}$$

where n_0 is the relay's operation threshold, i.e., the counting speed for which both relay states are equally probably. It is obvious that for the states in the absence of a controlled object on the control line (state 1) the magnitude of n will exceed n_0, and these states will be characterized by negative values of z. For the other state (state 2), the quantity z will be positive.

The essential disadvantage of (9) amd (10) is their nonuniform convergence. These series obviously have poor convergence for large values of z and small values of ν. For $\nu = 0$, the distribution function degenerates to the Heaviside unit function $\eta(x)$:

$$\eta(x) = \begin{cases} 0 & \text{for } x < 0, \\ 1 & \text{for } x \geqslant 0. \end{cases} \tag{17}$$

Therefore, for large z and small ν, it is meaningful to use expansions based on the function $\eta(x)$.

One is led to this type of expansion by a method analogous to that used by Maslov and Povzner [5].

As one may easily convince oneself, the desired probability density p(x) is the solution of the equation

$$\frac{\partial u}{\partial y} = \int_0^1 \frac{u(x-x', y) - u(x, y)}{x'}\,\nu\left(\ln x' + \frac{T}{RC}\right)dx' \tag{18}$$

with initial conditions

$$u(x, 0) = \eta(x) \tag{19}$$

and for the parameter value y = 1.

For y = 1, the distribution function F(x) also coincides with the solution of (18), but with the initial conditions

$$u(x, 0) = \eta(x). \tag{20}$$

With initial conditions (20), the solution of (18) can be obtained either by the methods of finite differences, or in the form of a series

$$F(x) = e^A[\eta(x)] = \eta(x) + A[\eta(x)] + \frac{1}{2!}A^2[\eta(x)] + \ldots + \frac{1}{m!}A^m[\eta(x)], \tag{21}$$

where the letter A denotes the integral operation

$$A[u(x)] = \int_0^1 \frac{u(x-x') - u(x)}{x'}\,\nu\left(\ln x' + \frac{T}{RC}\right)dx'. \tag{22}$$

The convergence of (21) is also nonuniform. For small x, the series converges rapidly, and it is meaningful to use it. For large x, it is more convenient to use finite-differences methods.

---

* A criterion for reliability of relay operation during the transient response could be the probability of just one transfer during the response time.

Computing the distribution function by some method or other, we can find the average time that the relay remains in a given state.

In addition, as has been stated, it is necessary to compute the mean number of "false" transfers per unit time. For an inertialess relay, this problem leads to the determination of the number of intersections of the current potential value with the potential value V_n for which the relay changes state. For state 1, $|\bar{V}| > |V_n|$, and the problem reduces to finding the number of intersections coming down from above ($S\downarrow$). For state 2, $|\bar{V}| < |V_n|$, it is necessary to compute the number of intersections going up from below ($S\uparrow$).

The general formula, well known in the literature [6], for finding the stated quantity ("mean number of blips") requires, for its practical use, a tremendous amount of computation.

In our case, finding the expression for the mean number of intersections poses no difficulty.

We consider a small interval of dimensionless time $\tau = t/RC$, $(\tau, \tau + \Delta\tau)$. The average number of intersections of some level x_0, both coming down from above and going up from below, in this interval is an infinitesimal quantity of the order of $\Delta\tau$. As is known [6], this quantity can be replaced, with an accuracy of second-order infinitesimals in $\Delta\tau$, by the probability $P_{\tau,\Delta\tau}$ of one intersection going up from below and the probability $P_{\tau,\Delta\tau}$ of one intersection coming down from above. Our aim is to find the following limits:

$$S^{\uparrow} = \lim_{\Delta\tau\to 0} \frac{1}{\Delta\tau} P^{\uparrow}_{\tau,\Delta\tau}, \tag{23}$$

$$S^{\downarrow} = \lim_{\Delta\tau\to 0} \frac{1}{\Delta\tau} P^{\downarrow}_{\tau,\Delta\tau}.$$

Thus, the quantities $P^{\uparrow}_{\tau,\Delta\tau}$ and $P^{\downarrow}_{\tau,\Delta\tau}$ can be found with an accuracy of second-order infinitesimals in $\Delta\tau$.

Each of the realizations of the process under consideration increases by a unit jump when a pulse is applied, and decays exponentially in the intervals between pulses.

A realization of the process can intersect the level x_0 from above to below if, and only if, the quantity $x(\tau)$ at time τ lies between the limits x_0 and $x_0e^{\Delta\tau}$ and, in the time interval τ, $\tau + \ln(x/x_0)$, no pulse is applied. Thus,

$$P^{\downarrow}_{\tau,\Delta\tau} = \int_{x_0}^{x_0e^{\Delta\tau}} p(x)\left(1 - \nu(\tau)\ln\frac{x}{x_0}\right)dx \approx x_0 p(x_0)\,\Delta\tau, \tag{24}$$

where the last equality holds with the accuracy required.

It immediately follows from (24) that

$$S^{\downarrow} = x_0 p(x_0). \tag{25}$$

If we now make the transition from dimensionless time to ordinary time, and take (1), (9), and (12)-(16) into account, we obtain the definitive formula

$$S^{\downarrow} = n_0 p(x). \tag{26}$$

Intersection of level x_0 from below upwards is possible if, and only if, $x(\tau)$ lies between x_0-1 and x_0 and a pulse is applied during an interval less than $\ln[x/(x-1)]$. This means that

$$\begin{aligned} P^{\uparrow}_{\tau,\Delta\tau} = \nu(\tau)\,\Delta\tau \int_{(x_0-1)e^{\Delta\tau}}^{x_0} p(x)\,dx + \nu(\tau)\, \times \\ \times \int_{x_0-1}^{(x_0-1)e^{\Delta\tau}} p(x)\ln\frac{x}{x_0-1}\,dx \approx \\ \approx \nu(\tau)\,\Delta\tau \int_{x_0-1}^{x_0} p(x)\,dx. \end{aligned} \tag{27}$$

Whence,

$$S^{\uparrow} = \nu(\tau) \int_{x_0-1}^{x_0} p(x)\,dx = \nu(\tau)\,[F(x_0) - F(x_0 - 1)]. \tag{28}$$

For values of $x_0 \gg 1$ (this corresponds, as is easily seen, to $n_0RC \gg 1$), we can set

$$S^{\uparrow} = \nu(\tau)\,p(x_0). \tag{29}$$

After simple transformations, we finally obtain†

$$S^{\uparrow} = np(x). \tag{30}$$

Starting from what has been presented, we can write the expression for the average blip duration. For state 1 we get

$$T^{\downarrow} = \frac{F(x)}{n_0 p(x)}, \tag{31}$$

and for state 2

$$T^{\uparrow} = \frac{1 - F(x)}{np(x)}. \tag{32}$$

It is of interest to find the expressions for the distribution of durations in "false" states and for the distribution of the number of "false" intersections. This is a complicated problem, and will not be treated in the present work. At the same time, for example, it is easily seen that, with the condition

$$\frac{1}{S^{\downarrow}} > T^{\downarrow} \quad \text{or} \quad \frac{1}{S^{\uparrow}} > T^{\uparrow} \tag{33}$$

the distribution of the number of "false" intersections is close to a Poisson distribution.

We now consider concrete results of computations based on the method presented here.

There is great interest in determining the quantities $1 - F(x)$, $F(x)$, $S^{\downarrow}$, $S^{\uparrow}$, $T^{\downarrow}$, $T^{\uparrow}$ for a wide interval of values of ν and $\underline{z}$.

Of practical interest are the solutions for large values of $\underline{z}$, corresponding to automation and control systems in which "false" transfers lead to very undesirable consequences, and for small ν. Such solutions are obtained effectively by means of computers, using the method presented above [(17)-(22)].

---

† For reliability characteristics based on the number of "false" intersections, one can also use functions of S which take on values from 0 to 1, for example, $P(S) = 1/(1+S)$.

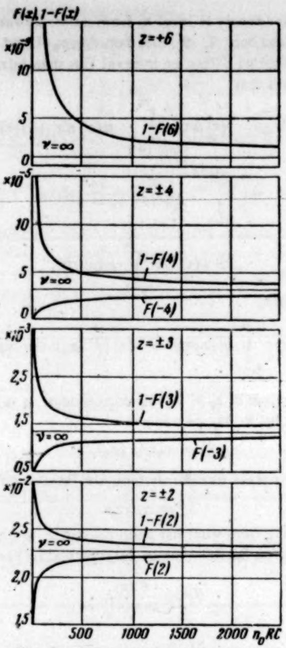

Fig. 1. Values of the probability of the potential remaining in a "false" state.

For widely used relay devices working with low values of z and large values of ν, one can use the Edgeworth series (9) and (10) for the direct computation of the quantities listed above. The values of $\Phi_n(z/\sqrt{2})$ are computed by means of Hermite polynomials:

$$\Phi_n\left(\frac{z}{\sqrt{2}}\right) = (-1)^{n-1} 2^{\frac{n-1}{2}} \frac{2}{\sqrt{\pi}} e^{-\frac{z^2}{2}} H_{n-1}(z). \qquad (34)$$

Figure 1 shows the values of the quantities F(x) and 1-F(x) for several values of z and $n_0RC \ll 2500$. These quantities equal the mean relative time the potential remains in a "false" state for, respectively, state 1 and state 2. The computations were made with all the terms actually written above in (10). For convenience in comparing the results with those previously obtained [1], the product n_0RC has been laid out along the axis of abscissas, being defined, as follows from (5) and (16), by the expression

$$n_0RC = \nu + 2\sqrt{\frac{\nu}{2}}. \qquad (35)$$

The first two terms in (10) do not depend on ν, and give a solution in a Gaussian approximation ($\nu = \infty$). As is clear from Fig. 1, in determining the relative time spent in a "false" state, the deviation from the Gaussian approximation is the larger, the larger is z and the smaller is the product n_0RC.

It should be mentioned that, for state 1, the computations carried out in the Gaussian approximation lead to an increase in the actual reliability of state 1 in comparison with the given value. With this, the value of the minimum necessary activity of the radiation source of 1 is somewhat overstated. In connection with this, as is clear from Fig. 1, the reliability of state 2 will be lower than that which follows from the computations in the Gaussian approximation, from whence the value of the limiting admissible activity of the radiation source turns out to be somewhat overstated. However, in devices in which the controlled object provides a significant attenuation of the emission, the magnitude of the limiting admissible activity significantly exceeds the value of the minimum necessary activity, as is clear from the calculations made in [1]. For these devices, one need not take into account, in calculating source activity, the deviations from the Gaussian approximation for state 2.

The deviations changing, by an order of magnitude, $0.5-\Phi(z)$ occur at $z = \pm 2$ for $n_0RC \overset{\sim}{<} 10$, at $z = \pm 3$ for $n_0RC \overset{\sim}{<} 30$ and at $z = \pm 4$ for $n_0RC \overset{\sim}{<} 50$. Therefore, the Gaussian approximation, as was already noted [1], encompasses a wide circle of problems, but is inadequate when one deals with devices designed for high reliability (large z), high speed of response (low RC) in conjunction with high sensitivity of the relay to radiation (small n_0).

At $z = -6$, the magnitude of $F(-6)$ is $(0.2 \text{ to } 0.5)10^{-9}$ for values of n_0RC from 500 to 2500. In calculating the value of $F(-6)$ for $n_0RC < 500$, the number of terms written in (10) turned out to be inadequate.

The table gives the upper limits on the error of computing the quantities 1-F(x) and f(x), using all the terms actually written in (10). The errors are stated to within 1%. As is clear from the table, the error in computing the relative time in a "false" state falls with decreasing ν and with increasing z.

The accuracy of the determination of the number of "false" transfers is determined by the accuracy of determining the quantity p(x), as is clear from (26) and (30). The accuracy of computing the quantities $S\downarrow$ and $S\uparrow$ varies in approximately the same manner as that for the relative duration of the relay in a "false" state (Cf. the table).

For various values of z and RC, Fig. 2 shows the number of "false" intersections of potential per unit time as a function of n_0. At $z = 6$, the number of terms of (9) taken into account permit the computations to be made only for relatively large values of n_0RC. For example, the computations give $S\uparrow \approx \text{const} \approx 2 \cdot 10^{-8}$ for $z = 6$, $RC = 50$ and $n_0 < 200$.

As is clear from Fig. 2, the number of intersections $S\downarrow$ and $S\uparrow$ do not equal each other for the same multiplicity of the standard deviation. This is particularly apparent for large values of z.

TABLE Error in Computing the Relative Time the Potential Remains in a "False" State

ν	Error less than δ_z, %							
	z							
	+2	−2	+3	−3	+4	−4	+6	−6
10	0	1	2	90	11	448		
20	0	0	1	8	6	325		
50	0	0	0	2	3	47		
100	0	0	0	0	1	9	28	
200	0	0	0	0	1	2	18	
500	0	0	0	0	0	1	8	148
1000	0	0	0	0	0	0	4	32
2500	0	0	0	0	0	0	2	6
5000	0	0	0	0	0	0	1	2

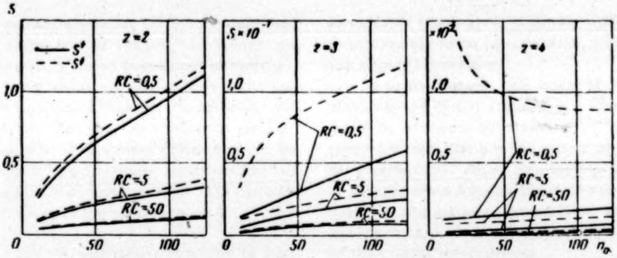

Fig. 2. Average number of "false" intersections of the potential per unit time.

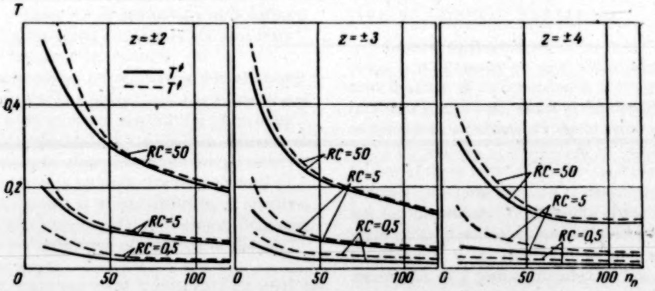

Fig. 3. Average time of "false" intersections.

Figure 3 shows the average time the potential remains in a "false" state for various values of z, n_0 and RC, calculated by (31) and (32).

It should be mentioned that the inertia of the electrical (for example, lamps or bells in the anode circuit of power amplifier relays) or electromechanical relay output (electromechanical relay) can lead to a certain lack of coincidence of the relative time the relay contacts (lamps, bells) remain in a "false" state as compared with the values computed by the method presented above.

On the one hand, a sufficiently inertial output at relay operation will not react on intersections less than some value T_0, determined by this inertia. On the other hand, relays with long release times will lead to a drawing out of the time that the relay device remains in a "false" state after the "false" intersection of the potential has terminated.

With respect to "false" relay transfers, it may be remarked that their number can be somewhat less than the number of "false" intersections of potential, due both to intersections lasting less than T_0 and to the appearance of more than one intersection while the contacts are to be found in a "false" state. These circumstances act to increase the relay's reliability, defined in terms of number of intersections, but limit its speed of response to a well-known extent.

Based on the results given above, one can calculate the relative duration of relay contacts in "false" states and the number of "false" contact transfers for concrete relays with known characteristics. Since the number of known relay types is very large, this question requires special consideration.

In conclusion, the authors wish to thank L. K. Tatochenko for the great interest shown in the present work, and for a number of very useful comments.

ESTIMATES, BASED ON USAGE, OF THE SERVICE LIFE OF CONTACT APPARATUS

D. A. Abdullaev

(Tashkent)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 2, pp. 254-259, February, 1960)
Original article submitted April 15, 1959

The region of useful life of contact apparatus is determined as a function of its modes of operation and of the given admissible number of transfers. Starting from the service life, we estimate the increment of use expenditure per element.

Hitherto, relay contact apparatus has been widely used in systems for automation, remote control, communication, etc. The breakdowns (out-of-order conditions) of individual elements and blocks† which are unavoidable under conditions of use require significant time for the detection and replacement of the faulty element. As a rule, the system must stand idle during this. The system's idle time can be reduced to a minimum by the opportune determination and replacement of the element or block at fault. On the other hand, this measure eliminates the possibility of faulty system operation.

It is well known that the probability of failure of the electromechanical (receiving) portion of a relay element is very much less than the probability of failure of its contacts [1]. This allows one to estimate, with a definite degree of accuracy, the useful state of an element from the probability of failure of its contacts.

A general methodology for estimating the reliability of operation of contacts in a given circuit as a function of such factors as contact pressure, possibilities of sparking or arcing, changes in the form of the contacts' surfaces and other physical reasons for their breakdown are given in [1, 2]. The essential obstacle to using this methodology in usage computations is that it is very difficult, in practice, to determine the data necessary for the computations and, consequently, for the estimation of the state of the contracts during their usage.

The method, described by N. Taylor [3] (the marginal checking method), for inspecting allows one to detect elements which are on the point of breaking down and to replace them. However, this method has been developed as applied to electronic apparatus. Its practical use for the estimation of contact apparatus is not worthwhile, since it entails superfluous operations.

The common feature of these methods is that testing and verifying of element states must be carried out directly at the location where the elements are mounted or by removing them which, in many cases, can turn out to be impossible or inadmissible in practice.

It follows from this that it would be of interest to develop a method for the indirect estimate of the state of contact apparatus. Such a method, which would permit one to determine, if only approximately, the length of serviceable life a given element, would make it possible to replace elements in good time, without detriment to the system's operation.

In actual systems, the modes of operation of different elements and blocks are diverse. Therefore, their breakdowns do not occur simultaneously. If the conditions imposed are such that a given system must operate properly for a period of H years, then the replacement of elements or blocks before the expiration of this period entails an increase in the material expenditure, a "use" expenditure in the given case. It is of interest to estimate the variation of these latter expenditures.

Admissible Duration of Continuous Operation of Contact Apparatus

In order to replace an element at the breakdown point, it is necessary to know beforehand what the admissible duration of its operation is in the given mode of work. It is well known that, under given conditions and modes of operation, an element's useful service life is determined by the number of transfers of its contacts [1]. Since failure of these latter is a random phenomenon, one of the principal problems amounts to determining the distribution law for the probability of failure of the contacts of an element under given conditions. We note that certain authors, for example, V. A. Moroz [4], in their works start with the assumption of a normal distribution law.

In this work we shall adopt the convention that, on the basis of tests and statistical data on the operation of elements whose mode of operation is given by the parameters and structure of the scheme under consideration, we shall have determined the distribution law of the probability of contact failure, and that from this we shall have found the admissible number of transfers of the latter, N_{adm}.

If we start from this condition, then we can determine the admissible duration of continuous operation of an element for a given speed of transfer of its contacts during a call cycle. For electromagnetic elements, this is

---

† By the term "block" in the present paper, we understand a set of elements implementing a definite function and which are found under identical operating conditions.

$$T_{\text{adm}} = \frac{N_{\text{adm}}}{v \cdot 3600} \text{ hr}, \qquad (1)$$

where v is the speed of contact transfers, in units of $\sec^{-1}$.

Definite types of reed frequency elements, in the process of signal reception, transfer the contacts in each period of current (voltage) oscillation, coinciding with their natural frequency (Cf., for example, [5]). If oscillations of frequency f, to which the frequency element is tuned, exist during time t, then the total number of contact transfers during this time will be ft. Consequently,

$$T_{\text{adm}} = \frac{N_{\text{adm}}\tau}{3600\, ft} \text{ hr}, \qquad (2)$$

where τ is the period of a call cycle, cycle, in seconds ‡.

Thus, the admissible duration of continuous operation of a reed element depends both on its natural tuned frequency, and on the time during which the signal exists.

Domain of Proper Operation of Contact Apparatus

If a given circuit element operates N_c times during one call cycle with transfer velocity v, then the duration of its continuous operation with transferring contacts will equal

$$T_c = \frac{N_c}{3600 v} \text{ hr}, \qquad (3)$$

We assume that n_h call cycles are made during one hour. Then, the time of continuous element operation during one hour is defined by the expression

$$T_h = \frac{n_h N_c}{3600\, v} \text{ hr}, \qquad (4)$$

Multiplying (4) by the number of hours in a year, we obtain the time of proper element operation during one year:

$$T_y = \frac{n_h N_c}{3600\, v} 8760 \text{ hr}, \qquad (5)$$

From the design conditions, the useful life of the system must be not less than H years. During this period, the element under consideration must be found in the mode of continuous operation during

$$T' = HT_y = \frac{Hn_h N_c}{3600\, v} 8760 \text{ hr}, \qquad (6)$$

where H is a dimensionless quantity expressing a quantity of years.

With the condition that

$$\frac{T_{\text{adm}}}{T'} \geqslant 1, \qquad (7)$$

the given element operates properly until the end of the proposed time of proper functioning of the entire system. It is therefore not necessary to replace it. Otherwise, replacement would be necessary.

By substituting (1) and (6) in (7), we get

$$\frac{N_{\text{adm}}}{8760\, Hn_h N_c} \geqslant 1. \qquad (7')$$

Whence,

$$n_h N_c \leqslant \frac{N_{\text{adm}}}{8760\, H}. \qquad (8)$$

The left member of (8) is the number of transfers of the element in one hour. We call it the hourly intensity of the element's operation, and we use the notation

$$Q = n_h N_c.$$

Then, (8) can be given in the form

$$Q \leqslant \frac{N_{\text{adm}}}{8760\, H}. \qquad (8')$$

Thus, we have established the possibility of proper element operation with a given N_{adm} as a function of the intensity of its operation. The appended figure gives the curve for $Q = \varphi(H)$, constructed from the condition of equality of the left and right members of (8'). It is therefore a boundary line: the region below it characterizes proper operation, and the upper region characterizes improper functioning of the element during the given period H. It should be mentioned that the character of variation of the curve $Q = \varphi(H)$ coincides with the character described by Feugel for the experimental reliability characteristic as a function of time [6]. This confirms the correctness of the initial premises of our analysis.

In a similar way, we can obtain the expression for estimating the useful life of reed frequency elements (Cf. the Appendix)

$$Q \leqslant \frac{N_{\text{adm}}}{8760\, H}\left(\frac{\tau}{t}\right). \qquad (9)$$

It follows from this that, to increase the useful life of a reed element, tuned to frequency f, it is necessary to shorten the signal's transmission time t. This is possible only if the speed of response of the element itself is increased.

Estimating the usage state of contact apparatus by the method presented here is most effective in the case of mass-produced devices, since the value of N_{adm}, established just once on an experimental basis for individual elements and blocks, can be used as a basic parameter for all the apparatus produced in the same production run.

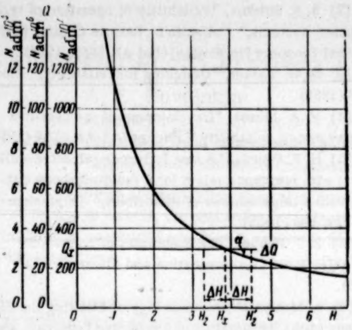
Influence of Useful Life of Apparatus on Its "Use" Expenditure

The economic efficiency of employing a system is usually estimated by the time taken to recoup its costs [7]

$$T = \frac{\Sigma K}{E_y}, \qquad (10)$$

---

‡ Here we have in mind parallel transmissions of frequency-indication pulses.



Boundary of the proper functioning characteristic of a relay contact element.

where Σ K is the total expenditure and E_y is the annual saving.

The total expenditure, together with the one-shot initial capital outlay and the wage fund for the personnel, includes deductions for amortization and maintenance, i.e., operating costs ("use" expenditures), a variable quantity which depends on maintenance and replacement periods of the system's individual elements and blocks.

Operating costs per element, in monetary units, we denote by K_A/A, where A is the total number of contact elements in the system. As a percentage of the sum of costs,[**] this quantity amounts to

$$K_A^{\bullet} = \frac{K_A \Sigma K}{A \cdot 100}. \tag{11}$$

By substituting the value of ΣK from (10), we obtain

$$K_A^{\bullet} = \frac{K_A}{100\,A}\,T E_y, \tag{11'}$$

whence,

$$T = \frac{K_A^{\bullet} A \cdot 100}{K_A E_y}. \tag{a}$$

The condition for proper apparatus functioning during the time taken to recoup the system's cost is

$$T \leqslant H_x, \tag{12}$$

where H_x, for a given mode of element operation, is determined from the proper curve of $Q = \varphi(H)$. We assume that

$$T = H_x \pm \Delta H.$$

Obviously, element replacement is necessary if it is the plus sign which stands before ΔH. We now analyze how the quantity $K_A^{\bullet}$ varies with this.

From the figure, we have

$$\frac{\Delta Q}{\Delta H} = \tan\alpha \tag{13}$$

or

$$\frac{dQ}{dH} = \tan\alpha.$$

Bearing in mind the condition for the construction of the curves $Q = \varphi(H)$, we find from (8') that

$$\frac{dQ}{dH} = -\frac{N_{adm}}{H^2 \cdot 8760}. \tag{14}$$

By substituting the value of tan α in (13), we get

$$\Delta H = -\frac{\Delta Q H^2 \cdot 8760}{N_{adm}}. \tag{15}$$

If we adopt the convention that the values of $K_A^{\bullet}$ determined from (11') correspond to $H_x \geq T$ then, for $H_x < T$, the magnitude of the operating costs is expressed by the formula

$$K_{A1}^{\bullet} = \frac{K_A}{100\,A}\,E_y H \left(1 + \frac{\Delta Q H}{N_{adm}}\,8760\right). \tag{16}$$

The relative increment of operating costs per element, as a function of the mode and intensity of its operation, is defined by the expression

$$\Theta = \frac{K_{A1}^{\bullet}}{K_A^{\bullet}} = 1 + \frac{\Delta Q H}{N_{adm}}\,8760. \tag{17}$$

We can, by a similar method, obtain the expression for the case when reed elements are used

$$\Theta = 1 + \frac{\Delta Q H}{N_{adm}}\left(\frac{t}{\tau}\right) 8760. \tag{18}$$

SUMMARY

1. The curves $Q = \varphi(H)$ for a system's individual elements and blocks allow timely replacement of elements on the verge of breakdown, and thereby reduce to a minimum the system's down time.

2. The expressions obtained permit the approximate estimation of and, if necessary, the correction of, initially assumed values for, the operating costs as applied to apparatus operating in identical conditions.

The development of a method for estimating the system as a whole is the subject of a special investigation.

The author takes this opportunity to express his profound gratitude to B. S. Sotskov for posing the problem and for giving his attention to its solution.

Appendix

Derivation of Expression (9)

The numbers of transfers of a frequency element during one call cycle is

$$N_c = ft.$$

If the given object is called n_h times an hour, then the total number of transfers of the element's contacts which participate in the selection of the given object, is

$$N_h = n_h N_c = n_h f t. \tag{19}$$

It is obvious that the quantity $n_h t = T_h$ is the duration of continuous transfer of the element's contacts during one hour. From (19),

---

[**] As in Russian. The correct percentage should be $\frac{K_A \cdot 100}{A \Sigma K}$ – Publisher.

$$T_h = \frac{N_c n_h}{f \cdot 3600} \text{ hr.} \tag{20}$$

The time of continuous transfer of the element's contacts during one year is

$$T_y = \frac{N_c n_h}{f \cdot 3600} \, 8760 \text{ hr} \tag{21}$$

Furthermore,

$$T' = HT_y = \frac{HN_c n_h}{f \cdot 3600} \, 8760 \text{ hr} \tag{22}$$

By denoting $Q = N_c n_h = ftn_h$, and dividing (22) by (2), we obtain (9)

$$Q < \frac{N_{adm}}{H \cdot 8760} \left(\frac{\tau}{t} \right).$$

A NUMERICAL-TO-ELECTRICAL CONVERTER

A. K. Zavolokin

(Moscow)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 2, pp. 260-265, February, 1960)
Original article submitted September 2, 1959

The block diagram is described of a transducer which converts numerical quantities to proportional values of voltage or current, the conversion being based on the principle of an intermediate transformation to time intervals. The converter's operation is analyzed, and some general considerations relating to the design of such devices are given.

For the purpose of transforming numerical quantities to voltages or currents proportional to them, one can, in many cases, make very effective use of the principle of intermediate transformation of the numbers to time intervals. Below we describe a device based on this principle. Its operation is characterized by this, that in each transformation cycle one counter is used to develop two successive signals whose durations are such that the time for the entire cycle remains invariant while the duration of one of the signals is proportional to the value of the input quantity. This signal is used for modulating a stabilized dc voltage or current. After being smoothed, the duration-modulated voltage (current) is converted to the electrical equivalent of the numerical quantity.

To elucidate the principle of operation, we consider the block diagram shown in Fig. 1. It consists of the output register of a computer (triggers T'_1-T'_n), gates for uncomplemented code (g_1-g_n), gates for complemented code (g'_1-g'_n), a counter (triggers with counter inputs T_1-T_n), controlling trigger T, key K and smoothing device SD. The rectangles with the sketches of the bipolar pulses in them in Fig. 1 denote differentiating networks. One of the pulses in each rectangle has a stroke through it. This means that the pulses of this polarity will not henceforth be used.

The converter's operation is comprised of two cycles. In the first cycle, via gates g_1-g_n, the code for the number N to be converted is written in parallel in the counter. Pulses continuously applied to the counter's input with frequency f are added to the number written there, so that the counter is returned to its zero state at some moment of time. At this moment, an overflow pulse is emitted by its last stage (trigger T_n). The emission of the overflow pulse terminates the first cycle of operation.

At the beginning of the second cycle, the overflow pulse reverses the state of trigger (flip-flop) T, opening key K. Simultaneously with the key's opening, a signal from the differentiating network is applied to gates g'_1-g'_n, by means of which the number N is again written in the counter, but this time in complemented code. Input pulses again are added into the counter until it is reset to zero. At the moment when the counter returns to its zero state, a second overflow pulse is emitted, transferring T to its original state. This leads to the closing of the key and to the writing of the number N in uncomplemented form in the counter. After this, the aforementioned two-cycle process is repeated.

It is easily seen that the duration $\bar{\tau}$ of the first cycle is linearly related to the number $\bar{N}$, the complement of the number N, namely

$$\bar{\tau} = \frac{\bar{N} + 1}{f}. \tag{1}$$

The equality just written is the mathematical expression of a well-known property of an n-place counter, staticizing input pulses in the number system, with radix b, which has been adopted. This property is formulated as follows. If some number is staticized in a counter, then the counter will be returned to its zero state after one adds to it a series of input pulses, the number of which would bring the counter total to b^n (i.e., the number of pulses is the 10's complement in the decimal system, the 2's complement in the binary system). This added number equals the complement of the given number (i.e., its 9's complement in the decimal system, its 1's complement in the binary system) plus one. Therefore, $\bar{\tau}$ can be defined as the product of $(\bar{N}+1)$ by the size of the interval between two neighboring input pulses.

As an example, we consider two special cases, when the numerical quantity to be converted, expressed in the binary system, has its maximum and minimum values. If $N = 0$ ($\bar{N} = 2^n - 1$), then the number written in the counter in the first cycle will equal zero. Consequently, the overflow pulse appears at the counter's output after 2^n input pulses, i.e., in the given case $\bar{\tau} = 2^n/f$. If the number to be transformed has its maximum value, that is, $N = 2^n - 1$ ($\bar{N} = 0$), then all the counter triggers will be in their "1" state at the beginning of the first cycle, and the application of the first input pulse will lead to the emission of the overflow pulse, i.e., for this case, $\bar{\tau} = 1/f$. We may show analogously that for any intermediate value, the magnitude of $\bar{\tau}$ is determined in accordance with (1).

The number written in the counter at the beginning of the second cycle equals $\bar{N}$. Therefore, the duration τ of the second cycle can be obtained from the expression

$$\tau = \frac{N + 1}{f}. \tag{2}$$

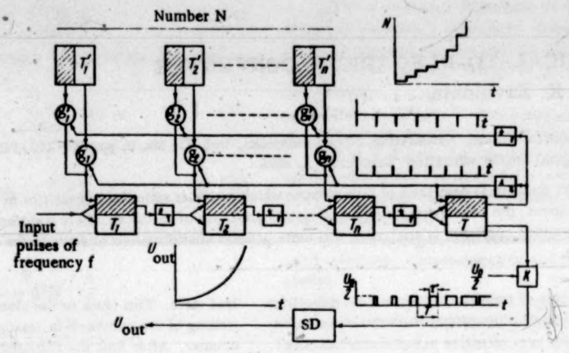

Fig. 1

On the basis of (1) and (2), the time T of a complete cycle, equal to the sum $\bar{\tau} + \tau$, is defined as

$$T = \frac{\overline{N} + N + 2}{f}. \qquad (3)$$

On the other hand, it is well known that the addition of an n-place binary number N to its complement $\overline{N}$ results in a constant which is independent of the absolute magnitude of N, namely:

$$N + \overline{N} = 2^n - 1 \qquad (4)$$

Consequently,

$$T = \frac{2^n + 1}{f}. \qquad (5)$$

On the basis of (5) and (2), we can draw the very important conclusion: in a converter executed in accordance with the block diagram of Fig. 1, the duration of a full cycle (composed of the two part cycles) does not depend on the value of the numerical quantity N to be converted. With this, each cycle consists of two part cycles; the duration of one of them, corresponding to the open state of key K, is a linear function of the number N.

The key K is connected in series in a current generator circuit, or in parallel to a dc voltage generator. In the first case, there will be at the smoothing device's input, duration-modulated current pulses and, in the second case, voltage pulses. Depending on which quantity is smoothed, the numerical quantity will be converted either to current or to voltage. For the sequel, this difference is immaterial so that, for the sake of definiteness, we shall assume that the number is converted to a voltage. Figure 2,a shows the curve of voltage variation at the smoothing device's input as a function of time u = f(t).

The output voltage U_{out} of the smoothing device is proportional to the mean value of the input voltage. If we denote the modulated dc voltage by $U_0/2$, we can write

$$U_{out} = \frac{U_0}{2}\frac{\tau}{T}. \qquad (6)$$

Or, taking (2) and (5) into account,

$$U_{out} = \frac{U_0}{2^{n+1} + 2}(N + 1). \qquad (7)$$

It is clear from (7) that the value of U_{out} is strictly proportional to the converted numerical quantity N. The constant term connected with the "1" in the parenthetical expression (N+1) can always be compensated, either by writing the number N-1, instead of N, in the computer's output register, or by biasing U_{out} by the quantity $U_0/(2^{n+1}+2)$.

Depending on the concrete requirements, the smoothing device can be executed in various ways. In particular, it may turn out to be advantageous to use the corresponding filters, special electronic devices or even simply pointer instruments indicating the average value of voltage (current). A consideration of all the possible practical variants

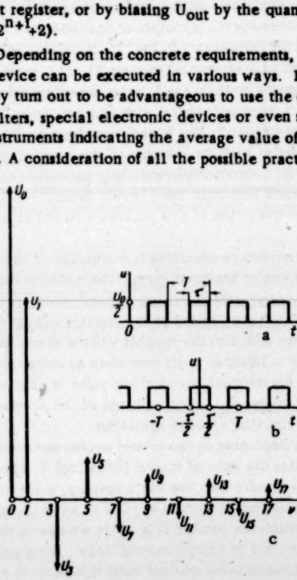

Fig. 2. The curve for u = f(t) and the frequency spectrum for θ = 0.5.

of the smoothing device is not part of our present task. It is relevant here to cite only several general considerations which should be kept in mind in designing it. For this, it is first necessary to look into the magnitude of the individual harmonic components of the curve u = f(t).

In accordance with the converter's principle of operation, u = f(t) for a given N is a periodic function. At any of its points it satisfies the Dirichlet condition, and may be expanded in a trigonometric series. We choose the origin of coordinates as is shown in Fig. 2,b. In this case, the function is an even one and, when expanded in a Fourier series, will have, in addition to the constant term defined by (6), only cosinusoidal terms. With this, the amplitude of the ν th harmonic U_ν is computed as the coefficient in the Fourier series

$$U_\nu = \frac{2}{T}\int\limits_{-T/2}^{+T/2} f(t)\cos\frac{2\pi}{T}\nu t\,dt. \tag{8}$$

If we bear in mind that the function f(t) has the constant value of $U_0/2$ in the interval $(-\tau/2+0) \leq t \leq (\tau/2-0)$ and equals zero in the intervals $-T/2 \leq t \leq (-\tau/2-0)$ and $(\tau/2+0) \leq t \leq T/2$, we can write Expression (8) in the form

$$U_\nu = \frac{U_0}{T}\int\limits_{-\tau/2}^{+\tau/2} \cos\frac{2\pi}{T}\nu t\,dt. \tag{9}$$

By carrying out the integration in (9), we get

$$U_\nu = \frac{U_0}{\pi\nu}\sin\pi\nu\frac{\tau}{T}. \tag{10}$$

By denoting the duty factor, equal to the ratio τ/T, by θ we can write

$$U_\nu = \frac{U_0}{\pi\nu}\sin\pi\nu\theta. \tag{11}$$

If we differentiate (11), we arrive at the expression

$$\frac{dU_\nu}{d\theta} = U_0\cos\pi\nu\theta. \tag{12}$$

Equating the right member of (12) to zero:

$$U_0\cos\pi\nu\theta = 0, \tag{13}$$

we can find the values of θ which correspond to maximum values of U_ν from the condition

$$\nu\theta = \frac{k}{2}, \tag{14}$$

where k is any odd integer.

It must be mentioned that not all solutions which satisfy (14) should be taken into consideration. In fact, it is clear from (2) and (5) that

$$\theta = \frac{N+1}{2^n+1}. \tag{15}$$

Since N is included in the interval

$$0 \leqslant N \leqslant 2^n - 1,$$

then

$$\frac{1}{2^n+1} \leqslant \theta \leqslant \frac{2^n}{2^n+1}. \tag{16}$$

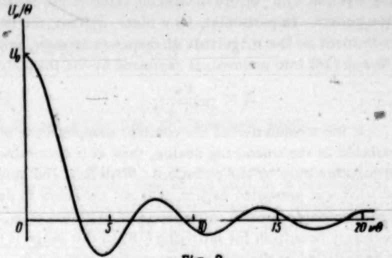

Fig. 3

Consequently, only those solutions of (14) have physical meaning for which the value of θ, for a given ν, satisfy (16). In particular, for $\nu = 1$, only the one value of θ equal to 0.5 is meaningful; for $\nu = 3$, the three values of θ, equal to 1/6, 1/2, and 5/6; for $\nu = 5$, the five values of θ equal to 0.1, 0.3, 0.5, 0.7, and 0.9, etc. It is characteristic of all this that there exists a unique value of θ, equal to 0.5, for which the peak voltage of all the harmonics, including the first, is a maximum. This can be confirmed by setting $\theta = 0.5$ in (14). After this substitution, we obtain the equation

$$\nu = k, \tag{17}$$

which is satisfied for any odd ν. Therefore, the computations of the admissible pulsations at the output of the smoothing device should be carried out for the case $\theta = 0.5$, which is the most disadvantageous from the point of view of the size of the harmonic component. The frequency spectrum for this case, constructed on the basis of (6) and (11), is given in Fig. 2,c.

Figure 3 shows the envelope of the frequency spectrum for any physically meaningful values of ν and θ. Here, the quantity U_ν/θ has been laid out along the axis of ordinates, instead of U_ν, and the product $\nu\theta$, instead of ν, has been taken as the independent variable. As a result of these replacements, we can use one graph to show, in general form, the relationships between ordinal number of harmonic, magnitude of the individual components' amplitudes and the duty factors, which are proportional to the number N to be converted. The graph was constructed on the basis of (11), which can be written in the form

$$\frac{U_\nu}{\theta} = U_0\frac{\sin\pi\nu\theta}{\pi\nu\theta}. \tag{18}$$

The harmonic components cause pulsations at the output of the smoothing device. In its turn, the size of the admissible pulsations is closely connected with the accuracy of the converter's operation. Indeed, if it is necessary to convert a numerical quantity into a voltage proportional to it, this then means that, over the entire range of variation of θ, the absolute error Δ at the smoothing device's output must not exceed the quantity which corresponds to one unit. In other words, Δ must be less than the fraction $1/b^n$ of the maximum value of the constant component. In particular, for a binary system, the requirement on the magnitude of the absolute error, taking (6) and (16) into account, is expressed by the inequality

$$\Delta < \frac{U_0}{2^{n+1}+2}. \qquad (19)$$

If the attenuation of the constant component is invariable in the smoothing device, then Δ is determined in practice only by the pulsations. With this, and based on what was presented earlier, it is not necessary to design the device for the entire range of variation of θ. The necessary condition for satisfying (19) in this range is that it be satisfied at the point corresponding to $\theta = 0.5$.

In practical designing, it should be kept in mind that the speed of a concrete converter, for given f and n, is almost completely determined by the frequency properties of the smoothing device. These, in turn, depend on the device's form, circuit and parameters. With this, as the maximum number of significant places of the numerical-quantity converter decreases, the requirements on the permissible pulsations at the smoothing device's output, in correspondence with (19), relax sharply, which permits a significant increase in speed of action. The speed of the converter can also be increased by decreasing the duration T of a complete cycle which, as is clear from (5), is inversely proportional to the frequency f of the input pulses. But increasing f leads to the use of higher-frequency elements. Therefore, one should significantly increase the frequency of the input pulses only after one has exhausted the possibilities of increasing speed of action by improving the frequency properties of the smoothing device.

Among the advantages of the converter herein described are its simplicity, its lack of precision elements or assemblies, requiring fine adjustment, the ease of executing the device with transistor or ferro-transistor elements, the absence of special requirements on frequency stability of the input pulses, or on the duration of a complete cycle. This latter advantage is due to the fact that any variation of frequency automatically leads to an inversely proportional variation both of τ and of T and, in accordance with (6), thus has no effect on the magnitude of U_{out}.

AUTOMATIC TELEMETRY SYSTEM FOR OIL-WELL FLOW

A. A. Abdullaev and I. A. Nabiev
(Baku)

(Translated from: Avtomatika i Telemekhanika, Vol. 21, No. 2, pp. 266-270, February, 1960)
Original article submitted October 3, 1959

The basis for establishing the correct operating conditions for exploiting oil wells is the measurement, and taking account of, the quantity of oil and water extracted from the wells.

An optimal technological mode of operation of a well can only be established where there is sufficient information concerning the well's output and its variations under various operating modes. Variations in the output of fluid, observed by measurements, allow the necessary measures to be taken to guarantee normal well operation.

In the southern petroleum regions of the Soviet Union, flow measurements are made by grouped measuring stands. The use of such stands permits a sizeable shortening of the pipelines on the fields. At these stands, measurement of well flow is carried out manually. This increases the staffs of the fields, does not allow frequent measurements to be made (the measurers work on one shift) and does not permit systematic observation of well flow. Moreover, manual measurement of well flow retards the transition to complex automation and remote control of the fields.

In the present paper we describe a system of automatic telemetry of oil-well flow, developed at the Research and Planning Institute (NIPI) "Neftekhimavtomat."

The system developed for the automatic measurement of oil-well flow permits the measurement of oil and water flow individually from a well, with transmission of the readings to a control point and their recording on special cards. This system is one of the basic devices (assemblies) of the system of complex automation and remote (central) control of oil fields, developed jointly with the Institute for Automation and Remote Control (IAT) of the AN SSSR and the All-Union Petroleum Research Institute. In 1957, on the fourth field of the "Ordzhonikidzeneft' " oil-field management, workers of the fields and of the NIPI equipped 24 wells with this system, these wells being still successfully exploited today.

Figure 1 shows the control desk (a) and a measuring stand (b). Each measuring trap (measuring tank) serves eight wells (the number of wells can be increased).

Figure 2 shows the scheme of the system for the automatic telemetering of oil-well flow based on grouped measuring stands. Each such stand is equipped with distributor valves with pneumatic-membrane executive mechanisms (MEM) 8, a manometer 17, and position signaller (PS) 21.

To measure the flow of any well, it is necessary to switch it from the common collector to a measuring tank. This is implemented by applying compressed gas to the MEM of the given well. With this, the well is switched from common collector 10 to measuring tank 5, the MEM distributor valves are controlled by the pneumatic stepping distributor (PSD) which has 16 positions; eight of these correspond to a connection of a well to the measuring tank, and eight to an empty measuring tank. Details as to the position of the PSD are obtained by means of the pneumoelectric transformer 21. The PSD drive is a bellows mechanism.

When compressed gas is fed to the chamber of the PSD's bellows mechanism, the PSD is switched from the given position to the following one. The supply of compressed gas to the bellows mechanism is implemented by electropneumatic valve 16. When this latter receives an electric impulse, it sends gas to the bellows mechanism's chamber, thereby switching the PSD. In addition to the eight valves which switch the wells from the common collector to the measuring tank, there is common valve 7 for controlling the measuring tank's drain line. The MEM of this valve is subject to combined control: by the PSD and by electropneumatic valve (EPV) 20. The MEM of the valve on the drain line is maintained in the closed state during the period when a well is connected to the measuring tank by means of the PSD and, after the well is disconnected from the measuring tank, by means of EPV 20. To control the emptying of the measuring tank, zero-level indicator 6 is connected in its lower portion and, to signal overflow of the measuring tank, trouble indicator 14 is connected in. Compressed gas, obtained from the same measuring tank, is used to supply all the system's pneumatic elements. For the pressure stabilization and cleaning of the gas, the system contains pressure reducer 18 and filter 19. Measurement of the oil and water levels in the measuring tank is implemented by level transducer 1 with two floats, 3 and 4, inside of which constant magnets are placed. One of the floats rests on the "water-oil" dividing level, the other rests on the oil level. The floats freely move along the vertical brass tube (or a tube of some other nonmagnetic material) inside of which is to be found indicator 2, set in motion by the transducer's synchronous motor.

Control of the automated measuring tank's operation, and implementation of the interconnections between the stand's individual elements is carried out by relay apparatus, located in the measuring tank's electrical block 13. At the central (control) point is to be found the control console, including program device 25, program-device commutator 26, relay apparatus 28, providing automatic system operation, fixed frequency generator 29, flow recorder 30, and array 27 of signal lamps, keys and knobs.

The program device automatically gives the time for filling the measuring tanks by the output of each well in accordance with a previously established central control program within the limits of 10 minutes to 4 hrs, at 10 min intervals. The time for filling is established by the position of a contact pin on the program device commutator for each well individually. The programing device is built around stepping selectors. An individual stepping selector is assigned to each measuring tank.

The relay apparatus, consisting of several assemblies, connects the basic blocks and elements of the central control point, and provides automatic cyclic operation of the entire measuring system. The output recorder is a number-printing device for recording the serial number of the measuring tank, the well and the levels of oil and water. The electronic frequency generator is a two-channel one. There are 12 fixed frequencies in each channel.

In the system, a frequency method is used for selecting the objects (measuring tanks), and for transmission of

the measurement signals, a pulse-time method of selection.

A given measuring stand is a continuously acting complex system, since each of the 12 measuring tanks comprising the system is, as it were, an independent unit, and has a closed operating cycle which is virtually independent of the state and operation of the other measuring tanks.

The system's functioning can be decomposed into several operations.

1. Interrogation as to the state of all the measuring tanks (periodically, at short intervals of from 2 to 5 minutes) with the aim of observing measuring tanks which are emptied subsequent to a prior measurement.

2. Switching an emptied measuring tank, observed during an interrogation period, to the filling mode.

3. Halting the filling of a measuring tank after the time for filling has elapsed.

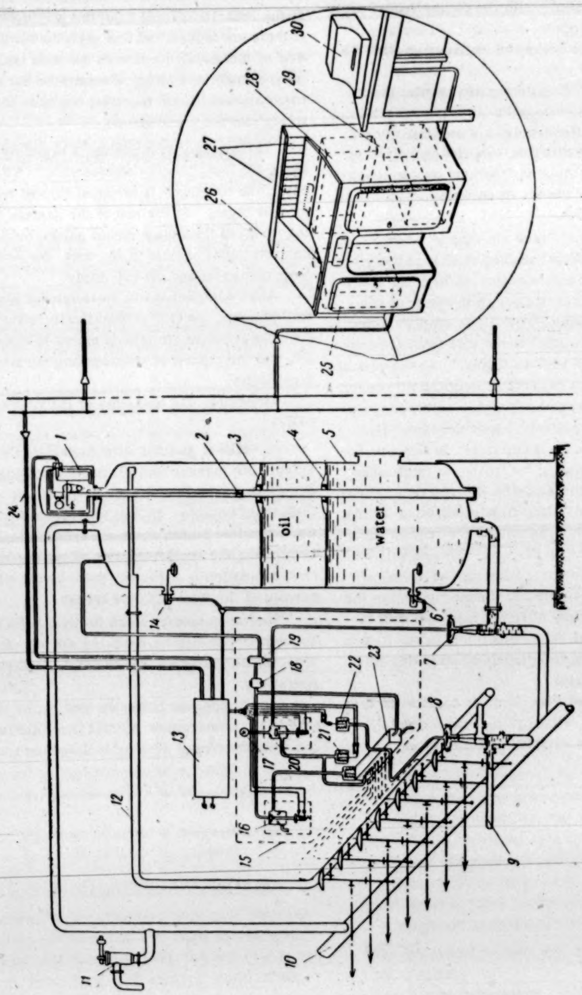

Fig. 2

4. Measuring and recording the results.

5. Switching to the emptying mode after completion of the measurement cycle.

Figure 3 shows the block schematic of the central control point and one of the 12 controlled points of the system of automatic telemetering of oil-well output. We shall consider the operation of the system as shown on the block diagram in accordance with the technological cycle of measuring oil-well output.

For convenience, we begin the explanation with the interrogation cycle.

At the beginning of the interrogation cycle, the interrogation block sends interrogation signals over the line, i.e., signals of 12 fixed frequencies are successively sent over the line. Each measuring tank has its own fixed selection frequency. Each frequency selects its corresponding measuring tank, which sends its answering signal back to the central control point.

If the answering signal "tank not empty" is received, the interrogation block ceases sending signals to the given tank, and switches to the interrogation of the next tank's state. This terminates interrogation of the state of the given tank. If the answering signal "tank empty" is received, then the order is sent over the line from the central control point, "switch tank to filling." At the controlled point, by means of the pneumatic stepping distributor, the next well in turn is switched from the common collector to the measuring tank, and filling of the tank begins.

The time that each well is connected to the measuring tank, i.e., the time alloted for filling, is established beforehand on the program device by the dispatcher (central controller). After the filling time established for the given well has elapsed, the program device sends a signal over the line to halt filling of the tank. This signal, by means of the pneumatic stepping selector and valve, effects switching of the well from the measuring trap to the common collector. The flow of liquid from the well to the measuring tank ceases. The filled tank awaits its turn to be measured. With this, the process of preparing for a flow measurement terminates.

It should be mentioned that, in those cases when the well does not supply fluid, although the measuring tank was in the fill state for the established time, after the well is switched from the measuring tank an answering signal, "filling stopped" (no fluid) is sent. This signal is fixed at the central control point and, when it again is time to interrogate the given tank, it is set up to be filled from the following well.

A measuring tank filled with liquid remains in that state until the recorder is released from operation. As soon as the recorder is freed from the previous measurement and if there are tanks filled and ready to be measured, the process of measuring the flow in the next tank begins. The measurement and fixing of results of the measurement is implemented by one recorder, common to all the tanks entering into the given system.

The measurement process is begun by the order, sent along the line, "begin measurement." At the controlled point, the transducer is switched in, and the measurement process begins. At the end of the process, the recorder, having received the measurement pulses, prints on a special card the serial number of the tank, the well and the well's output of water and oil separately.

After completing the measurement process at the controlled point, the tank automatically switches to emptying, i.e., the liquid in the tank is routed to the common collector, and the process of interrogating the state of the next tank begins.

Thereafter, the operation of the system repeats cyclically.

In addition to automatic operation, the system is equipped for manual control, manual calling of tanks and out-of-sequence flow measurement of any well, at the dispatcher's option. Both at the central control and at the controlled points, there are synchronization blocks, controlling the synchronization of system operation. If synchronization is disrupted, these blocks signal the dispatcher of the trouble in the system.

There is a special block for fixing the disruptions in the system's operation, notifying the dispatcher of the character of the disruption if such occurs, and preventing false operations.

In the apparatus presently used in the system for the automatic measurement of well flow, the recorder is a specially developed device for the given system.

ESTIMATING THE EFFECT OF QUANTIZATION BY LEVEL ON THE PROCESSES IN AUTOMATIC DIGITAL SYSTEMS

Ya. Z. Tsypkin

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 3, pp. 281-285, March, 1960
Original article submitted July 28, 1959

An estimate is given of the effect of the level-quantization interval in automatic digital systems whose continuous portions contain both constant and variable parameters.

INTRODUCTION

In automatic digital systems (ADS) at least one quantity is subject to quantization by level and by time. The quantization process consists in fixing previously given discrete levels at discrete moments of time. Level-quantization interval σ_z is determined by the accuracy, and time-quantization interval T by the speed of action, of the digital devices which belong to the automatic system.

The effect of the time-quantization interval was studied earlier [1,2]. An estimate of the effect of the level-quantization interval was made in [3] on the basis of the canonical forms of equations. Due to this, the results of the estimation process were obtained in an unnecessarily complicated form. Moreover, it is not possible to concur with all the conclusions of [3].

Below, we present a simple way of estimating the effect of the level-quantization interval which is not related to the canonical forms of equations, and which is valid for ADS with constant and with variable parameters.

1. Equivalent Scheme of an ADS

We consider the ADS scheme shown on Fig. 1. The functional schematic of the device (AD) for analog-to-digital conversion (Fig. 2, a) may be presented in the form of a series connection of a pulse element and a relay element with a multistep characteristic (Fig. 2,b).

In its turn, the relay element can be presented in the form of a parallel connection of an amplifying element with gain k = 1 and a nonlinear element (Fig. 2, c) whose characteristic Ψ equals the difference between a linear and the relay characteristic.

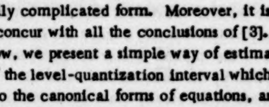

Fig. 1.

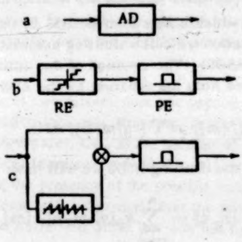

Fig. 2.

By using this representation of the AD converter, we can replace the ADS scheme by the equivalent scheme of a limiting sampled-data system in which the effect of the level quantization is taken into account by the stimuli applied to it via the nonlinear element with characteristic Ψ. In Fig. 3, a, this system is represented as a sampled-data system with a linear feedback path; on Fig. 3, b, the feedback path is included in the limiting system.

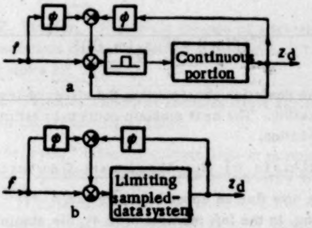

Fig. 3.

We denote the impulse characteristic of the closed linear sampled-data system, which can also contain variable parameters, by $k_c[n, m, \epsilon]$. Methods of determining $k_c[n, m, \epsilon]$ were described in [4]. If there are no variable parameters, then

$$k_c[n, m, \varepsilon] = k_c[n - m, \varepsilon]. \tag{1.1}$$

By using the impulse characteristic, we can write the equation of the ADS of Fig. 3, b in the form

$$z_d[n, \varepsilon] = \sum_{m=0}^{n} k_c[n, m, \varepsilon]\{[\Psi(f[m]) - \Psi(z_d[m, 0])] + f[m]\}. \tag{1.2}$$

2. Deviations Engendered by Level Quantization

A system which differs from an ADS by its absence of level quantization we call a limiting automatic sampled-data system (ASDS). The equation of the limiting ASDS can be obtained from the equation for the ADS (1.2) by setting in it

$$\Psi(f[m]) \equiv \Psi(z_d[m, 0]) \equiv 0. \tag{2.1}$$

Thus, for the limiting ASDS we will have

$$z_s[n, \varepsilon] = \sum_{m=0}^{n} k_c[n, m, \varepsilon] f[m] \tag{2.2}$$

or

$$z_s[n, \varepsilon] = \sum_{m=0}^{n} k_c[n, n - m, \varepsilon] f[n - m]. \tag{2.3}$$

The difference between $z_d[n, \epsilon]$ and $z_s[n, \epsilon]$, defining the effect of level quantization, may be presented on the basis of (1.2) and (2.2), in the form

$$\delta z[n, \varepsilon] = z_d[n, \varepsilon] - z_s[n, \varepsilon] = \sum_{m=0}^{n} k_c[n, m, \varepsilon] \{\Psi(f[m]) - \Psi(z_d[m, 0])\}. \tag{2.4}$$

The deviation characterizes the effect of level quantization. The next problem consists in estimating this deviation.

3. Estimate of the Maximum Deviation

We now find an upper bound for $|\delta z[n, \epsilon]|$. By replacing, in the left member of (2.4), the absolute magnitude of the sum by the sum of the absolute magnitudes, we get

$$|\delta z[n, \varepsilon]| \leqslant \sum_{m=0}^{n} |k_c[n, m, \varepsilon]| \{|\Psi(f[m])| + |\Psi(z_d[m, 0])|\}. \tag{3.1}$$

But the difference between the linear and the relay characteristics or, what amounts to the same thing, between the nonquantized and the quantized quantities, may not, in absolute magnitude, exceed half the quantization interval $\sigma/2$. Therefore,

$$|\Psi(f[m])| \leqslant \frac{\sigma}{2}, \quad |\Psi(z_d[m, 0])| \leqslant \frac{\sigma}{2}. \tag{3.2}$$

By using these inequalities, and replacing the left member of (3.1) by the maximum value, we obtain

$$\max|\delta z[n, \varepsilon]| \leqslant \sum_{m=0}^{n} |k_c[n, m, \varepsilon]| \sigma \tag{3.3}$$

or, after replacing the variable of summation m by $n-m$,

$$\max|\delta z[n, \varepsilon]| \leqslant \sum_{m=0}^{n} |k_c[n, n - m, \varepsilon]| \sigma. \tag{3.4}$$

On the basis of (1.1), for an ADS with constant parameters we obtain from (3.3) and (3.4), respectively,

$$\max|\delta z[n, \varepsilon]| \leqslant \sum_{m=0}^{n} |k_c[n - m, \varepsilon]| \sigma \tag{3.5}$$

or

$$\max|\delta z[n, \varepsilon]| \leqslant \sum_{m=0}^{n} |k_c[m, \varepsilon]| \sigma. \tag{3.6}$$

Thus, the process' maximum deviation engendered by level quantization does not exceed the sum of the absolute values of the impulse characteristic of the limiting ASDS multiplied by the quantization interval.

An estimate of the steady-state deviation is found from (3.4), (3.6) if the limit of summation n tends to ∞.

For an ADS with constant parameters, the estimate of the steady-state deviation is the greatest possible one.

This estimate corresponds to the maximum possible accumulation in the limiting ASDS for stimuli which are modulus-limited, and is the discrete analog of the accumulation problem of B. V. Bulgakov.

4. Comparison of Some Properties of the Limiting ASDS and the ADS

If a step function stimulus

$$f[n] = \begin{cases} 1 & \text{for} \quad n \geqslant 0, \\ 0 & \text{for} \quad n < 0, \end{cases}$$

is applied to the limiting ASDS, its reaction is determined by its time or, more accurately, by its transient characteristic. By using (2.3), for example, we can present the transient characteristic $h[n, \epsilon]$ in the form

$$h[n, \varepsilon] = z_s[n, \varepsilon] = \sum_{m=0}^{n} k_c[n, n - m, \varepsilon]. \tag{4.1}$$

The steady-state characteristic will be

$$h_{\mathrm{ste}}[n, \varepsilon] = \sum_{m=0}^{\infty} k_{\mathrm{c}}[n, n-m, \varepsilon]. \tag{4.2}$$

It is a function of n and ϵ. For an ADS with constant parameters,

$$h_{\mathrm{ste}}[n, \varepsilon] = h(\varepsilon) = \sum_{m=0}^{\infty} k_{\mathrm{c}}[m, \varepsilon] \tag{4.3}$$

is a function of ϵ only. If the ASDS is designed to reproduce the stimuli applied to it then, in general,

$$h_{\mathrm{ste}}[n, \varepsilon] = h(\varepsilon) \leqslant 1. \tag{4.4}$$

We assume that the impulse characteristic of the limiting ASDS, $k_c[n, n-m, \epsilon]$, for given n and ϵ and arbitrary m, is nonnegative, i.e.,

$$k_{\mathrm{c}}[n, n-m, \varepsilon] \geqslant 0, \tag{4.5}$$

so that we shall have, from (3.4) and (4.1),

$$\max|\delta z[n, \varepsilon]| \leqslant \sum_{m=0}^{n} k_{\mathrm{c}}[n, n-m, \varepsilon]\sigma = h[n, \varepsilon]\sigma. \tag{4.6}$$

Thus, in this case the maximum deviation at the given moment of time which is engendered by the level quantization does not exceed the quantity equal to the product of the quantization interval by the value of the characteristic at that same moment of time.

The estimate of the steady-state deviation will have the form

$$\max|\delta z_{\mathrm{ste}}[n, \varepsilon]| \leqslant \sum_{m=0}^{\infty} k_{\mathrm{c}}[n, n-m, \varepsilon]\sigma = h_{\mathrm{ste}}[n, \varepsilon]\sigma. \tag{4.7}$$

Let us consider in somewhat more detail an ADS with constant parameters. For it, the [(4.5)] that $k_c[m, \epsilon] \geq 0$ is equivalent to the condition that $h[n, \epsilon]$ be monotonic for ϵ = const. By taking into account that $h[n, \epsilon] \leq h_{ste}[n, \epsilon] = h(\epsilon)$, we find that

$$\max|\delta z[n, \varepsilon]| \leqslant h[n, \varepsilon]\sigma < h_{\mathrm{ste}}[n, \varepsilon]\sigma = h(\varepsilon)\sigma \tag{4.8}$$

or, by taking (4.4) into account,

$$\max|\delta z[n, \varepsilon]| \leqslant \sigma. \tag{4.9}$$

Thus, for a monotonic characteristic, the deviation due to level quantization does not exceed the quantization interval. In this case, and only in this case, we can deduce the stability of the ADS from the stability of the limiting ASDS. If the characteristic is not monotonic, i.e., the impulse characteristic changes sign, the sum of the absolute values of the impulse characteristic may significantly exceed unity, and instead of (4.6) we shall therefore have

$$\max|\delta z[n, \varepsilon]| \leqslant \alpha\sigma. \tag{4.10}$$

where $\alpha > 1$. Under these conditions, it is possible to have, in an ADS with constant parameters, an autooscillatory mode with an "amplitude" not exceeding $\alpha\sigma$. The greater the oscillation of the characteristic $h[n, \epsilon]$ for ϵ = const, i.e., the greater the oscillation of the limiting ASDS, the greater will be the "amplitude" of the autooscillatory modes possible in the ADS.

Thus, in spite of the assertion made in [3], it is, strictly speaking, impossible in this case to conclude that the ADS is stable from the fact that the limiting ASDS is stable.

The result just derived does not depend on the size of the quantization interval. However, as the quantization interval σ decreases, i.e., as the number of places in the digital devices increases, $\max|\delta z[n, \epsilon]|$ will increase and, despite the presence of the possible autooscillations, their amplitude will be so small that the processes in the ADS and the ASDS will differ less and less from each other.

The estimates given above allow one to determine the maximum quantization interval for which the difference of the processes in the ADS and the ASDS will not exceed a given magnitude.

DETERMINATION OF THE OPTIMAL IMPULSIVE RESPONSE FUNCTION IN THE PRESENCE OF INTERNAL NOISE

P. S. Matveev

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 3, pp. 286-292, March, 1960
Original article submitted May 8 , 1959

The problem of determining the optimal transfer function [1, 2] is generalized to the cases when the input stimuli are applied to n different elements of a servosystem and to systems with variable parameters.

In [1, 2] a solution was given to the problem of determining the optimal impulsive response function for cases when input stimuli are applied to two different elements of a servosystem. The aim of the present work is to generalize the results obtained in [1, 2] to the case when the stimuli are applied to n elements of a servosystem, and to systems with variable parameters.

1. Determination of the Impulsive Response Function in the Class of Systems with Constant Parameters

We assume that the servosystem has n elements to which stimuli are applied, whereby a controlling signal

$$y(t) = g(t) + m(t), \tag{1}$$

is applied to one basic element, where g (t) is a given function of time, with

$$g(t) = \sum_{i=0}^{r} g_i t^i, \tag{2}$$

and m (t) is a stationary random function.

In addition, noise n(t), in the form of a stationary random function, is superimposed on the controlling signal. To the remaining n−1 elements of the servosystem (Fig. 1), stimuli are applied in the form of stationary random functions $u_1(t), u_2(t), \ldots, u_{n-1}(t)$. We assume for simplicity that m(t), n(t), $u_1(t), u_2(t), \ldots, u_{n-1}(t)$ have zero mean values and are mutually uncorrelated. We also assume that the transfer functions $W_1(p), W_2(p), \ldots, W_{n-1}(p)$ [or the corresponding impulsive response functions $b_1(t), b_2(t), \ldots, b_{n-1}(t)$] are known. What is not known is the transfer function $W_c(p)$ (impulsive response function) of the correcting device. We initially determine the optimal impulsive response function k(t) of the closed system from which, by using well-known methods [2, 3], we can easily determine the transfer function $W_c(p)$ of the correcting device . The problem may be formulated in the following way: from given correlation functions $R_m(\tau), R_n(\tau), R_{u_1}(\tau), R_{u_2}(\tau), \ldots, R_{u_{n-1}}(\tau)$ [spectral densities $S_m(\omega), S_n(\omega), S_{u_1}(\omega), S_{u_2}(\omega), \ldots, S_{u_{n-1}}(\omega)$], given duration T of the transient response, given reproduction operator H(p), error coefficients C_i and transfer functions $W_1(p), W_2(p), \ldots, W_{n-1}(p)$, to find the impulsive response function k(t) such that the mean-square error will be a minimum.

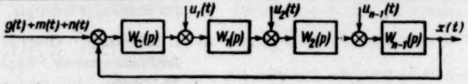

Fig. 1.

It is easily shown that the scheme shown on Fig. 2, for n = 3, is equivalent to the scheme of Fig. 1. This scheme will be used for the subsequent argument. Then [4], the system's output quantity can be written in the following way :

$$x(t) = \int_0^T [g(t-\tau) + m(t-\tau) + n(t-\tau)]\, k(\tau)\, d\tau -$$

$$- \int_0^T k(\tau)\, d\tau \int_{-\infty}^{\infty} b_1(\sigma)\, d\sigma \int_{-\infty}^{\infty} u_1(t-\tau-\sigma-\mu)\, b_2(\mu)\, d\mu - \tag{3}$$

$$-\int_0^T k(\tau)\,d\tau \int_{-\infty}^{\infty} u_2(t-\tau-\sigma)\,b_2(\sigma)\,d\sigma + \int_{-\infty}^{\infty} b_1(\tau)\,d\tau \int_{-\infty}^{\infty} u_1(t-\tau-\sigma)\,b_2(\sigma)\,d\sigma$$

$$+\int_{-\infty}^{\infty} u_2(t-\tau)\,b_2(\tau)\,d\tau,$$

where

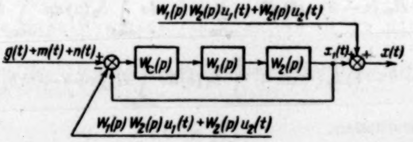
$$k(\tau) = N(t) + \sum_{j=0}^{q} E_j\,\delta^{(j)}(t) + \sum_{j=0}^{q} \delta^{(j)}(t-T) \qquad (0 < t < T). \tag{4}$$

Let the ideal system be required to reproduce at its output the signal

$$h(t) = H_g(p)\,g(t) + H(p)\,m(t), \tag{5}$$

where

$$H(p) = \sum_{i=0}^{r} \frac{H_i}{i!} p^i, \quad H_g(p) = H(p) - \sum_{j=0}^{r} \frac{C_j}{j!} p^j \qquad (i \neq j). \tag{6}$$



$W_1(p)\,W_2(p)\,u_1(t)+W_2(p)\,u_2(t)$

Fig. 2

Here, for convenience, we have introduced the operator $H_g(p)$ which simultaneously takes into account the operation of reproducing g(t) and the errors with which it is reproduced.

Then the reproduction error can be written in the form

$$\varepsilon(t) = h(t) - x(t).$$

If it now be required that the mean error of reproduction equal zero, then [2, 4, 5] we are led to limitations of k(t) of the form

$$\mu_\nu = (-1)^\nu \int_0^T \tau^\nu k(\tau)\,d\tau \qquad (\nu = 0, 1, 2, \ldots, r) \tag{7}$$

or

$$H_i = (-1)^\nu \int_0^T \tau^i k(\tau)\,d\tau, \quad -C_j = (-1) \int_0^T \tau^j k(\tau)\,d\tau \qquad (j \neq i = 0, 1, 2, \ldots, r). \tag{8}$$

If (8) holds, the reproduction error can be written in the following way:

$$\varepsilon(t) = \int_{-\infty}^{\infty} m(t-\tau)\,\varkappa(\tau)\,d\tau - \int_0^T k(\tau)\,d\tau\,[m(t-\tau) + n(t-\tau) -$$

$$-\int_{-\infty}^{\infty} b_1(\sigma)\,d\tau \int_{-\infty}^{\infty} u_1(t-\tau-\sigma-\mu)\,b_2(\mu)\,d\mu - \int_{-\infty}^{\infty} u_2(t-\tau-\sigma)\,b_2(\sigma)\,d\sigma\Big] - \tag{9}$$

$$-\int_{-\infty}^{\infty} b_1(\tau)\,d\tau \int_{-\infty}^{\infty} u_1(t-\tau-\sigma)\,b_2(\sigma)\,d\sigma - \int_{-\infty}^{\infty} u_2(t-\tau)\,b_2(\tau)\,d\tau,$$

where

$$\varkappa(t)=\frac{1}{2\pi}\int_{-\infty}^{\infty}H(j\omega)e^{j\omega t}\,d\omega.$$

Further, by using the same arguments as in [2, 4, 5, 6], we obtain the necessary and sufficient condition for the minimum average value of the square of (9), when (7) holds, in the form of an integral equation

$$\begin{gathered}\int_0^T\Big[R_m(\tau-\theta)+R_n(\tau-\theta)+\int_{-\infty}^{\infty}b_1(\sigma)d\sigma\int_{-\infty}^{\infty}b_2(\mu)\,d\mu\int_{-\infty}^{\infty}b_1(\lambda)\,d\lambda\\ \times\int_{-\infty}^{\infty}R_{u_1}(\tau+\sigma+\mu-\theta-\lambda-\eta)\,b_2(\eta)\,d\eta+\\ +\int_{-\infty}^{\infty}b_2(\sigma)\,d\sigma\int_{-\infty}^{\infty}R_{u_2}(\tau+\sigma-\theta-\lambda)\,b_2(\lambda)\,d\lambda\Big]k(\theta)\,d\theta=\\ =\int_{-\infty}^{\infty}R_m(\tau-\theta)\varkappa(\theta)\,d\theta+\int_{-\infty}^{\infty}b_1(\sigma)\,d\sigma\int_{-\infty}^{\infty}b_2(\mu)\,d\mu\int_{-\infty}^{\infty}b_1(\theta)\,d\theta\int_{-\infty}^{\infty}R_{u_1}(\tau+\sigma+\\ +\mu-\theta-\lambda)\,b_2(\lambda)\,d\lambda+\int_{-\infty}^{\infty}b_2(\sigma)d\sigma\int_{-\infty}^{\infty}R_{u_2}(\tau+\sigma-\theta)\,b_2(\theta)\,d\theta+\sum_{i=0}^{r}\gamma_i\tau^i,\end{gathered}\tag{10}$$

where the γ_i are Lagrange multipliers.

We now introduce the notation

$$\begin{gathered}R^*_{u_1}(\tau-\theta)=\int_{-\infty}^{\infty}b_1(\sigma)\,d\sigma\int_{-\infty}^{\infty}b_2(\mu)\,d\mu\int_{-\infty}^{\infty}b_1(\lambda)\,d\lambda\times\\ \times\int_{-\infty}^{\infty}R_{u_1}(\tau+\sigma+\mu-\theta-\lambda-\eta)\,b_2(\eta)\,d\eta,\end{gathered}\tag{11}$$

$$R^*_{u_2}(\tau-\theta)=\int_{-\infty}^{\infty}b_2(\sigma)\,d\sigma\int_{-\infty}^{\infty}R_{u_2}(\tau+\sigma-\theta-\lambda)\,b_2(\lambda)\,d\lambda.\tag{12}$$

With the use of the notation of (11) and (12), (10) can be presented in the following form:

$$\begin{gathered}\int_0^T[R_m(\tau-\theta)+R_n(\tau-\theta)+R^*_{u_1}(\tau-\theta)+R^*_{u_2}(\tau-\theta)]\,k(\theta)\,d\theta=\\ =\int_{-\infty}^{\infty}R_m(\tau-\theta)\varkappa(\theta)\,d\theta+R^*_{u_1}(\tau)+R^*_{u_2}(\tau)+\sum_{i=0}^{r}\gamma_i\tau^i\quad(0\leqslant\tau\leqslant T).\end{gathered}\tag{13}$$

Equation(13) does not differ in form from the integral equations obtained in [2, 4, 5, 6] and, therefore, the same methods of solution may be used for the determination of k(t). Obviously , integral equation (13) is easily generalized to the case of n inputs. For this, integral equation (13) can be written in the form

$$\begin{gathered}\int_0^T[R_m(\tau-\theta)+R_n(\tau-\theta)+R^*_{u_1}(\tau-\theta)+R^*_{u_2}(\tau-\theta)+\\ +\ldots+R_{u_{(n-1)}}(\tau-\theta)]\,k(\theta)\,d\theta=\int_{-\infty}^{\infty}R_m(\tau-\theta)\varkappa(\theta)\,d\theta+\\ +R^*_{u_1}(\tau)+R^*_{u_2}(\tau)+\ldots+R^*_{u_{(n-1)}}(\tau-\theta)+\sum_{i=0}^{r}\gamma_i\tau^i\quad(0\leqslant\tau\leqslant T).\end{gathered}\tag{14}$$

If the correlation function $R_m(\tau)+R_n(\tau)+R^*_{u_1}(\tau)+\ldots+R^*_{u(n-1)}(\tau)$ corresponds to a rational-fraction spectral density

$$S(\omega)=\frac{a_0+a_1\omega^2+\ldots+a_k\omega^{2k}}{b_0+b_1\omega^2+\ldots+b_l\omega^{2l}}=\frac{M(\omega)M^*(\omega)}{L(\omega)L^*(\omega)}, \tag{15}$$

then, by using the same arguments as in [5], we can shown that the impulsive response function is defined by the expression *

$$\begin{aligned}k(t)=\sum_{i=0}^{r}A_i t^i+\sum_{i=1}^{2k}B_i e^{\lambda_i t}+\sum_{j=0}^{q}E_j\delta^{(j)}(t)+\sum_{j=0}^{q}D_j\delta^{(j)}(t-T)+\\+L(p)L^*(p)M^{-1}(p)M^{*-1}(p)\Big[\int_{-\infty}^{\infty}R_m(t-\tau)\times(\tau)\,d\tau+\\+R^*_{u_1}(t)+R^*_{u_2}(t)+\ldots+R^*_{u_{(n-1)}}(t)\Big]\quad(0\leqslant t\leqslant T),\end{aligned} \tag{16}$$

where $q=l-k-1$ and $L(p)$ and $M(p)$ equal $L(\omega)$ and $M(\omega)$ for $p=j\omega$, which are easily determined from the spectral density of (15).

The unknowns A_i, B_i, E_j, D_j in (16) are determined as in [5]. Further, by the usual methods [3], the transfer function of the closed system was determined and later, also, the transfer function of the correcting device.

2. Determination of the Impulsive Response Function in the Class of Systems with Variable Parameters

We assume that the system (Fig. 3) is acted upon by stationary random noise $n(t)$ and signal $y(t)=g(t)+m(t)$ consisting of the given function of time

$$g(t)=\sum_{i=0}^{r}g_i t^i, \tag{17}$$

where the g_i are unknown coefficients and the t^i are known functions of time, plus the stationary random function $m(t)$. To the system's second element there is applied a disturbing stimulus in the form of the stationary random function $u(t)$.

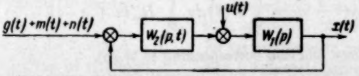

Fig. 3.

The problem solved below may be formulated as follows: from given correlation functions $R_m(\tau)$, $R_n(\tau)$, and $R_u(\tau)$ (spectral densities) and given object transfer function $W_1(p)$, to find the servosystem's impulsive response function such that the system will provide an exact reproduction of $g(t)$ at each moment of time $t>0$ and a minimum dispersion of the random process at the system's output at each moment of time.

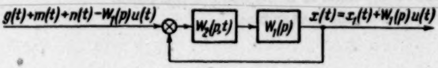

Fig. 4.

It may be shown that the scheme of Fig. 4 is equivalent to that shown on Fig. 3. Henceforth, the scheme of Fig. 4 will be used.

The reproduction error of the system (Fig. 3) can be given in the form

$$\begin{aligned}\epsilon(t)=g(t)+m(t)-x(t)=[1+W_1(p)W_2(p,t)]^{-1}[g(t)+m(t)-Q(t)]-\\-[1+W_1(p)W_2(p,t)]^{-1}W_1(p)W_2(p,t)n(t),\end{aligned} \tag{18}$$

where

$$Q(t)=W_1(p)u(t).$$

The reproduction error of the system given by Fig. 4 may be written in the form

---

* An analogous generalization can also be made for the case when $g(t)$ is a harmonic function [4].

$$\begin{aligned}\varepsilon_1(t) &= g(t) + m(t) - Q(t) - x_1(t) = \\ &= [1 + W_1(p) W_2(p, t)]^{-1} [g(t) + m(t) - Q(t)] - \\ &- [1 + W_1(p) W_2(p, t)]^{-1} W_1(p) W_2(p, t) n(t).\end{aligned} \tag{19}$$

By comparing (18) and (19), we find that $\epsilon(t) = \epsilon_1(t)$ and, consequently, just as in [4, 7], the reproduction error can be written in the form

$$\begin{aligned}\varepsilon(t) &= g(t) + m(t) - Q(t) - x(t) = g(t) + m(t) - Q(t) - \\ &- \int_{-\infty}^{t} [g(\tau) + m(\tau) - Q(\tau) + n(\tau)]\, k(t, \tau)\, d\tau \quad (t > \tau).\end{aligned} \tag{20}$$

The requirement that there be no bias, i.e., zero dynamic error, leads to $r + 1$ conditions of the form

$$t^i = \int_0^t \tau^i k(t, \tau)\, d\tau. \tag{21}$$

If (21) holds, the expression for the error has the form

$$\varepsilon(t) = m(t) - Q(t) - \int_{-\infty}^{t} [m(\tau) - Q(\tau) + n(\tau)]\, k(t, \tau)\, d\tau. \tag{22}$$

It may be shown [7] that the necessary and sufficient condition for a minimum mean value of the square of (22) amounts to this–that the impulsive response function $k(t, \tau)$ satisfy the integral equation

$$\begin{aligned}&\int_{-\infty} [R_m(\tau - \theta) + R_n(\tau - \theta) + R_Q(\tau - \theta)]\, k(t, \theta)\, d\theta \\ &\qquad = \sum_{i=0}^{r} \gamma_i \tau^i + R_m(t) + R_Q(t),\end{aligned} \tag{23}$$

where

$$R_Q(\tau - \theta) = \int_{-\infty}^{\infty} b(\sigma)\, d\sigma \int_{-\infty}^{\infty} R_u(\tau + \sigma - \theta - \lambda)\, b(\lambda)\, d\lambda, \tag{24}$$

and $b(\tau)$ is the impulsive response function corresponding to $W_2(p)$.

For the class of stationary processes for which spectral density corresponding to $R_m(\tau) + R_n(\tau) + R_Q(\tau)$ can be given in the form of (15), the solution of (23) can be written [7] in the following form:

$$\begin{aligned}k(t, \tau) &= \sum_{i=1}^{k} B_i(t) e^{\lambda_i \tau} + \sum_{i=0}^{r} A_i(t) \tau^i + \sum_{j=0}^{q} E_j \delta^{(j)}(t - \tau) \\ &+ L(p) L^*(p) M^{-1}(p) M^{*-1}(p) [R_m(t) + R_Q(t)] \quad (t > \tau).\end{aligned} \tag{25}$$

The rest of the argument is the same as in Section 1 of this paper.

In conclusion, we consider two simple examples.

Example 1. Let

$$S_{u_1}(\omega) = N^2, \quad S_{u_2}(\omega) = \frac{2\alpha M^2}{\omega^2 + \alpha^2}, \quad W_1(p) = \frac{k_1}{p + \tau_1}, \quad W_2 = \frac{k_2}{p + \tau_2},$$

$$H(p) = H_g(p) = 1, \quad g(t) = g_0 + g_1 t.$$

Then [3],

$$S^*_{u_1}(\omega) = |W_1(j\omega)|^2 |W_2(j\omega)|^2 S_{u_1}(\omega) = \frac{k_1^2 k_2^2 N^2}{(\omega^2 + \tau_1^2)(\omega^2 + \tau_2^2)},$$

$$S^*_{u_2}(\omega) = |W_2(j\omega)|^2 S_{u_2}(\omega) = \frac{2\alpha k_2^2 M^2}{(\omega^2 + \tau_2^2)(\omega^2 + \alpha^2)},$$

$$S(\omega) = S^*_{u_1}(\omega) + S^*_{u_2}(\omega) = \frac{k_2^2}{\omega^2 + \tau_2^2}\left[\frac{(2\alpha M^2 + k_1^2 N^2)\omega^2 + 2\alpha\tau_1^2 M^2 + 2\alpha^2 k_1^2 N^2}{(\omega^2 + \alpha^2)(\omega^2 + \tau_1^2)}\right].$$

On the basis of (16), the impulsive response function will have the form

$$k(t) = A_0 + A_1 t + B_1 e^{\lambda_1 t} + B_2 e^{\lambda_2 t} + E_0 \delta(t) + E_1 \delta'(t) + D_0 \delta(t-T) + \\ + D_1 \delta'(t-T) + L(p) L^*(p) M^{-1}(p) M^{*-1}(p) [R^*_{u_1}(t) + R^*_{u_2}(t)],$$

where

$$M(p) M^*(p) = k_2^2 [-(2\alpha M^2 + k_1^2 N^2) p^2 + 2\alpha \tau_1^2 M^2 + 2\alpha^2 k_1^2 N^2],$$

$$L(p) L^*(p) = (\tau_2^2 - p^2)(\alpha^2 - p^2)(\tau_1^2 - p^2)$$

and λ_1 and λ_2 are the roots of the equation $M(\lambda) M^*(\lambda) = 0$.
The expressions for $R^*_{u_1}(t)$ and $R^*_{u_2}(t)$ are determined from (11) and (12).

Example 2. Let

$$g(t) = g_0 + g_1 t, \quad S_u(\omega) = N^2, \quad W_1(p) = \frac{k_1}{p+\tau}.$$

Then,

$$S^*_u(\omega) = |W_1(j\omega)|^2 S_u(\omega) = \frac{k_1^2 N^2}{\omega^2 + \tau^2}.$$

On the basis of (25), we have

$$k(t, \tau) = A_0(t) + A_1(t)\tau + E_0(t)\delta(t-\tau) + D_0(t)\delta(t-\tau) \\ + L(p) L^*(p) M^{-1}(p) M^{*-1}(p) R^*_u(t),$$

where

$$M(p) M^*(p) = k_1^2 N^2, \quad L(p) L^*(p) = \tau^2 - p^2.$$

ON THE AUTOOSCILLATIONS OF A DYNAMIC TABLE PLATFORM

G. P. Miroshnichenko

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 3, pp. 293-300, March 1960
Original article submitted December 1, 1959

Determined in this paper are several properties of the motion of the platform of a single-axis dynamic table with an asynchronous motor with a tubular rotor, as well as the conditions under which autooscillations will arise when there is dry friction in the bearings.

In the design and testing of autopilots, one uses tables, that is, dynamic models comprised of a device with a platform on which the autopilot's sensitive element is placed. The platform turns about its center of mass in accordance with the aircraft's law of motion.

Tables may be divided into two classes.

a) Tables whose drives work like a servosystem at whose input a signal from an electronic computer is applied. The errors of such tables, given a small coefficient of friction, are basically determined by the inertia of the drive and the platform.

b) Tables which operate on the principle of dynamic similarity. The output element of such a table is the platform on which torques act which are proportional to the aerodynamic torques acting on the aircraft. The coefficient of similarity equals the ratio of the inertial torques relative to the corresponding axes of the platform (with the autopilot's sensitive element mounted on it) and the aircraft. In this case, the platform's moment of inertia is, in some scale, the aircraft's moment of inertia. The table's viscous friction can be taken into account by the proper decrease of the aerodynamic damping. In this case, the table's errors are principally determined by the presence of dry friction, which may introduce significant distortions in the simulation of certain modes, for example, motion at high altitudes where the damping is small.

Therefore, the study of the effect of friction and of other factors causing distortions in dynamic similarity, including the autooscillations to be studied here, is of practical interest, the more so since tuning of the coefficient of static stability a_2 is carried out by measuring the frequency of the platform's autooscillations.

A single-axis mechanical dynamic table was used by Oppelt [1]. The theory of such tables was developed by him.

In the present paper, the nonlinear problem is solved by a method similar to that of A. A. Andronov.

The single-axis dynamic table is represented by a mathematical two-dimensional model leading, in one case, to Milne's equation and, in the other to Liénard's equation.

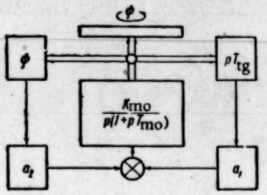

Fig. 1.

The table (Fig. 1) consists of a platform turned by an asynchronous motor with a tubular rotor whose transfer function (if the motor is considered as a linear link) is $k_{mo}/p(1 + pT_{mo})$, where k_{mo} and T_{mo} are the motor's gain and time constant, equal to the aircraft's time constant, and p is the Laplace operator.

On the motor's shaft are fitted the slider of potentiometer ψ and a tachometer generator with gain k_{tg}. The signals are applied to the motor's control winding via dividers a_2 and a_1 and a summing device. However, in actuality the motor has a nonlinear characteristic. In the absence of any signal to the control winding, with a sufficiently weak impulse about its axis, the rotor slowly turns and stops (due to the dry friction), and for a sufficiently strong impulse, the rotor begins to rotate more rapidly. For certain values of a_1 and a_2, after a shock (an impulse about the rotor's axis) there is set up an autooscillation whose frequency can be varied by varying a_2.

For investigating the autooscillation, one must find the nonlinear motor equation.

The adjustment of the table (Fig. 1) under the system to be studied consists of a sequential regulation of the table parameters to quantities defined by the equations of motion of the aircraft relative to the axis under consideration.

Let us consider, in the Liénard plane $\{\psi, \omega\}$, where $\omega = \dot{\psi}$, the phase trajectory and its mathematical expressions, which correspond to the nontrivial steady-state platform modes. It is known [2] that, for a two-dimensional system, such modes can only be periodic.

We denote by I the total moment of inertia of the platform and load with respect to the motor axis, by M_{ro} the rotational torque applied to the motor's rotor and by $M_{fr}(\omega)$ the dry frictional torque in the bearings and platform reducer. By using Newton's second law, we can write the platform's equation of motion in the form

$$I\dot{\omega} = M_{ro} + M_{fr}. \qquad (1)$$

If we express the dry frictional torque in terms of the platform's weight G and the constant frictional coefficient with respect to the motor's axis $k > 0$, we get

$$M_{fr}(\omega) = \begin{cases} -kG & \text{for } \omega > 0, \\ M_{ro} & \text{for } \omega = 0, \\ kG & \text{for } \omega < 0. \end{cases} \qquad (2)$$

By applying a signal depending on ω to the motor's control winding, we can obtain the artificial damping torque $a_1\omega$, where a_1 is the damping coefficient. A torque depending on ω also arises as the result of the voltage induced in the control winding when the rotor moves, from viscous friction in the bearing, from air friction of the rotating parts, etc.

By denoting this torque by $f(\omega)\omega$, and by ignoring the lag in the motor's control winding, we write the expression for the rotational torque:

$$M_{ro} = [a_1 + \varphi(\omega)]\,\omega + a_2\psi, \qquad (3)$$

where $a_1 > 0$ and $a_2 > 0$, and the function $\varphi(\omega)$ is even, bounded and continuous, together with its first two derivatives, in each finite segment $\{\omega_1, \omega_2\}$.

It has been experimentally established that there exists an angular platform velocity ω_0 such that

$$\varphi(\omega) < 0 \text{ for } |\omega| < \omega_0,\ \varphi(\omega) =$$

$$= 0 \text{ for } |\omega| = \omega_0,\ \varphi(\omega) > 0 \text{ for } |\omega| > \omega_0. \qquad (4)$$

Moreover, $\varphi(\omega)$ does not decrease for $\omega > 0$ and does not increase for $\omega < 0$.

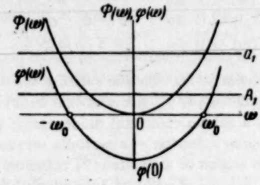

Fig. 2.

By adding and subtracting $\varphi(0)$ in (3), and by denoting [(Fig. 2)] $\Phi(\omega) \equiv \varphi(\omega) - \varphi(0)$, $A_1 \equiv a_1 + \varphi(0)$, we obtain

$$M_{ro} = [A_1 + \Phi(\omega)]\,\omega + a_2\psi. \qquad (5)$$

It is essential to note that the function $\Phi(\omega)$ is even and positive-definite, i.e., $\Phi(\omega) > 0$ for $\omega \neq 0$ and $\Phi(0) = 0$. At the same time, $A_1 > 0$ for $|a_1| > |\varphi(0)$ $A_1 < 0$ for $|a_1| < |\varphi(0)|$ and $A_1 > \varphi(0)$ since $a_1 > 0$.

By substituting (5) in (1), we get

$$I\dot{\omega} + [A_1 + \Phi(\omega)]\,\omega + a_2\psi = M_{fr}(\omega). \qquad (6)$$

The investigation of (6) breaks down into two cases:

1) $A_1 \geq 0$, i.e., $a_1 \geq -\varphi(0)$, $(a_1 \geq 0)$;

2) $A_1 < 0$, i.e., $a_1 < -\varphi(0)$.

Case I. ($A_1 \geq 0$). If, with this, $M_{fr}(\omega) \equiv 0$, then (6) reduces to a form considered by Milne [3] and Sansone [4].

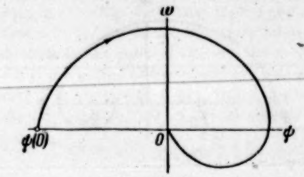

Fig. 3.

We now consider the phase trajectory for $M_{fr}(\omega) \equiv 0$. If $D = A_1^2 - 4Ia_2 \geq 0$, then the solution $\psi \equiv \psi(t)$, $[\psi(0) \neq 0]$ cannot have more than one zero in the time interval $t[0, \infty]$, which corresponds to a stable node (Fig. 3).

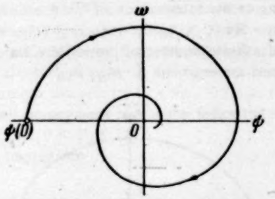

Fig. 4.

In the opposite case for $D < 0$, all solutions oscillate, and the phase trajectory corresponds to a stable focus (Fig. 4). With this, if we denote neighboring zeros of $\psi(t)$ by t_s and t_{s+1}, $t_s < t_{s+1}$, then the Milne-Sansone inequality holds:

$$t_{s+1} - t_s \leqslant \frac{2(\pi - \alpha_0)}{\nu},$$

where $\nu^2 = -D/4I^2 > 0$ and α_0 is an arc between 0 and $\pi/2$ such that $\tan\alpha_0 = \nu I/A_1$.

Consequently, if $T_0 = 2\pi/\nu$ is the period of the platform's free oscillations for $\Phi(\omega) \equiv 0$, and $T = t_{s+1} - t_{s-1}$ is the period of free oscillations for $\Phi(\omega) \neq 0$ then, since $t_{s+1} - t_{s-1} \leq 2(t_{s+1} - t_s)$, we obtain the inequality

$$T \leqslant T_0\left(1 - \frac{\alpha_0}{\pi}\right). \qquad (7)$$

For example, for $a_1 = -\varphi(0)$ (i.e., for $A_1 = 0$), $\alpha_0 = \pi/2$, and the period T satisfies the obvious relationship $T < T_0$, since the case $T = T_0$ occurs only for $\Phi(\omega) \equiv 0$.

We now consider the phase trajectory corresponding to (6) for $M_{fr} \neq 0$. Motion is possible if the angle of the platform's initial position $\psi(0)$, $[\psi = 0]$ lies outside the angle of stagnant dry friction — the segment

$\{-\psi_{fr}, \psi_{fr}\}$, where $\psi_{fr} = KG/a_2$, that is, if $|\psi(0)| > \psi$. In this case, for constructing the trajectory we can use (6), in which the point $\{-\psi_{fr}, 0\}$ is chosen for the origin of coordinates for the upper half-plane (since for $\omega > 0$, $-\psi_{fr} = \text{const}$) and, for the lower half-plane, the point $\{\psi_{fr}, 0\}$ is chosen (since for $\omega < 0$, $\psi_{fr} = \text{const}$).

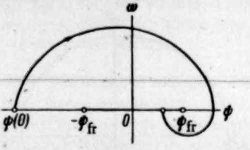

Fig. 5.

Then, on the basis of [3] and [4], in the case $D \geq 0$ the trajectory (Fig. 5) will consist of not more than two pieces, the second of which abuts the segment $(-\psi_{fr}, \psi_{fr})$. The initial conditions will be the point $\{\psi(0) + \psi_{fr}, 0\}$ for the upper piece and the point $\{\psi(t_1) - \psi_{fr}, 0\}$ for the lower piece, where t_1 is the moment of time corresponding to the intersection of the ψ axis by the trajectory. For $D < 0$, the trajectory (Fig. 6) will consist of a finite number of pieces, the last one of which abuts the segment $\{-\psi_{fr}, \psi_{fr}\}$.

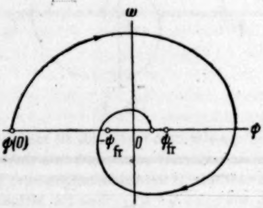

Fig. 6.

For each piece of the trajectory in the case under consideration ($M_{fr}(\omega) \neq 0$), (7) is valid. Consequently, the dry friction does not change the period T of free oscillations, but increases the decrement of damping in such fashion that the radius vector ρ ($\rho^2 = \psi^2 + \omega^2$) during one period T is additionally decreased by the amount $2\psi_{fr}$. Thus, if the radius vector is decreased by $\Delta\rho_{M_{fr}=0}$ for $M_{fr}(\omega) \equiv 0$, then for $M_{fr}(\omega) \neq 0$, it is decreased by $\Delta\rho_{M_{fr} \neq 0} = \rho_{t=T} - \rho_{t=0} = \Delta\rho_{M_{fr}=0} - 2\psi_{fr}$.

From the last relationship (for arbitrary D) and from the Archimedean axiom follows the finitude of the number of previously mentioned arcs, the last of which abuts the segment $\{-\psi_{fr}, \psi_{fr}\}$

Case 2. ($A_1 < 0$). If we introduce into (6) the function

$$F(\omega) = \frac{1}{\mu}[A_1 + \Phi(\omega)]\,\omega,$$

where μ is the angular frequency of the undamped free oscillations, $\mu^2 = a_2/I$, we get

$$\dot{\omega} + \mu F(\omega) + \mu^2\psi = \frac{1}{I} M_{fr}(\omega). \tag{8}$$

For $M_{fr} \equiv 0$ we obtain, by differentiating (8),

$$\ddot{\omega} + \mu f(\omega)\,\dot{\omega} + \mu^2\omega = 0, \tag{9}$$

where

$$f(\omega) \equiv F\frac{\partial F}{\partial \omega} \equiv \frac{1}{\mu}[a_1 + \varphi(\omega) + \varphi'(\omega)\,\omega].$$

For sufficiently small ω, $\omega\varphi'(\omega) \approx 0$ and

$$f(\omega) = \frac{1}{\mu}[a_1 + \varphi(\omega)], \tag{10}$$

but with our condition that $-\omega_0 < \omega < \omega_0$, $\varphi(\omega) < 0$.

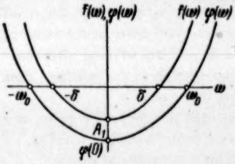

Fig. 7.

Since $A_1 = a_1 + \varphi(0) < 0$, and $\varphi(\omega)$ is continuous, then, for neighboring values of ω, $a_1 + \varphi(\omega) < 0$ and, consequently, $f(\omega) < 0$ for some ω (Fig. 7).

Since, by our assumptions, $\varphi(\omega)$ and $\varphi'(\omega)$ are continuous and bounded, $f(\omega)$ is continuous and satisfies the Lipschitz condition (guaranteeing existence and uniqueness) and, moreover since $\varphi(\omega)$ satisfies (4), then $f(\omega)$, for increasing ω, intersects the axis of abscissas at some point δ and, for decreasing ω, at the point $-\delta$, i.e.,

$$\begin{aligned} f(\omega) &< 0 \text{ for } \quad -\delta < \omega < \delta, \\ f(\omega) &= 0 \text{ for } \quad \omega = \delta, \quad \omega = -\delta \\ f(\omega) &> 0 \text{ for } \quad -\delta > \omega > \delta. \end{aligned} \tag{11}$$

Consequently, the function satisfies the Sansone-Massera condition [4, 6], asserting that to (9) there corresponds a unique nontrivial mode, stable according to the Lyapunov criterion — a periodic solution — a cycle whose region of attraction [7] coincides with the entire $\{\omega, \dot{\omega}\}$ plane with the exception of the origin of coordinates.

From whence it follows [5] that the homogeneous equation corresponding to (8):

$$\dot{\omega} + \mu F(\omega) + \mu^2\psi = 0 \tag{12}$$

also has a unique nontrivial mode — a stable cycle. The phase trajectory of (10) contains a cycle which intersects an arbitrary half-line — the ray $\overline{OA}$ — in the unique point B (Fig. 8).

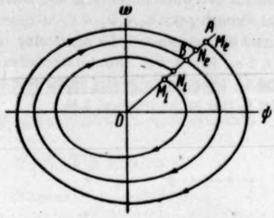

Fig. 8.

Let M_i be an interior point of the segment $\overline{OB}$ of ray $\overline{OA}$. Then the trajectory passing through M_i at time $t = t_0 = 0$ intersects $\overline{OB}$ in the point N_i at time $t' > 0$, where $\overline{ON_i} > \overline{OM_i}$. The last inequality follows from Bendixon's theorem [8]. Analogously, if M_e is an exterior point of ray $\overline{OA}$, i.e., $\overline{OM_e} > \overline{OB}$, then the trajectory defines another point N_e, where $\overline{OM_e} > \overline{ON_e}$.

We consider the phase trajectory of (8) for a sufficiently small coefficient k of dry friction. We assume that the stagnant angle segment $\{-\psi_{fr}, \psi_{fr}\}$ – lies inside the region bounded by the arcs of trajectory $\overset{\frown}{M_iN_i}$ and by the segment $\overline{M_iN_i}$. As in the first case, each trajectory consists of a segment, or segments, lying in the upper ($\omega > 0$) and lower ($\omega < 0$) half-planes. The equations of these segments are led to the form of (10) by changing the variable ψ – translating the origin of coordinates to the point $\{\psi_{fr}, 0\}$ for the transition from the upper to the lower half-plane, and to the point $\{0, -\psi_{fr}\}$ for the converse transition. We assume that the friction angle $2\psi_{fr}$ is so small that the interior $\overset{\frown}{M_iN_i}$ and exterior $\overset{\frown}{M_eN_e}$ trajectories are so little deformed, that the inequalities $\overline{OM_i} < \overline{ON_i}$ and $\overline{OM_e} > \overline{ON_e}$ retain their validity.

Since the continuous dependency of the trajectory on the initial conditions is retained, each point of the closed segment $\overline{M_iM_e}$ can be put into correspondence with a point of segment $\overline{N_iN_e}$, lying strictly interior to $\overline{M_iM_e}$. On the basis of the Bolya-Brauer theorem [9], with such a correspondence there is at least one point of the segment $\overline{M_iM_e}$ which corresponds to itself. It defines the periodic mode described by (9) for sufficiently small k. However, it is impossible to assert in this case that such a mode w be unique. This is borne out by the following example:

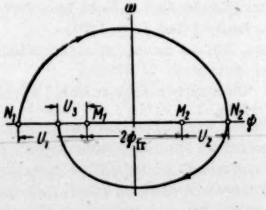

Fig. 9.

Let there exist an interval of variation of the angular velocity $\{-\Omega_0, \Omega_0\}$ such that $\Phi(\omega) = 0$ for $|\omega| < |\Omega_0|$. We then consider the trajectory defined by the equation

$$I\omega + A_1\omega + a_2\psi = M_{fr}(\omega) \tag{13}$$

and passing at time $t = t_0 = 0$ through the point $\{-(U_1 + \psi_{fr}), 0\}$ (Fig. 9), where $U_1 > 0$ and $\psi_{fr} = kG/a_2$.

At time $t_1 = T_0/2 > 0$, the trajectory intersects the axis of abscissas in the point $\{U_2 + \psi_{fr}\ 0\}$. Here, $T_0 = 2\pi/\nu$ is the period of the platform's free oscillations.

Solving (13), we get $U_2 + 2\psi_{fr} = U_1 \exp(-A_1\pi/2I\nu)$, where $A_1 = a_1 + \varphi(0) < 0$, $\nu = \frac{\sqrt{-D}}{2I}$ and $D = A_1^2 - 4Ia_2 < 0$. Whence, $U_2 = U_1 \exp\left(-\frac{\pi A_1}{\sqrt{-D}}\right) - 2\psi_{fr}$.

Motion is possible for $U_2 > 0$, i.e., for

$$U_1 \exp\left(-\frac{\pi A_1}{\sqrt{-D}}\right) > 2\psi_{fr}$$

or

$$U_1 > 2\psi_{fr} \exp\left(\frac{\pi A_1}{\sqrt{-D}}\right).$$

Since the laws of motion in the upper ($\omega > 0$) and lower ($\omega < 0$) half-planes are identical with respect to their own centers of rotation, M_1 (for $\omega > 0$) and M_2 (for $\omega < 0$), it is then necessary and sufficient that, for the representative point of the trajectory moving in the lower half-plane and passing through the point $\{U_2 + \psi_{fr}, 0\}$ at time $t_1 = T_0/2$ to fall on segment $\overline{N_1M_1}$, the following two inequalities hold: $0 < U_3 < U_2$.

From the inequality

$$U_3 = U_2 \exp\left(-\frac{\pi A_1}{\sqrt{-D}}\right) - 2\psi_{fr} =$$

$$= \left[U_1 \exp\left(-\frac{\pi A_1}{\sqrt{-D}}\right) - 2\psi_{fr}\right] \exp\left(-\frac{\pi A_1}{\sqrt{-D}}\right) - 2\psi_{fr} < U_1$$

follows

$$U_1 < \frac{2\psi_{fr}}{\exp\left(-\frac{\pi A_1}{\sqrt{-D}}\right) - 1}.$$

From the inequality $U_3 > 0$ follows

$$U_2 > \frac{2\psi_{fr}}{\exp\left(-\frac{\pi A_1}{\sqrt{-D}}\right)} \quad \text{or} ,$$

$$U_1 > \frac{2\psi_{fr}\left[1 + \exp\left(\frac{\pi A_1}{\sqrt{-D}}\right)\right]}{\exp\left(-\frac{\pi A_1}{\sqrt{-D}}\right)}.$$

Whence.

$$\frac{1 + \exp\left(\frac{\pi A_1}{\sqrt{-D}}\right)}{\exp\left(-\frac{\pi A_1}{\sqrt{-D}}\right)} 2\psi_{fr} < U_1 < \frac{1}{\exp\left(-\frac{\pi A_1}{\sqrt{-D}}\right) - 1} 2\psi_{fr}. \tag{14}$$

For $U_1 > \dfrac{2\psi_{\mathrm{fr}}}{\exp\left(-\dfrac{\pi A_1}{\sqrt{-D}}\right)-1}$ the representative point falls on the segment $\{-\psi_{\mathrm{fr}}, \psi_{\mathrm{fr}}\}$, and motion ceases.

For $U_1 < \dfrac{1+\exp\left(\dfrac{\pi A_1}{\sqrt{-D}}\right)}{\exp\left(-\dfrac{\pi A_1}{\sqrt{-D}}\right)}$ the representative point falls on the ray defined by the inequality $\psi < -(U_1 + \psi_{\mathrm{fr}})$; the system will oscillate.

From the single-valuedness and continuous dependency on the initial conditions of the solution of (13) there flows the existence of a nontrivial steady-state mode-cycle with fixed frequency $f = \nu/2\pi$ and with oscillation spread of $\Psi = |\psi_{\min}| + |\psi_{\max}|$, where

$$|\phi_{\min}| = U_1 + \phi_{\mathrm{fr}} = \frac{2\phi_{\mathrm{fr}}}{\exp\left(-\dfrac{\pi A_1}{\sqrt{-D}}\right)-1} + \phi_{\mathrm{fr}},$$

$$|\phi_{\max}| = U_2 + \phi_{\mathrm{fr}} = \frac{2\phi_{\mathrm{fr}}}{1+\exp\left(\dfrac{\pi A_1}{\sqrt{-D}}\right)} - \phi_{\mathrm{fr}}.$$

From whence,

$$\Psi = \frac{2\psi_{\mathrm{fr}}\left[\exp\left(-\dfrac{2\pi A_1}{\sqrt{-D}}\right)+1\right]}{\exp\left(-\dfrac{2\pi A_1}{\sqrt{-D}}\right)-1}. \qquad (15)$$

This mode is unstable in the strong sense, according to the Lyapunov criterion, i.e., both on the interior and the exterior sides of the region, the orbits of this mode are limited. The topological picture of the interior portion of the domain is a set of trajectories consisting of a finite number of rays, the last one of which abuts the resting segment $\overline{M_1M_2}$. The exterior side consists of trajectories swept out with the cycle's orbits.

In the example considered, it is natural to assume that, for sufficiently large values of the distance R of the representative point from the origin of coordinates ($R^2 = \psi^2 + \omega^2$), there will appear additional dissipative torques applied to the table's platform. The mathematical form of these torques can be found if we start from the assumption that coefficient A_1 of viscous friction in (13) varies as a function of R according to the law

$$A_1 = \begin{cases} a_1 + \varphi(0) < 0 & \text{for} \quad R < \frac{1}{2}\Psi + \varepsilon, \\ E > 0 & \text{for} \quad R \geqslant \frac{1}{2}\Psi + \varepsilon, \end{cases}$$

where ϵ and E are certain fixed positive numbers.

We consider two trajectories (Fig. 10), the first of which passes through point S_1, $\overline{S_1N_1} = \epsilon$, at time $t = t_0 = 0$ and the second through point S_2 for decreasing time parameter t, i.e., for $t < 0$. These trajectories define two points $\overline{S_1}$ and $\overline{S_2}$, where point $\overline{S_1}$ lies to the left of point S_1, and point $\overline{S_2}$ lies in the interval S_2N_1.

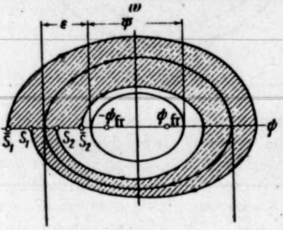

Fig. 10.

Based on what has been said, we conclude that there exists a periodic mode which lies in the hashed portion of the figure. Since all the $R < \Psi/2 + \epsilon$ define points lying on trajectories swept out with unstable orbits, and since all $R > \Psi + \epsilon$ define points corresponding to damped motion ($A_1 > 0$), then $R = \Psi + \epsilon$ defines a point lying on the trajectory corresponding to a stable cycle with spread $\Psi_1 = \Psi + 2\epsilon$ and frequency f.

The author wishes to thank B. V. Shirokorad for his aid in the preparation of this paper.

PHASE-LOCK AUTOMATIC FREQUENCY CONTROL OPERATION IN THE PRESENCE OF NOISE

V. I. Tikhonov

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, pp. 301-309, March, 1960
Original article submitted May 20, 1959

It is established, by means of the two-dimensional Fokker-Planck equation, that due to external and internal fluctuations the mean frequencies of the fundamental and the synchronized generators in a standard phase-lock automatic frequency control scheme do not equal each other. An approximate method is suggested for computing the mean difference of the generators' frequencies and its dispersion.

INTRODUCTION

In [1] there was considered the effect of noise on the operation of a simplified circuit of a phase-lock automatic frequency control scheme (a phase-locked oscillator, henceforth denoted by PLO) in which the low-frequency filter was considered to be ideal. In this work, the circuit was described by a nonlinear first-order differential equation.

In actual PLO circuits, one may use, as a low-frequency filter, either a low-frequency amplifier or a series-connected RC network. The voltage from this latter filter is applied to a reactive tube.

If it is possible to approximate the low-frequency amplifier's frequency characteristic by the frequency characteristic of the RC network, then the operation of the PLO scheme will be described by the two equations [1]

$$\dot{\varphi} = \Delta_0 - su + \dot{\psi}, \tag{1}$$

$$RC\dot{u} + u = \frac{1}{2}\mu A_2 [(A_1 + E_l)\sin\varphi - E_s\cos\varphi]. \tag{2}$$

We now adopt the following nomenclature:

$$\varphi = \Phi_2 - \Phi_1, \ \dot{\psi} = \dot{\theta}_2 - \dot{\theta}_1, \ \Delta_0 = \omega_{l_0} - \omega_0; \tag{3}$$

μ is the transformation coefficient of the phase detector, $\underline{s}$ is the reactive tube's transconductance, ω_{l0} is the mean frequency of the locked (synchronized) generator for $u(t) = 0$. With this, the expressions for the oscillations of the fundamental and the locked generators take the form

$$\begin{aligned} u_f(t) &= A_1 \cos\Phi_1 = A_1\cos(\omega_0 t + \theta_1), \\ u_l(t) &= A_2 \sin\Phi_2 = A_2 \sin(\omega t + \theta_2), \end{aligned} \tag{4}$$

where A_1 and A_2 are constant amplitudes, ω_0 and ω are the mean frequencies, $\theta_1(t)$ and $\theta_2(t)$ are the random phases of the generators' oscillations, resulting from the noise of the generators' tubes and the impedance losses of their elements. The normal fluctuation noise n(t), whose spectral density is symmetric about frequency ω_0, is described in the form of a quasi-harmonic oscillation

$$n(t) = E(t)\cos(\omega_0 t + \theta), \ E_l(t) = E(t)\cos(\theta - \theta_1),$$
$$E_s(t) = E(t)\sin(\theta - \theta_1). \tag{5}$$

By differentiating (1) with respect to time, and then substituting the expressions for $\underline{\dot{u}}$ from (2) and for $\underline{u}$ from (1), we obtain

$$\ddot{\varphi} + \alpha\dot{\varphi} + \alpha\Delta\sin\varphi = \alpha\Delta_0 + \xi(t, \varphi), \tag{6}$$

where

$$\alpha = \frac{1}{RC}, \qquad \Delta = \frac{1}{2}\mu s A_1 A_2, \quad \xi(t, \varphi) =$$
$$= \ddot{\psi} + \alpha\dot{\psi} + \frac{\alpha\Delta}{A_1}(E_s\cos\varphi - E_l\sin\varphi).$$

Nonlinear second-order differential equation (6), with a specific random function in the right member, describes the operation of a PLO scheme when one has taken into account the natural instability of the generators' frequencies and the presence of fluctuation noise in the fundamental generator's channel.

It should be mentioned that the investigation of (6) is of interest apart from its connection with the concrete problem being considered here. Such equations describe many physical systems. Thus, for example, an analogous equation holds for a pendulum acted upon by random disturbances and, under certain conditions, for a gyroscope as well [2].

The basic purpose of the present paper is to compute the mean difference $\overline{\dot{\varphi}}$ of the fundamental and locked generators' frequencies, which is of the greatest practical interest. Here and in the sequel, a superscript bar denotes the operation of averaging over the set of different realizations.

The Two-Dimensional Fokker-Planck Equation

We use the Fokker-Planck equation to solve our problem. It is well known [3] that for the investigation of the behavior of a system with time constant τ_s on which there acts a stationary random disturbance $\zeta(t)$ with correlation time $\tau_c \ll \tau_s$, one can use the apparatus of Markov processes and, in particular, the Fokker-Planck equation. By the correlation time we understand the quantity $\tau_c = \int_{-\infty}^{\infty} |R_\zeta(\tau)|\, d\tau$, where $R_\zeta(\tau)$ is the autocorrelation function of $\zeta(t)$.

We assume that this condition holds for the system described by the differential equation

$$\ddot{x} = F(\dot{x},\ x,\ \zeta(t)), \tag{7}$$

If we consider, instead of the nonlinear differential equation (7), the equivalent system of two first-order equations $\dot{x} = y$, $\dot{y} = F(y, x, \zeta(t))$, we may then, by employing the usual procedure [4, 5], find that the two-dimensional probability density $w_2(\dot{x}, x, t)$ for $\underline{x}$ and $\underline{\dot{x}}$ must satisfy the following two-dimensional Fokker-Planck equation:

$$\dot{w}_2 = -\dot{x}\frac{\partial w_2}{\partial x} - \frac{\partial}{\partial \dot{x}}\left\{\left(\overline{F} + \int\limits_{-\infty}^{0} K\left[\frac{\partial F}{\partial \dot{x}},\ F_\tau\right] d\tau\right) w_2\right\} + $$
$$+ \frac{\partial^2}{\partial \dot{x}^2}\left\{w_2 \int\limits_{-\infty}^{0} K\,[F,\ F_\tau]\,d\tau\right\}. \tag{8}$$

Here, in computing $\overline{F}$ and the integrand correlation functions, denoted by the symbol K, the arguments $\underline{x}$ and $\underline{\dot{x}}$ are considered fixed.

In seeking the solution of (8), it is necessary to add to it the initial and boundary conditions, which are determined by the physics of the concrete problem. Certainly, the probability density $w_2(\dot{x}, x, t)$ must satisfy the normalization condition. By giving some distribution, $w_2(\dot{x}, x, t_0) = w_{20}(\dot{x}, x)$, at some initial moment, we then find, by solving (8), the subsequent deformation of this distribution for $t > t_0$. If the random functions $x(t)$ and $\dot{x}(t)$ can assume all possible values between plus and minus infinity then, as the boundary conditions, one should use the convergence of the probability density to zero as $x, \dot{x} \to \pm\infty$, i.e., $w_2(\pm\infty, \pm\infty, t) = 0$. If the random functions $x(t)$ and $\dot{x}(t)$ assume values which are limited to a certain region, then it is necessary to seek the solution of (8) only in this region. In the problem we are considering, (6), we shall use, as the boundary condition, the condition that the probability density be periodic in φ.

If we limit consideration to a stationary solution of (8), when the probability density w_2 does not depend explicitly on time, i.e., $\dot{w}_2 = 0$, we then obtain the following Fokker-Planck equation for the stationary state:

$$\frac{\partial^2}{\partial \dot{x}^2}\left\{w_2 \int\limits_{-\infty}^{0} K\,[F,\ F_\tau]\,d\tau\right\} - \frac{\partial}{\partial \dot{x}}\left\{\left(\overline{F} + \int\limits_{-\infty}^{0} K\left[\frac{\partial F}{\partial \dot{x}},\ F_\tau\right] d\tau\right) w_2\right\} - \dot{x}\frac{\partial w_2}{\partial x} = 0. \tag{9}$$

As applied to (6), it is now necessary to set

$$F = \alpha\Delta_0 - \alpha\dot{\varphi} - \alpha\Delta\sin\varphi + \xi(t,\ \varphi), \quad x = \varphi. \tag{10}$$

We now compute the individual quantities which enter into (9). It can be shown [6] that

$$\overline{\xi(t,\ \varphi)} = \overline{\ddot{\Psi}} + \alpha\overline{\dot{\Psi}} + \frac{\alpha\Delta}{A_1}\left(\overline{E}_s\cos\varphi - \overline{E}_l\sin\varphi\right) = 0.$$

Therefore,

$$\overline{F} = \alpha\Delta_0 - \alpha\dot{\varphi} - \alpha\Delta\sin\varphi,$$

$$K\,[F,\ F_\tau] = \overline{[F - \overline{F}]\,[F_\tau - \overline{F}_\tau]} = \overline{\xi(t,\ \varphi)\,\xi(t + \tau,\ \varphi)} =$$

$$= \overline{[\ddot{\psi} + \alpha\dot{\psi} + \frac{\alpha\Delta}{A_1}(E_s\cos\varphi - E_l\sin\varphi)][\ddot{\psi}_\tau + \alpha\dot{\psi}_\tau + \frac{\alpha\Delta}{A_1}(E_{s\tau}\cos\varphi - E_{l\tau}\sin\varphi)]} =$$

$$= \overline{\ddot{\psi}\ \ddot{\psi}_\tau} + 2\alpha\,\overline{\dot{\psi}\ \ddot{\psi}_\tau} + \alpha^2\,\overline{\dot{\psi}\ \dot{\psi}_\tau} + \left(\frac{\alpha\Delta}{A_1}\right)^2\sigma^2 r(\tau),$$

where it is assumed that the correlation function of the noise $n(t)$ has the form

$$k_n(\tau) = \sigma^2 r(\tau)\cos\omega_0\tau.$$

From (10) we also have

$$\frac{\partial F}{\partial \dot{\varphi}} = -\alpha, \qquad \frac{\partial F}{\partial \dot{\varphi}} - \frac{\overline{\partial F}}{\partial \dot{\varphi}} = 0, \qquad K\left[\frac{\partial F}{\partial \dot{\varphi}},\ F_\tau\right] = 0$$

By substituting the individual quantities in (9), we obtain the following definitive form of the Fokker-Planck equation which describes the stationary operating mode in the PLO system under consideration:

$$K_2\frac{\partial^2 w_2}{\partial \dot{\varphi}^2} - \frac{\partial}{\partial \dot{\varphi}}\{(\alpha\Delta_0 - \alpha\dot{\varphi} - \alpha\Delta\sin\varphi)\,w_2\} - \dot{\varphi}\frac{\partial w_2}{\partial \varphi} = 0. \tag{11}$$

Here,

$$K_2 = \int_{-\infty}^{0} \{\overline{\ddot{\psi}\ \ddot{\psi}_\tau} + 2\alpha\,\overline{\dot{\psi}\ \ddot{\psi}_\tau} + \alpha^2\,\overline{\dot{\psi}\ \dot{\psi}_\tau} + \left(\frac{\alpha\Delta}{A_1}\right)^2 \sigma^2 r(\tau)\}\, d\tau. \tag{12}$$

Second-order partial differential Eq. (11) is linear and of parabolic type. Its general solution depends on two arbitrary constants, which are defined by the condition that the probability density be normalized and be periodic in φ, i.e.,

$$\int_0^{2\pi}\int_{-\infty}^{\infty} w_2(\dot{\varphi}, \varphi)\, d\dot{\varphi}\, d\varphi = 1, \quad w_2(\dot{\varphi}, \varphi + 2\pi) = w_2(\dot{\varphi}, \varphi). \tag{13}$$

An exact solution of (11) for (13) exists only in the particular case when the initial mistuning of the generators equals zero: $\Delta_0 = 0$. We easily convince ourselves that the solution of the equation

$$K_2 \frac{\partial^2 w_2}{\partial \dot{\varphi}^2} + \frac{\partial}{\partial \dot{\varphi}} \{(\alpha\dot{\varphi} + \alpha\Delta \sin\varphi)\, w_2\} - \dot{\varphi}\, \frac{\partial w_2}{\partial \varphi} = 0, \tag{14}$$

satisfying (13) has the form

$$w_2(\dot{\varphi}, \varphi) = \sqrt{\frac{\alpha}{2\pi K_2}}\, \frac{1}{2\pi I_0\left(\frac{\alpha^2\Delta}{K_2}\right)} \exp\left[-\frac{\alpha\dot{\varphi}^2}{2K_2} + \frac{\alpha^2\Delta}{K_2}\cos\varphi\right], \tag{15}$$

where $I_0(z)$ is a Bessel function of zero order and imaginary argument.

From (15) we find the one-dimensional probability density for the frequency difference $\dot{\varphi}$:

$$w(\dot{\varphi}) = \int_{-\pi}^{\pi} w_2(\dot{\varphi}, \varphi)\, d\varphi = \sqrt{\frac{\alpha}{2\pi K_2}} \exp\left(-\frac{\alpha\dot{\varphi}^2}{2K_2}\right). \tag{16}$$

From this we easily obtain

$$\overline{\dot{\varphi}} = 0,\ \sigma^2_{\dot{\varphi}} = \overline{\dot{\varphi}^2} = \frac{1}{\alpha} K_2 \int_{-\infty}^{0} \left\{RC\, \overline{\ddot{\phi}\ddot{\phi}_\tau} + \frac{1}{RC}\, \overline{\dot{\phi}\dot{\phi}_\tau} + \frac{1}{RC}\left(\frac{\Delta\sigma}{A_1}\right)^2 r(\tau)\right\} d\tau. \tag{17}$$

In many practical cases one can neglect the generators natural fluctuations in comparison with the external noise. Then, the basic role in (17) will be played by the last term in the integrand.

Thus, if the initial mistuning of the generators at the moment when the PLO is switched in is zero, then the average frequencies of the fundamental and locked generators remain equal to each other during PLO operation, and the dispersion of the frequency difference $\sigma^2\dot{\phi}$, as is obvious from (17), increases with increasing intensity of the external noise σ^2 and the generators' natural fluctuations, and decreases with increasing time constant of the RC filter. These results are comprehensible physically.

In the sequel we shall consider approximately the cases when, in (11), the initial mistuning of the generators is different from zero ($\Delta_0 \neq 0$).

Approximate Method of Solving the Fokker-Planck Equation

It is difficult to find a solution in compact form of (11) which satisfies (13). Below, we present an approximate method of solving (11).

We shall seek a solution in the form of a series:

$$w_2(\dot{\varphi}, \varphi) = \sum_{n=0}^{\infty} w^{(n)}(\dot{\varphi})\, L_n(\varphi), \tag{18}$$

where the functions $L_n(\varphi)$ are to be defined, and

$$w(\dot{\varphi}) = \exp\left(-\frac{\alpha\dot{\varphi}^2}{2K_2}\right). \tag{19}$$

By direct differentiation, we easily convince ourselves that the following recursion formulas are valid for the derivatives of the function $w(\dot{\varphi})$:

$$\dot{\varphi} w^{(n)}(\dot{\varphi}) = -\frac{1}{\alpha} K_2 w^{(n+1)}(\dot{\varphi}) - n w^{(n-1)}(\dot{\varphi}) \quad (n = 0, 1, 2, \ldots). \tag{20}$$

By substituting the expression for $w_2(\dot{\varphi}, \varphi)$ from (18) in (11), then using (20) and collecting similar terms, we obtain

$$\frac{1}{\alpha}K_2\sum_{n=0}^{\infty} w^{(n+1)}(\dot{\varphi})\,L_n'(\varphi) - \alpha(\Delta_0 - \Delta\sin\varphi)\sum_{n=0}^{\infty} w^{(n+1)}(\dot{\varphi})\,L_n(\varphi) =$$
$$= \alpha\sum_{n=0}^{\infty} n w^{(n)}(\dot{\varphi})\,L_n(\varphi) - \sum_{n=0}^{\infty} n w^{(n-1)}(\dot{\varphi})\,L_n'(\varphi)$$

or

$$\sum_{n=0}^{\infty} w^{(n+1)}(\dot{\varphi})\,L_n'(\varphi) - \frac{\alpha^2}{K_2}(\Delta_0 - \Delta\sin\varphi)\sum_{n=0}^{\infty} w^{(n+1)}(\dot{\varphi})\,L_n(\varphi) =$$
$$= \frac{\alpha^2}{K_2}\sum_{n=0}^{\infty} n w^{(n)}(\dot{\varphi})\,L_n(\varphi) - \frac{\alpha}{K_2}\sum_{n=0}^{\infty} n w^{(n-1)}(\dot{\varphi})\,L_n'(\varphi). \qquad (21)$$

By equating coefficients of like orders of the derivatives $w^{(n)}(\dot{\varphi})$, we obtain the following system of differential equations for the definition of the $L_n(\varphi)$:

$$\begin{aligned}
&L_1'(\varphi) = 0,\\
&L_0'(\varphi) - \frac{\alpha^2}{K_2}(\Delta_0 - \Delta\sin\varphi)\,L_0(\varphi) = \frac{\alpha^2}{K_2}L_1(\varphi) - 2\frac{\alpha}{K_2}L_2'(\varphi),\\
&L_1'(\varphi) - \frac{\alpha^2}{K_2}(\Delta_0 - \Delta\sin\varphi)\,L_1(\varphi) = 2\frac{\alpha^2}{K_2}L_2(\varphi) - 3\frac{\alpha}{K_2}L_3'(\varphi),\\
&L_2'(\varphi) - \frac{\alpha^2}{K_2}(\Delta_0 - \Delta\sin\varphi)\,L_2(\varphi) = 3\frac{\alpha^2}{K_2}L_3(\varphi) - 4\frac{\alpha}{K_2}L_4'(\varphi),\\
&\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots
\end{aligned} \qquad (22)$$

In general,

$$L_{n-1}'(\varphi) - \frac{\alpha^2}{K_2}(\Delta_0 - \Delta\sin\varphi)\,L_{n-1}(\varphi) = n\frac{\alpha^2}{K_2}L_n(\varphi) - (n+1)\frac{\alpha}{K_2}L_{n+1}'(\varphi).$$

We may suggest the following order for solving (22). The equations are solved successively, starting with the first, whereby, in solving each successive equation, we ignore the last terms in the right member, containing derivatives of higher-order functions $L_n(\varphi)$.

For an approximate estimate of the value of the mean frequency difference of the generators, we shall henceforth limit ourselves to computing the first two functions, $L_0(\varphi)$ and $L_1(\varphi)$. From the first equation of (22) we have that $L_1 = c = \text{const.}$ By neglecting the term containing $L_2'(\varphi)$ in the second equation, we obtain the following differential equation for defining $L_0(\varphi)$:

$$L_0'(\varphi) - \frac{\alpha^2}{K_2}(\Delta_0 - \Delta\sin\varphi)\,L_0(\varphi) = \frac{\alpha^2}{K_2}c.$$

The solution of this equation, as we easily convince ourselves, can be written in the form

$$L_0(\varphi) = c\frac{\alpha^2}{K_2}\exp(D_0\varphi + D\cos\varphi)\int_{\varphi_0}^{\varphi}\exp(-D_0\gamma - D\cos\gamma)\,d\gamma,$$

where φ_0 is some arbitrary constant and

$$D_0 = \frac{\alpha^2\Delta_0}{K_2}, \quad D = \frac{\alpha^2\Delta}{K_2}. \qquad (23)$$

Thus, in our approximation, we obtain the following solution of (11):

$$w_2(\dot{\varphi}, \varphi) = w(\dot{\varphi})\,L_0(\varphi) + w'(\dot{\varphi})\,L_1(\varphi) =$$
$$= c\frac{\alpha}{K_2}\exp\left(-\frac{\alpha\dot{\varphi}^2}{2K_2}\right)\left\{-\dot{\varphi} + \alpha\exp(D_0\varphi + D\cos\varphi)\int_{\varphi_0}^{\varphi}\exp(-D_0\gamma - D\cos\gamma)\,d\gamma\right\}. \qquad (24)$$

To satisfy the condition for periodicity (13), it is necessary that the following equation hold:

$$\exp(D_0\varphi + 2\pi D_0 + D\cos\varphi)\int_{\varphi_0}^{\varphi+2\pi}\exp(-D_0\gamma - D\cos\gamma)\,d\gamma =$$
$$= \exp(D_0\varphi + D\cos\varphi)\int_{\varphi_0}^{\varphi}\exp(-D_0\gamma - D\cos\gamma)\,d\gamma.$$

From this equation, the following relationship derives:

$$\int_{\varphi_0}^{\varphi} \exp(-D_0\gamma - D\cos\gamma)\,d\gamma = \frac{\exp(2\pi D_0)}{1-\exp(2\pi D_0)} \int_{\varphi}^{\varphi+2\pi} \exp(-D_0\gamma - D\cos\gamma)\,d\gamma, \tag{25}$$

which permits the arbitrary constant φ_0 to be eliminated.

To determine the second arbitrary constant c, we use the normalization condition

$$\int_0^{2\pi}\int_{-\infty}^{\infty} w_2(\dot{\varphi},\varphi)\,d\dot{\varphi}d\varphi = c\alpha\sqrt{\frac{2\pi\alpha}{K_2}}\,\frac{\exp(2\pi D_0)}{1-\exp(2\pi D_0)}\int_0^{2\pi}\exp(D_0\varphi + D\cos\varphi)\,d\varphi \times$$
$$\times \int_{\varphi}^{\varphi+2\pi} \exp(-D_0\gamma - D\cos\gamma)\,d\gamma = 1. \tag{26}$$

It can be shown [1, 7] that

$$J = \int_0^{2\pi}\exp(D_0\varphi + D\cos\varphi)\,d\varphi \int_{\varphi}^{\varphi+2\pi} \exp(-D_0\gamma - D\cos\gamma)\,d\gamma =$$
$$= 4\pi^2\exp(-\pi D_0)\,|I_{iD_0}(D)|^2,$$

where $I_{i\nu}(z)$ is a Bessel function of imaginary order and imaginary argument. Therefore, we obtain from (26)

$$c = \frac{1}{4\pi\alpha^2}\sqrt{\frac{K_2}{2\pi\alpha}}\,\frac{1-\exp(2\pi D_0)}{\exp(\pi D_0)}\,|I_{iD_0}(D)|^{-2} \tag{27}$$

By using (25) and (27), we can write the approximate expression for the probability density in its definitive form:

$$w_2(\dot{\varphi},\varphi) = \sqrt{\frac{1}{2\pi\alpha K_2}}\,\frac{1-\exp(2\pi D_0)}{4\pi^2\exp(\pi D_0)}\,|I_{iD_0}(D)|^{-2}\exp\left(-\frac{\alpha\dot{\varphi}^2}{2K_2}\right)\times$$
$$\times\left\{-\dot{\varphi} + \alpha\frac{\exp(2\pi D_0)}{1-\exp(2\pi D_0)}\exp(D_0\varphi + D\cos\varphi)\int_{\varphi}^{\varphi+2\pi}\exp(-D_0\gamma - D\cos\gamma)\,d\gamma\right\}. \tag{28}$$

It is easily verified that this formula goes over into the exact formula (15) for zero initial mistuning ($D_0 = 0$). This attests to the fact that the suggested approximate method of solving the Fokker-Planck equation gives logically-noncontradictory results.

By integrating (28) over φ and $\dot{\varphi}$ between the proper limits, we obtain the one-dimensional probability densities for, respectively, $\dot{\varphi}$ and φ:

$$w(\dot{\varphi}) = \left\{\sqrt{\frac{\alpha}{2\pi K_2}} - \dot{\varphi}\sqrt{\frac{2\pi}{\alpha K_2}}\,\frac{1-\exp(2\pi D_0)}{4\pi^2\exp(\pi D_0)}\,|I_{iD_0}(D)|^{-2}\right\}\exp\left(-\frac{\alpha\dot{\varphi}^2}{2K_2}\right). \tag{29}$$

$$w(\varphi) = \frac{1}{4\pi^2}\exp(\pi D_0)\,|I_{iD_0}(D)|^{-2}\exp(D_0\varphi + D\cos\varphi)\int_{\varphi}^{\varphi+2\pi}\exp(-D_0\gamma - D\cos\gamma)\,d\gamma. \tag{30}$$

The last formula for the probability density of φ coincides in form with that obtained in [1]. The difference consists in this, that here the coefficients D_0 and D depend on the low-frequency filter's passband [cf. (23)]. This fact also gives us some confidence that, in taking only the first two functions in (22) into account, we obtain results which are in qualitative agreement with those obtained in [1].

By using (29), we find the average difference of the generators' frequencies and the dispersion of this difference:

$$\overline{\dot{\varphi}} = \overline{\omega} - \omega_0 = \frac{K_2}{2\pi\alpha^2}\,\frac{\exp(2\pi D_0)-1}{\exp(\pi D_0)}\,|I_{iD_0}(D)|^{-2} = \Delta_0\,\frac{\operatorname{sh}\pi D_0}{\pi D_0}\,I_{iD_0}(D)\,|^{-2},\ \sigma^2_{\dot{\varphi}} \approx \frac{1}{\alpha}K_2. \tag{31}$$

For $D_0 = 0$, these formulas coincide with (17).

Particular Examples

Let the external noise n(t) be obtained as the result of the action of a sufficiently wide-band fluctuation on a narrow-band oscillatory loop with resonant frequency ω_0 and, consequently, let the noise have correlation function

$$k_n(\tau) = \sigma^2 e^{-\beta|\tau|} \cos \omega_0 \tau.$$

We assume that we may ignore the natural instability of the frequencies of the fundamental and locked generators in comparison with the noise n(t). Then,

$$K_2 = \left(\alpha\Delta \frac{\sigma}{A_1}\right)^2 \int\limits_{-\infty}^{0} e^{\beta\tau}\, d\tau = \frac{1}{\beta}\left(\alpha\Delta \frac{\sigma}{A_1}\right)^2.$$

By substituting this value of K_2 in (23) and (31), we get

$$D_0 = \frac{\beta\Delta_0}{\Delta^2}\left(\frac{A_1}{\sigma}\right)^2, \quad D = \frac{\beta}{\Delta}\left(\frac{A_1}{\sigma}\right)^2,$$

$$-\Delta = \frac{1}{2}\mu s A_1 A_2, \; \sigma^2_{\dot\varphi} = \frac{\alpha}{\beta}\Delta^2\left(\frac{\sigma}{A_1}\right)^2. \qquad (32)$$

In the given concrete case, D_0 and D do not depend on α. With this, as is clear from (32) and (31), the dispersion of the frequencies' difference depends on α, but the average discrepancy of the frequencies does not depend on α. This last result is seemingly a consequence of the approximate solution of (11). Recently, A. G. Zhuravlev showed that, although the term containing $L_2(\varphi)$ in (18) for the probability density does not of itself give a correction to the mean frequency difference, its being taken into account does result in the function $L_0(\varphi)$ assuming a different form:

$$L_0(\varphi) = C\frac{\alpha}{K_2}\frac{\exp(2\pi D_0)}{1-\exp(2\pi D_0)}\exp \times$$
$$\times (D_0\varphi + D\cos\varphi)\int\limits_{\varphi}^{\varphi+2\pi}(\alpha - \Delta\cos\gamma)\times \qquad (33)$$
$$\times \exp(-D_0\gamma - D\cos\gamma)\, d\gamma.$$

We now make some numerical estimates. It is known [8] that, in the absence of noise, the maximum voltage at the phase detector's output can not exceed twice the magnitude of the least of the applied voltages. We replaced the phase detector by a device implementing multiplication of the voltages $u_f(t)$ and $u_l(t)$. In accordance with what has been said, for $A_2 > A_1$, the maximum value of the voltage at the multiplier's output is determined by the relationship

$$U_{\max} = \frac{1}{2}\mu A_1 A_2 < 2A_1.$$

We take $u_{out} \approx 0.5U_{\max}$, i.e., $\mu A_1 A_2 / 2 \approx A_1$. Whence $\mu \approx 2/A_2$ and $\Delta \approx sA_1$.

The parameters of the PLO scheme are so chosen that stable operation is guaranteed. As follows from [9], for $\Delta_0/\Delta \lesssim 0.6$, stability is guaranteed if the following inequality holds:

$$\sqrt{\frac{1}{RC\Delta}} \geqslant \frac{\pi}{4}\frac{\Delta_0}{\Delta}. \qquad (34)$$

Let $A_1 \approx 1$v, s = 0.1 kg/v, $\alpha = 20\ \text{sec}^{-1}$, $\beta = 300\ \text{sec}^{-1}$, $\Delta_0/\Delta = 0.5$. With these parameters, Ineq. (34) holds and, simultaneously, the conditions hold for the applicability of the Fokker-Planck equation. Then, $\Delta \approx sA_1 = 100$ cps, $D_0 = 1.5\,(A_1/\sigma)^2$, $D = 3\,(A_1/\sigma)^2$ and $\sigma^2_{\dot\varphi} \approx 700(\sigma/A_1)^2$. By using the graphs of I. G. Akopyan, given in [1], we get

$$\bar\omega - \omega_0 \approx 35\text{cps}, \; \sigma_{\dot\varphi} \approx 36\text{ cps for } \left(\frac{A_1}{\sigma}\right)^2 \approx 0.7,$$

$$\bar\omega - \omega_0 \approx 10\text{cps}, \; \sigma_{\dot\varphi} \approx 18\text{ cps for } \left(\frac{A_1}{\sigma}\right)^2 \approx 2.0.$$

From what has been considered above, we may draw the following conclusions:

1. From (32) and the quantitative estimates adduced, it is clear that, when the conditions hold for the applicability of the Fokker-Planck equation ($\alpha \ll \beta$), the mean frequency difference and its mean square decrease as the ratio A_1/σ increases. For sufficiently small signal-to-noise ratios, the average frequency difference may turn out to be significantly less than the mean square value, and it is necessary to take it into account.

2. When stability condition (34) holds, a decrease of the time constant RC provides a shorter duration of the PLO's transient response, but the dispersion of the frequency difference is thereby increased. Therefore, the requirements of short establishment time and high noise immunity are, in a very definite sense, contradictory.

In conclusion, I wish to thank R. L. Stratonovich for his interest in the present work.

ANALYSIS OF A TWO-POSITION COMPENSATING CONTROL SYSTEM UNDER CONSTANT PROLONGED DISTURBANCES

A. I. Cherepanov

(Pert')

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 3, pp. 310-316, March, 1960
Original article submitted October 28, 1959

It is shown that the simplified graphico-analytic method developed in [1] for computing the processes in a two-position regulator may be employed for analyzing the processes in two-position compensating control systems [2] under constant prolonged disturbances.

In [2] of this author there was described a new method for improving the quality of the processes in a two-position regulator by the use of a special relay-type correcting device. The basic advantage of this method in comparison with prior ones [3, 4, 5, 8] is that, with essentially reduced amplitude of controlled quantity oscillations, of temperature for example, it provides the minimum increase in the required number of switchings of the object's heater in and out of the system, computed on the basis of a nonsymmetric mode of operation.

It should be mentioned that, at the present, of all the types of two-position compensating controllers, those with thermoelectric correcting (compensating) devices have been most widely used [6, 7].

However, electromechanical correcting devices have certain advantages: e.g., such devices can be used both in regulators which employ some electrical means of measuring the controlled parameter and in many industrial two-position regulators of dilatometric, bimetallic, or magnometric types which use some nonelectric means of measuring the controlled quantity. Moreover, the use of an electromechanical correcting device permits the employment of the regulator's measuring portion for measuring or recording the true temperature in the object. When a thermoelectric device is used, it is necessary to have an additional intrument for this purpose, since the action of the device distorts the output signal of the measuring portion.

Simple formulas were obtained in [2] for calculating the correcting device's adjustment parameters and the basic parameters of the compensating control process in the steady state. It was noted in [2] that the character of the possible disturbances in the system should be taken into account in choosing the correcting device's parameters.

In the present paper we provide an analysis of the processes with disturbances in a two-position control system with an electromechanical correcting device. The possibility is demonstrated of the existence in such a system of complex periodic motions, somewhat similar to those considered in [5, 8]. Recommendations are given for the choice of the adjustment parameters of the correcting device which will provide the very best quality processes given the disturbances.

As in [2], the analysis is made by means of a simplified graphico-analytic method of calculating the two-position controller's processes [1], thanks to which the formulas obtained are simple, and may be used without difficulty for engineering computations.

By the adjustment parameters of the correcting device we shall understand the following quantities: t_0t_1 is the duration of the make state of contact K-1, t_{bre} is the duration of the break state of contact K-1, $t_{bre} = t_1t_2$, t_{mak} is the total duration of the make state of contact K-1 during one disk rotation, $t_{mak} = t_0t_1 + t_0t_3 - t_1t_2$, t_{ro} is the time for one complete disk rotation, $t_{ro} = t_0t_3$.

1. Pulse Repetition Period as a Function of the Load

The distinguishing feature of a two-position control system with an electromechanical correcting device is that the repetition period of the pulses of heat admission to the object, for invariant adjustment parameters, depends on the load. This is achieved due to the use in the device of two controlling disks, one of which switches in the flow of energy to the object at a definite previously specified time while the other disk returns the first disk to its initial position in the time following a positive deviation of the parameter from its given value*. With this, if the magnitude of the energy efflux changes within certain limits, for example, if it increases, then the new switching in of the relay's motor would occur somewhat earlier than for the previous value of the efflux. The pulses switching in the influx would have the same duration, but their repetition frequency would increase, and the correction process would not be disrupted.

Figure 1, a shows the graph of the process in a two-position controller with compensation, where the influx multiplicity is $n_1 = 8$, and the degree of correction is $k = 2.86$. In Fig. 1 and in the sequel, we adopt the nomemclature: $\Delta\vartheta$ is the deviation of the controlled parameter (temperature), $\Delta\vartheta'$ is the deviation of the object's controlled temperature with compensation

---

* For a more detailed description of the correcting device's operation, cf. [2].

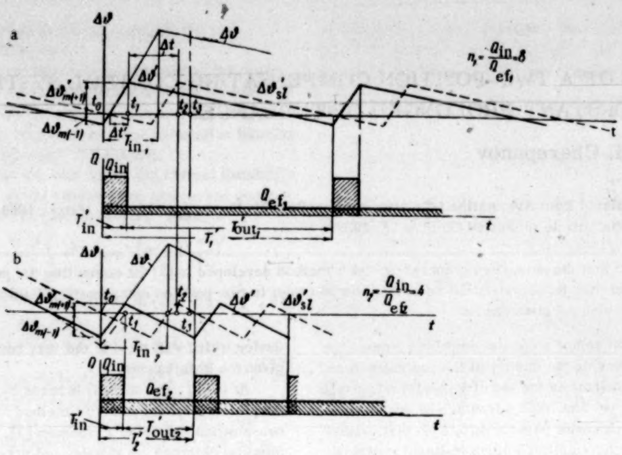

Fig. 1.

(correction), $\Delta\vartheta_{se}$ is the temperature deviation of the sensitive element with compensation, $\Delta\vartheta'_{m(+)}$ is the positive amplitude of the deviation with compensation, $\Delta\vartheta_{m(-)}$ is the negative deviation amplitude. Q_{in} is the influx of heat, Q_{ef} is the efflux of heat, T_{in} is the duration of switching in for control without correction, T'_{in} is the duration of switching in when the corrective device is used, T_{out} is the duration of switching out, T is the period of oscillation, t_0 is the moment of switching in, t_1 is the moment of switching the influx off when correction is used, t_2 is the moment of the new making of controlling contact K-1, t_3 is the moment of disk cessation, Δt is the system's lag time, $\Delta t'$ is the residual lag time when correction is used.

Figure 1,b shows the control process in the same system when the heat efflux is increased twofold, i.e., for $n_2 = 4$. As is clear from the graph, the correction process is not disrupted. The duration of switching in of the heater, T'_{in}, remains as before. The duration of switching out T'_{out_1} is decreased, and becomes equal to T'_{out_2}. The positive amplitude of the deviation is also decreased. The negative deviation amplitude $\Delta\vartheta_{m(-)}$ increases, as with ordinary two-position controllers. The period of influx switching in is shortened to T'_2. The total amplitude of the oscillations, $\Delta\vartheta_{m(+)} + \Delta\vartheta_{m(-)}$ is somewhat decreased.

It may be seen from a comparison of Fig. 1, a and b that the degree of correction k became larger in the second case: k = 6.2.

We now find the dependence of the variation in the degree of correction k on the magnitude of the influx multiplicity n for a constant (given) duration of switching in T'_{in}. As is known [2],

$$k = \frac{\Delta t}{\Delta t'}. \tag{1}$$

The quantity $\Delta t'$ can be expressed in terms of the duration of switching in T'_{in} and the influx multiplicity n by use of the formula [2]

$$T'_{in} = \Delta t' \frac{Q_{in}}{Q_{in} - Q_{ef}} + (\Delta t - \Delta t') \frac{Q_{ef}}{Q_{in} - Q_{ef}}. \tag{2}$$

From (2) we obtain

$$\Delta t' = T'_{in} - \Delta t \frac{1}{n-1}. \tag{3}$$

By substituting (3) in (1), we find that

$$k = \frac{\Delta t}{T'_{in} - \Delta t \frac{1}{n-1}}. \tag{4}$$

From (4) one can calculate the degree of correction for various values of influx multiplicity n and switching in duration T'_{in}.

Equation (4) shows that, for some value of n, the denominator vanishes and k becomes infinite.

This value of n will be, in some sense, a critical one; we denote it by n_{cr}†. Obviously,

$$n_{cr} = 1 + \frac{\Delta t}{T'_{in}}. \tag{5}$$

When the influx multiplicity has the value n_{cr}, the temperature in the object during the given time T'_{in} rises exactly to the given limit. For values of n less than n_{cr}, the temperature in the object during the switching in time T'_{in} does not attain the given value, and the normal course of the correction process is disrupted.

---

† In [2] n_{cr} has a different connotation.

For the case shown on Fig. 1,a, the calculated value of $n_{cr} = 3$. On Fig. 1,b, the dashed line represents the temperature variations in the object for this value $n = 3$. The calculated value of n_{cr} is well borne out by the graph.

Thus, in the system under consideration, the repetition period of the influx switching-in pulses depends on the load, and the correction process flows normally only for influx multiplicities greater than the critical value.

For values of influx multiplicity $n < n_{cr}$, the normal course of the correction process is disrupted, and there arise complex periodic temperature oscillations in the system, examples of which are considered in the following section.

2. Complex Periodic Motions

As was shown in the previous section, the correction process can proceed normally for disturbances up to some value n_{cr}. With this, as the disturbance increases (the value of n decreases) there will be an increase of the negative amplitude and a decrease of the positive amplitude. The given condition ($n > n_{cr}$) for the guarantee of normal correction process is necessary but not sufficient. As is clear from Figs. 2, 3, and 4, it is necessary, for the normal flow of the correction process, that the following additional conditions be met:

$$t_2 > T_{in}, \quad t_{ro} < T'. \tag{6}$$

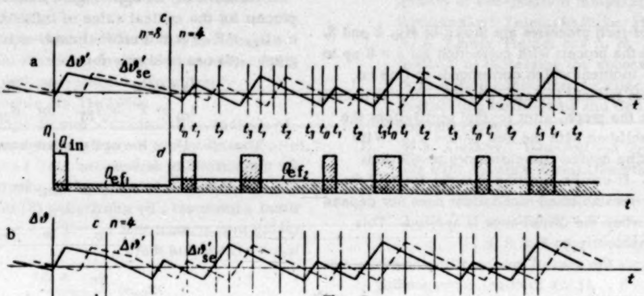

Fig. 2.

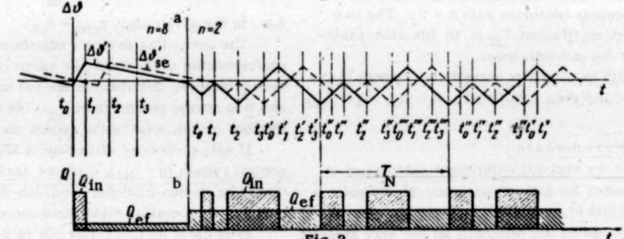

Fig.3.

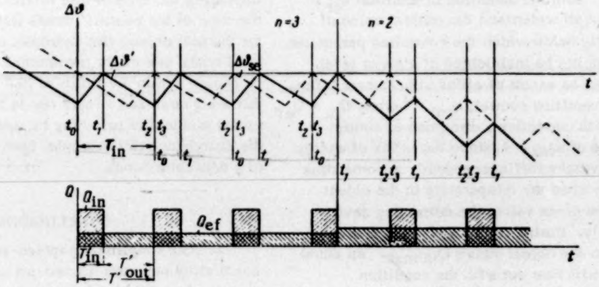

Fig. 4.

If the correcting device's parameters, selected so as to permit processing of the greatest possible disturbances be so chosen that inequalities (6) are transgressed for values of _n_ higher than n_{cr}, then complex periodic motions, similar to those considered in [5, 8], will arise in the system.

Examples of such processes are shown in Fig. 2 and 3. Figure 2,a shows the process with correction for n = 8 up to line cd. At the moment which corresponds to line cd, and instantaneous twofold increase of efflux (n = 4) occurs. As is clear from the graph, after several oscillations the process is reestablished with the new period T_N. With this, the correcting device completes two revolutions during a period. It can be assumed that the form of the postdisturbance-reestablished oscillations does not depend on the moment when the disturbance is applied. This is confirmed graphically on Fig. 2, b.

Figure 3 shows the control process with correction up to line ab for n = 8. At the moment corresponding to ab, a disturbance is applied (a fourfold increase in heat efflux) and the process continues with n = 2. The new period of complex oscillations T_N is, in this case, somewhat less than in the previous case.

Thus, complex oscillations occur in the system if one of the following conditions is not met: $n > n_{cr}$, $t_2 > T_{in}$, $t_{ro} < T'$.

3. Optimal Parameters

We now seek the optimal adjustment parameters of the correcting device for a given accuracy of control (degree of correction _k_), starting from the condition that the correction process not be disrupted for the very greatest disturbance, i.e., from the condition of minimal n_{cr}.

By n_{cm} we shall understand the critical value of influx multiplicity below which the controlled parameter (temperature) can not be maintained at a given level. This occurs due to an excess of efflux of heat over influx. For ordinary two-position control, $n_{cm} = 1$ when $Q_{in} = Q_{ef}$. For regulation with correction, disruption of control occurs for a value of $n_{cm} > 1$, since the influx of energy to the object is switched off independently at some time t_{bre}. In the case when the temperature in the object remains below the given value, the correcting device works continuously. During one rotation, the amount of heat applied to the object equals $Q_{in}t_{mak}$. An equal quantity of heat will flow out with the condition

$$Q_{in}t_{mak} = (t_{bre} + t_{mak})\overline{Q}_{ef},$$

where $\overline{Q}_{ef}$ is the critical value of heat efflux. If $Q_{ef} > \overline{Q}_{ef}$, then the temperature does not rise to the given level.

From whence we find n_{cm} as

$$n_{cm} = \frac{Q_{in}}{\overline{Q}_{ef}} = \frac{t_{mak} + t_{bre}}{t_{mak}} = 1 + \frac{t_{bre}}{t_{mak}}.$$

It is clear that $t_{mak} = t_{ro} - t_{bre}$. We finally obtain

$$n_{cm} = 1 + \frac{t_{bre}}{t_{ro} - t_{bre}} \tag{7}$$

or

$$n_{cm} = \frac{f}{f-1}, \quad \text{where} \quad f = \frac{t_{ro}}{t_{bre}}.$$

We have (5) for n_{cr}. Figure 4 shows the control process for the critical value of influx multiplicity $n = n_{cr} = 3$. For this critical case, as is clear from the graph, (6) can hold only for

$$\begin{aligned} t_2 &= T_{in} && \text{for } n_{cr}, \\ t_{ro} &= T' = T_{in} && \text{for } n_{cr}. \end{aligned} \tag{8}$$

Thus, (8) gives the optimal adjustment parameters for the correcting device.

We now find the value of n_{cm} for the case of optimal adjustment. By substituting (8) in (7), and by taking into account that $t_{ro} = T'_{in} + t_{bre}$ and that $t_{bre} = \Delta t$, we find that

$$n_{cm} = \frac{T'_{in} + \Delta t}{T'_{in}}, \tag{9}$$

i.e., in the given case, $n_{cm} = n_{cr}$.

The correcting device's adjustment parameters corresponding to (8) should be taken in those cases when very protracted disturbances are not observed in practice and _n_ is always greater than n_{cr}. We note that complex motions cannot arise in the system under these conditions.

If very protracted disturbances are possible in the control system ($n < n_{cr}$), then the device's parameters should be chosen from the condition that the system be capable of processing these disturbances.

As is clear from (8), this can be achieved by increasing the time of disk rotation t_{ro} or by decreasing the time of the contact's break state t_{bre}. In practice, for thermal objects (for example, of the dessicator hood type), one might recommend that the rotation time be chosen within the limits of (0.6 to 0.7)T', since with this are guaranteed a rapid rise in temperature at the initial moment of switching in, and good processing of the disturbance (for example, upon opening the door of a dessicator hood).

CONCLUSIONS

1. The simplified graphico-analytic theory of calculating processes in two-position controllers may be used for the analysis of processes with disturbances in two-position controller systems with time correction.

2. The distinguishing feature of the two-position control system with an electromagnetic correcting device is that the pulse repetition period (the mark-space ratio) depends on the load.

3. Under definite conditions, complex periodic motions of the controlled quantity (temperature) arise in the system.

4. With optimal adjustment parameters of the correcting device, normal course of the correction process is guaranteed for the very greatest disturbances.

ON THE ERRORS OF AN INTERPOLATING DEVICE FOR A GIVEN CIRCULAR MOTION

V. V. Karibskii

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 3, pp. 317-322, March, 1960
Original article submitted July 7, 1959

An algorithm for a digital interpolating device for a given circular motion is described. A theoretical investigation of the interpolation errors is given. A brief description of the device's circuit is provided.

Today, in various domains of technology, the necessity arises of so controlling an object that it moves along a given trajectory. Frequently this is implemented by means of sampled-data servosystems. Each system controls the motion corresponding to one coordinate and, at each input pulse, there results a translation by unit length in the scale chosen, this length being called the value of the pulse. The pulses for each coordinate axis must be distributed in accordance with a given trajectory of the object's motion. Distribution of the pulses is ordinarily implemented by means of special digital computers.

In the present paper we consider the design principles, and estimate the errors, of a device of this type which provides motion along a circle.

The equation for a circle centered at the origin has the form

$$x^2 + y^2 = R^2, \qquad (1)$$

where x and y are the current coordinate values and R is the circle's radius.

We assume that the motion begins at point A with coordinates x = 0, y = R (Fig. 1), and must proceed clockwise about the circle.

We now find the value of x^2 for which the coordinate y is decreased by unity, i.e., becomes equal to y−1, for which we substitute the new value of the coordinate y in (1):

$$x_1^2 = R^2 - (y-1)^2.$$

By taking into account that y = R, we get $x_1^2 = 2R-1$.

Analogously, we can find the values of $x_2^2, x_3^2, \ldots, x_k^2$ for which there are corresponding changes of the coordinate y by 2, 3, . . ., k units. Knowing these values, we can find the corresponding differences, which will have the form

$$\begin{aligned} x_1^2 &= 2R-1, \\ x_2^2 - x_1^2 &= 2R-3, \\ &\ldots\ldots\ldots\ldots \\ x_k^2 - x_{k-1}^2 &= 2R-(2k-1) \quad (k = 1, 2, 3, \ldots). \end{aligned} \qquad (2)$$

Based on the formulas obtained, we can suggest the following method of constructing a circle. First, we must vary the coordinate x until the value of x_1^2 equals 2R-1 and, as soon as this happens, we must change y by one unit, after which we change the coordinate x until the difference $x_2^2-x_1^2$ becomes equal to 2R-3, at which time we again change y by one unit, etc. It is obvious that, in this case, the approximation error is nowhere larger than unity. However, due to the discreteness of the system's operation, such a method is not implementable, since translations of less than the value of a pulse are impossible. Consequently, R and the quantity x_k^2 are integers. However, the quantity x_k may be expressed by a noninteger at points where y_k is expressed by an integer, and conversely. We shall, therefore, in moving from point A, vary coordinate x by unity and then compute the value of x^2. As soon as the coordinate x reaches the integral value x_{i-m} for which the condition $x_{i-m}^2 \geq 2R-1$ holds, we change coordinate y by unity and determine whether the condition holds that

$$\Delta_1 = x_{i-m}^2 - (2R-1) \geqslant 2R-3.$$

If so, then a unit increment of coordinate x at the given point of the circle corresponds to an increment of coordinate y greater than, or equal to, two units. Therefore, coordinate y should be changed by one unit, the quantity $\Delta_2 = x_{i-m}^2 - (2R-1) - (2R-3)$ computed, and the condition $\Delta_2 \geq (2R-5)$ verified etc. Such operations are carried out until the condition $\Delta_k < 2R-[2(k+1)-1]$ begins to hold. As soon as this happens, we again change coordinate x by unity and then compute the increment of x^2 obtained, with account being taken of the residue, i.e., in this case $x_{i+1-m}^2 - x_{i-m}^2 + \Delta_k$ where $x_{i+1-m} - x_{i-m} = 1$. If now the following condition holds:

$$x_{i+1-m}^2 - x_{i-m}^2 + \Delta_k \geqslant 2R - [2(k+1)-1], \qquad (2')$$

then coordinate y should be changed by one unit, and the process just described should be repeated. The sequence of actions described above and (2') comprise the algorithm in accordance with which the scheme described at the end of this paper operates. In this case, naturally, coordinate y will be changed by one unit somewhat later than the time when x reaches a value corresponding to a one-unit change of y, rather than simultaneously. As a result, the circle will be approximated by a broken line with an error. We now estimate this error. For this, we prove that, with the method chosen, varying the magnitude of $\underline{x}$ by unity at any point x_l in the interval $0< x < R/\sqrt{2}$ cannot give rise to a change of the quantity $x^2_{l+1}-x^2_l$ greater than what is necessary to change $\underline{y}$ by one unit.

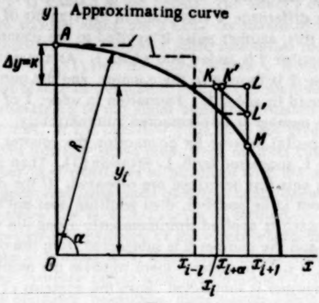

Fig. 1.

A. With motion along an approximating curve in accordance with the method we have adopted, let the moving point reach point K (Fig. 1) where, at this moment, coordinate $\underline{x}$ is changed by x_l units and coordinate $\underline{y}$ by $\underline{k}$ units. Then, a subsequent increment of coordinate $\underline{x}$ by one unit engenders the increment

$$x_{i+1}^2 - x_i^2 = 2x_i + 1. \tag{3}$$

For coordinate y_l to be changed by one unit, with the condition that $\Delta_k = 0$ at point K, it is necessary that the following equation hold:

$$x_{i+1}^2 - x_i^2 = 2R - [2(k+1) - 1]. \tag{4}$$

It follows from this that for all relationships of $\underline{x}$ and $\underline{y}$ which satisfy the condition

$$2R - (2k+1) \geqslant 2x_i + 1, \tag{5}$$

an increment of one unit in coordinate $\underline{x}$ will give rise to an increment of coordinate $\underline{y}$ equal to or less than unity if, at these points, it can be assumed that $\Delta_k = 0$. After transformation, (5) assumes the form

$$R - k \geqslant x_i + 1 \tag{6}$$

or, taking into account that $y_l = R-k$,

$$y_i \geqslant x_{i+1}. \tag{7}$$

For $\underline{x}$ equal to y_l, a unit increment of coordinate $\underline{x}$ engenders, for $\Delta_k = 0$, a unit increment of coordinate $\underline{y}$, which corresponds to an angle of 45 degrees, or $x = R/\sqrt{2}$. In other words, for motion from point A to point K, each unit change of coordinate $\underline{x}$ engenders a smaller variation in $\underline{y}$. Only, when, as the result of successive variations of $\underline{x}$ by unity, coordinate $\underline{x}$ becomes equal to coordinate $\underline{y}$ at the preceding point does the coordinate $\underline{y}$ also change by unity.

B. We now determine the maximum possible deviation of the approximating curve along the axis of ordinates from the given circle in the interval $0 < x < R/\sqrt{2}$, with account being taken of the Δ_k. Let the motion begin at point A (Fig. 1) and be directed clockwise, with the coordinate $\underline{x}$ being given a unit increment. By virtue of what has already been proved, each unit increment of coordinate $\underline{x}$ requires a variation of coordinate $\underline{y}$ by a quantity less than unity.

However, in accordance with the method chosen for constructing the circle, this change does not occur until the resulting increment of x^2 satisfies the condition $x^2 \geq 2R-1$. This means that, for such a value of $\underline{x}$, the deviation along the axis of ordinates of the approximating curve from the given one is $\delta_y \geq 1$. Let such a point, where the condition $x^2 > 2R-1$ holds, be the point with abscissa x_{l-m}. Then, at the point x_{l-m-1} where $x_{l-m}-x_{l-m-1} = 1$, $\delta_y < 1$. But by virtue of the fact that on this segment a unit increment of coordinate $\underline{x}$ cannot engender an increment of coordinate $\underline{y}$ by more than unity, the transition from point x_{l-m-1} to point x_{l-m} can increase δ_y by at most unity. Thus, the resulting error along the axis of ordinates can lie within the limits $0 \leq \delta_y < 2$. It should be kept in mind that, after transition to the point with coordinates (x_{l-m}, y_{l-m}), there occurs a change of $\underline{y}$ by unity, and δ_y becomes less than unity.

By an analogous argument we can successively check each value of $\underline{x}$ in the given interval, coming to the same conclusion each time.

We now consider the very worst case. Let the moving point be at point K with coordinates (x_l, y_l) such that the next increment of coordinate $\underline{x}$ by unity engenders the incrementation of $\underline{y}$ by unity for $\Delta_k = 0$, i.e., $x^2_{l+1}-x^2_l = 2R-(2k+1) = 2y_l-1$, where $\underline{k}$ is the number of units by which coordinate $\underline{y}$ was changed at the moment of transition to point K. We assume that, at the moment of transition to point K, the total accumulated increment is $x^2_l-x^2_{l-l}$, where x_{i-l} is the abscissa of the point at which the last change of $\underline{y}$ occurred, or that the magnitude of the residual Δ_k. If we hit point K after the latest change by unity of coordinate $\underline{y}$ rather than $\underline{x}$, had the maximum possible value $\Delta_{k\ max}$. In accordance with the algorithm for the operation of the scheme, $\Delta_{k\ max}$ must, at point K, be at least one unit less than $2y_l-1$, i.e., must satisfy the equation $\Delta_{k\ max} = 2y_l-2$.

In making the transition from point K to point L, the residual $\Delta_{k\ max}$ increases by $2y_l-1$, as a result of which coordinate $\underline{y}$ changes by unity and executes a transition to point L'. However, the residual at point L', $\Delta_{k+1} = \Delta_{k\ max}$, turns out to be larger than the quantity, $2(y_l-1)-1$, necessary for changing the ordinate of point L' by unity. As a result of this, a transition occurs to point M, and the following residual is formed:

$$\Delta_{k+2} = 2y_i - 2 - 2(y_i - 1) + 1 = 1.$$

A third change of coordinate $\underline{y}$ by unity can only occur for the condition $2(y_l-2)-1 = 1$, i.e., for $y_l = 3$.

By taking (7) into account, we can write $x_{l+1} \leq y_l = 3$. It follows from this that variation of coordinate $\underline{y}$ at point L by three units in succession is only possible for $R = \sqrt{2}\, x_{l+1} \leq 3\sqrt{2}$. For all values of $R > 3\sqrt{2}$, change of coordinate y at point L can occur only by two units. For large R ($R \approx 100$), the magnitude of $2(y_l-2)-1 \gg 1$ and, by neglecting unity in comparison with $2(y_l-2)-1$, we can assume that in the worst case the change of coordinate y is by exactly two units, and point M lies on the circle. Thus, the maximum error, equal to two, will be at point L.

If the order of applying incrementation is somewhat varied, this error can be reduced to unity. For this, we shall first carry out all the computations and then, when it becomes clear that a unit incrementation in y must occur, we execute it simultaneously with the incrementation in x which was giving rise to it. In the actual scheme, this leads to motion at an angle of 45 degrees from point K to point L' (Fig. 1). As a result, the error in coordinate y, equal to δ_y, will everywhere be less than unity. The expression for x in terms of y which is obtained from the equation of the circle coincides with the expression for y in terms of x. Therefore, all the argument already given for x is also valid for y within the limits of variation of angle α from 0 to 45°, i.e., for variation of α within the limits $R \geq x \geq R/\sqrt{2}$, and the approximating curve is symmetric about the line passing through the first quadrant at a 45° angle. At the limits of the interval $0 < x \leq R/\sqrt{2}$, the radial error at any point x will equal

$$\delta_R = \sqrt{(\sqrt{R^2 - x^2} + \delta y)^2 + x^2} - R. \qquad (8)$$

The error δ_y equals the difference between the true value y corresponding to a given x and the next larger integer if y itself is not an integer.

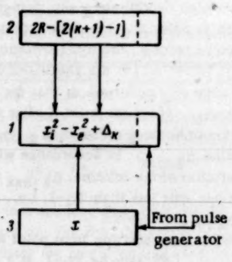

Fig. 2.

Figure 2 shows the simplified block schematic of the interpolating computer which operates in accordance with the principles described above. The circuit consists of counter 3, to which quantity x is fed, adder 1 which stores the current value of the difference $x^2_i - x^2_l + \Delta_k$, and adder 2 which stores the current value of 2R-[2(k+1)-1]. The dashed lines on Fig. 2 mark off the adders' least significant places. If the motion is clockwise, starting from point A (Fig. 1) then, before operations commence, the counter and adder 1 are set to zero and the number 2R-1 is placed in adder 2. Then, from the pulse generator, one pulse is applied to the x counter, storing a "1" in the counter and in adder 1. From the contents of the adder 1 the number 2R-1 is subtracted and, if the difference formed in adder 1 is negative, the number 2R-1 is added to it, and one pulse is applied along the x axis. The sign of the difference is staticized in the sign bit of adder 1. After this, another pulse is applied to the counter, and the number 3 is added into adder 1. As a result, the number 2 is formed in the counter, and the number 4 (2^2) is formed in adder 1. Formation in adder 1 of the square of the number is implemented automatically, thanks to a special scheme for connecting the counter with adder 1, suggested by B. L. Ermilov [1]. Then the arithmetic acts just described are repeated. If the difference turns out to be positive, then addition does not occur, one pulse each is applied simultaneously along the x and y axes, and the number 2 is subtracted from the contents of adder 2, i.e., in adder 2 there remains the number 2R-3. This number is subtracted from the contents of adder 1 and, if the difference is positive, then another pulse is applied along the y axis, and the number 2 is again subtracted from the contents of adder 2, etc., until the difference becomes negative. As soon as the difference does become negative, addition again ensues, and the next pulse is applied from the pulse generator to the counter, etc.

If motion begins from some arbitrary point with coordinates [x_0, y_0], then the initial establishment of values must be the following: in the counter the number x_0 is established, in adder 1 the number $x_0^2 - R^2 + y_0$, and, in adder 2, the number $2y_0 - 1$, where y_0, is the value of y corresponding to the value x_0 and rounded off to the next higher integer.

For processing the complete circle, the initial established values and the direction of motion along the axes are changed in making the transition from one quadrant to the next.

Thus, by means of addition and subtraction, comparisons are made in the scheme proposed of the quantities

$x^2_{j+1} - x^2_j + \Delta k$ with the quantities $2y_j - 1$, where x_j and y_j are the coordinates of any point of the approximating broken line. In a comparison the indication (sign of the difference) is developed which is used for controlling the distribution of the generator pulses along the x and y axes in correspondence with the given law of motion (circular). With such a computational algorithm for circular motion there occurs a variation of the path velocity by a factor of $\sqrt{2}$ which, in the majority of cases, is admissible. Moreover, by using velocity feedback, one can so control the frequency of the pulse generator that the velocity can be kept constant and equal to a given value. (For a more detailed description of the scheme, cf. [2].)

The scheme suggested by B. L. Ermilov [3] operates by such a mathematical algorithm, but with the use of another computational algorithm, the mathematical algorithm not being described in general form. The scheme of B. L. Ermilov consists of two counters and one adder of the accumulative type. Pulses from the generator are applied to the x axis and to the input of one of the counters, forming the quantity x in it; with this, the quantity x^2 is formed in the adder. The adder's overflow pulses are applied along the y axis. By means of the second counter, each overflow pulse introduces the quantity $2^n-(2y_j-1)$ into the adder, where n is the number of places in the adder, adding this number to the number remaining in the adder after transmission of the overflow unit. If the overflow pulse does not give rise to a second overflow pulse then, from the first counter, the number $2x-1$ continues to be added with the arrival of each generator pulse until overflow again occurs, whereby since $x = 1, 2, 3, \ldots, x^2$ is formed.

Since, on the segments of the circle where the coordinate x is close to R, there are emitted $\sqrt{2R-1}$ successive overflow pulses with the frequency of the scheme's elements' operation, there occurs a sharp change in the path velocity. Indeed, the generator's frequency must be approximately $\sqrt{2R-1}$ times less than the frequency of the overflow pulses so that $\sqrt{2R-1}$ overflow pulses can be disseminated between any two generator pulses. As a result, motion at the beginning of the processing of a quadrant of the circle (from 90 to 45°) will occur with a velocity smaller by a factor of $\sqrt{2R-1}$ than that at the end. Such a sharp variation of path velocity in cases when the device is designed to guide a cutting tool is inadmissible. It should be mentioned that control of the path velocity by variation of the generator frequency is not possible in the scheme given, since the frequency of the overflow pulses does not depend on the generator frequency.

SUMMARY

1. For constructing a circle, we use the derived formula $x^2_{j+1} - x^2_j + \Delta_k \geqslant 2R - [2(k+1) - 1]$.

2. In constructing a circle in accordance with the computational algorithm suggested, there occurs no accumulation of errors, and one obtains an absolute radial approximation error δ_R which is less than one unit in the chosen scale.

3. The scheme suggested makes it possible to control path velocity by varying the pulse generator's frequency.

EXPERIMENTAL INVESTIGATION OF RUBBER-FABRIC MEMBRANE CHARACTERISTICS

G. T. Berezovets and Chou Ching-leng

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 3, pp. 323-332, March, 1960
Original article submitted September 3, 1959

The results are given of an experimental investigation of rubber-fabric membrane characteristics, these membranes being used in pneumoautomation devices.

1. Aim and Methodology of the Investigation

Modern pneumoautomation devices, designed for the regulation and control of various continuous productive processes, are constructed on the principle of force compensation.

As one of their basic physical elements, these devices usually contain either bellows or rubber-fabric membranes. The pneumatic instruments of unified aggregate systems (UAS), produced domestically, as well as the instruments of the majority of foreign companies—Moore, Sunvic, Taylor, Bristol, Brown, Electroflo, DRD, etc. are constructed with membranes. The membranes delimit the individual pneumatic chambers inside the instruments, and it is on the membranes that forces from the compressed air in these chambers are balanced.

Such indicators of quality of operation of modern pneumatic devices as their accuracy and sensitivity, as well as their static and dynamic characteristics, depend to a large extent on the properties and characteristics of their membranes.

There are many works in the literature on the investigation of metallic membranes, but there are only a few works [1-4] devoted to the investigation of rubber-fabric membranes. In connection with this, and because precisely these rubber-fabric membranes have attained their greatest dissemination in pneumatic devices for the control and regulation of productive processes, the necessity for a more careful investigation of these membranes arose.

The membranes investigated had plane and conic profiles (Fig. 1, a and b), prepared from brand 1520 caprone, from glass cloth and TD cloth covered with brand 44-9 rubber, and also included corrugated membranes of AM-93 rubber, used in UAS instruments (Fig. 1, c).

The experimental investigation was to determine the following characteristics:

1) the dependence of the membrane's effective area on its travel, $F_e = f(S)$;

2) the dependence of the membrane's effective area on the pressure drop across it, $F_e = f(\Delta p)$;

3) the membrane's hysteresis.

In addition, we determined the effect of the membrane's geometry, of the dimensions of its rigid center, and of the material's quality on the course of the characteristics $F_e = f(S)$ and $F_e = f(\Delta p)$, investigated the stability of membrane operation, and determined the possible skewing of the membrane which might arise during its operation.

The experiments were carried out on stands specially developed for this purpose, in which atmospheric pressure acted on one side of the membrane and, on the other side, compressed air or a vacuum, the magnitudes of which were controlled.

The forces arising from the pressure drops acting on the membranes were equalized by weights attached to the membranes' rigid centers. The membrane characteristics were taken off for the following weight sizes: 0.540, 0.728, 4.62, 8.85, 13.09, and 17.32 kg. A cathetometer measured the membrane displacements.

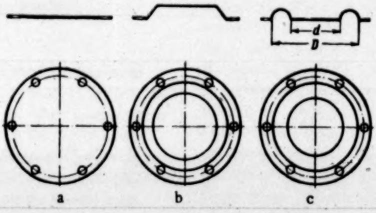

Fig. 1. Forms of the membranes investigated.

For measuring skewing, pressure was introduced into a chamber over the membrane, with a long pointer attached to the membrane's rigid center on the load side. Membrane skewing was determined by the position of the end of the pointer fixed to a scale under the pointer. The scale was a uniform lattice of concentric circles and radial lines. Angles were read off from the radial lines, while the displacement of the pointer's end from the center was read off from the concentric circles.

The magnitude of the membranes' effective area was computed from the formula

$$F_e = \frac{G}{\Delta p},$$

where F_e is the magnitude of the effective area in cm^2, G is the size of the weight placed at the membrane's rigid center, in kg, and Δp is the pressure drop across the membrane, in kg / cm^2.

For the testing of the plane and conical membranes we used rigid centers of two sizes: d = 20 mm and d = 45 mm; the diameter D of the seals of these membranes was the same for all, and equal to 60 mm. A corrugated membrane (Fig. 1, c) was tested with a rigid center d = 45 mm and a value of D equal to 62 mm.

EXPERIMENTAL RESULTS

Stability of Membrane Characteristics and Membrane Skewing

The characteristic $F_e = f(S)$, for new membranes, was only stabilized after the membrane had operated under pressure for several hours. The characteristics of one and the same membrane, in an unchanged set-up, may be repeated only in the case when they are taken off, one after another, without any interruption in membrane operation. Membrane characteristics taken off after an interruption in operation are initially unstable, but then, after some time, are stabilized and begin to coincide with each other; but they almost never coincide exactly with the characteristics taken off before the interruption. The difference between these effective area characteristics can reach 10 to 12 %.

With a readjustment of the membrane, the characteristics taken off before and after the readjustment never coincide. As the pressure drop acting on the membrane becomes larger, the characteristics become more stable.

In investigating membrane skewing, it was observed that they are unstable, but depend basically on the membrane's positioning and, particularly, on the presence of nonconcentricity between the membrane's rigid center and the seal's circle.

Figure 2 shows part of the scale plus the graphs of the motion of the end of the pointer for two different positionings of one and the same membrane. The solid line shows the course of the pointer as the pressure in the chamber over the membrane was increased (forward travel), and the dashed lines show it for decreasing pressure (reverse travel). It was established that the skewing angle between the plane of the flapper, fixed on the membrane's rigid center, and the plane of the nozzle's face end, which this flapper must cover, can oscillate, for different membranes, from 0.5° to 1.5°.

Investigation of Plane Membranes

A comparison of the characteristics $F_e = f(S)$, taken off for membranes prepared of caprone, glass cloth, and TD cloth, led to the following conclusions:

a) the membranes of TD cloth possessed the greatest hysteresis; for them, the relative magnitude of the maximum hysteresis per effective area ΔF_h can reach 18 %, while for membranes of glass cloth, having minimum hysteresis, it was about 7 to 8 % (computing ΔF_h

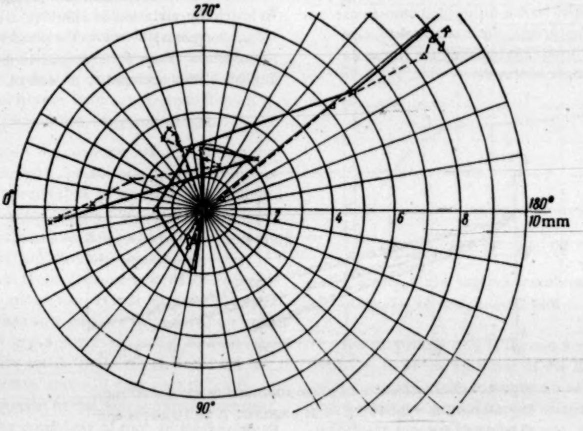

Fig. 2. Graphs characterizing the skewing of a membrane's rigid center.

as the maximum absolute value of the hysteresis divided by the maximum value of effective area $F_{e\ max}$ for forward travel of the membrane);

b) for one and the same pressure drop on the membrane (i.e., for one and the same value of F_e), the least travel was observed in glass cloth membranes; the travels of membranes of caprone and TD cloth were almost identical, and were larger than the travels of glass cloth membranes.

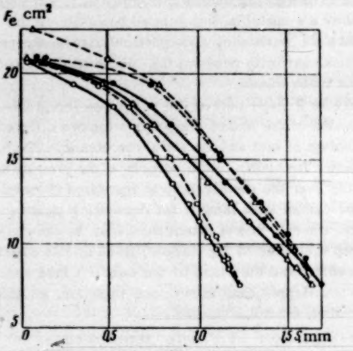

Fig. 3. Characteristics of plane membranes for d = 45 mm, D = 60 mm, G = 0.540 kg. Solid lines are for forward travel, dashed lines for reverse travel; ● is caprone, △ is TD cloth, ○ is glass cloth.

A comparison of plane membrane characteristics (Figs. 3 and 4) with large (d = 45 mm) and small (d = 20 mm) rigid centers leads to the following conclusions:

a) for large rigid centers, the characteristics are nonlinear, while for small centers they are linear for almost the entire length of travel;

b) with small centers, the hysteresis per area equals 1.6 to 2%, i.e., is much less than for membranes with large centers, in which it may oscillate between 7 and 18%;

c) when the rigid center is decreased, the membrane travel is increased, but not by the same amount: in caprone membranes this increase is about 53% of the travel for d = 45 mm and, for glass cloth membranes, about 23%;

d) as the diameter of the rigid center is varied from 45 to 20 mm, or as its area varies from 16.2 to 3.2 cm², the maximum effective area F_e (with S = 0) is varied, for all the membranes, approximately from 21 to 12 cm².

Figure 5 shows the characteristics $F_e = f(S)$ for plane caprone membranes with a large rigid center (d = 45 mm), taken off for weights of different magnitudes.

By considering the characteristics obtained, one can establish the following regularities in their behavior:

1. The larger the weight, i.e., the greater the initial value of the drop necessary for the membrane to begin to move, the greater is the steepness of the characteristic $F_e = f(S)$ as the pressure drop thereafter increases, i.e., the less does the effective area change over the course of the membrane's travel.

This is explained by the circumstance that, with a large weight, there is a large pressure drop across the membrane even before it begins to move, under the action of which pressure drop the membrane's free surface is deformed, forming a semispherical crimp. With a further increase in pressure drop, a motion begins which is analogous to the motion of a crimped (corrugated) membrane.

The formation of crimps in plane membranes occurring under the action of a pressure drop (thanks to which the variation of effective area as a function of travel decreases) increases the possibility of using plane membranes. Thus, for example, in the regulators of the English Sunvic company, instead of using doubled

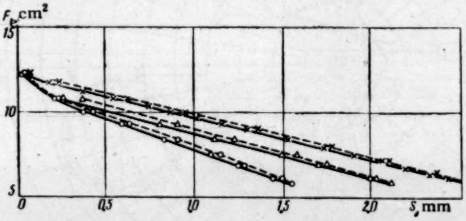

Fig. 4. Characteristics of plane membranes for d = 20 mm, D = 60 mm, G = 0.540 kg. × is caprone, △ is TD cloth and ○ is glass cloth.

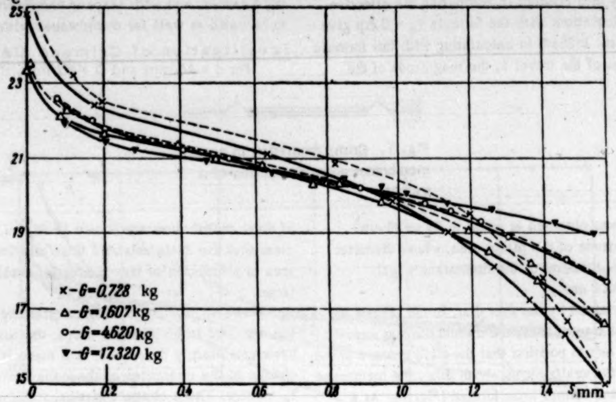

Fig. 5. Plane caprone membrane characteristics, taken off for different weights. d = 45 mm, D = 60 mm.

corrugated membranes with atmospheric pressure between them, as is done in the UAS blocks, doubled plane membranes are used, with the pressure between them being obtained from the supply channel. Since the supply pressure is necessarily greater than the pressure in any of the regulator chambers, crimps are always formed under the action of this pressure.

2. The greater the size of the weight, the less the hystersis per area ΔF_h : if ΔF_h = 3.6 % for a weight G = 0.728 kg, then ΔF_h = 0.2% for G = 4.62 kg and, for G = 8.85 kg, it vanishes completely.

The decrease in hysteresis observed for increase in weight is explained by this, that the internal frictional force which engenders the phenomenon of hysteresis becomes vanishingly small in comparison with the forces generated in the membrane from the pressure drop on it which is necessary to equalize the given weight.

3. Figure 6 shows the characteristic $F_e = f(\Delta p)$ for a caprone membrane with d = 45 mm and D = 60 mm, constructed for different values of travel S[*]. It is clear from the graphs that the effective area varies only for small values of pressure drop, after which, with increasing pressure drop, it remains virtually constant.

This means that if the displacement of the membrane is severely limited, i.e., if it is virtually clamped into the position when it is initially established for values of travel of S = 0.4 to 0.8 mm then, as the pressure drop across the membrane varies within the limits of 0.1 to 1 kg/cm^2, the effective area will vary very insignificantly. The explanation of this fact is very important, since it opens up the possibility of such an establishment of initial membrane position in devices for which deviations of effective membrane area should be minimal.

Investigation of Membranes with Conic Profiles

In the investigation of membranes with conic profiles, it was established that, with small weights

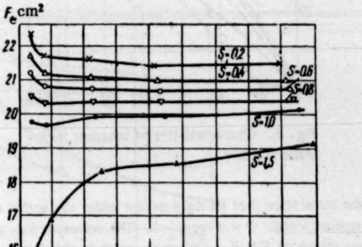

Fig. 6. Plane caprone membrane characteristics. d = 45 mm, D = 60 mm.

---

[*] The magnitude of S is figured from the neutral position, in which the plane of the rigid center coincides with the plane of the membrane's seal. An increase in the travel S corresponds to a displacement of the membrane upward from the neutral position.

(G = 0.540 g), it was necessary to take the membrane's natural rigidity into account in computing the effective area, since calculations with the formula $F_e = G/\Delta p$ give incorrect results. Indeed, in calculating with this formula for small values of the travel S, the magnitude of the effective area was obtained as equal to 30 to 35 cm², while the magnitude of the piston area, whose diameter would equal the diameter of the membrane's seal, equalled only 28.8 cm².

Fig. 7. Crimp formation in conical membranes under the action of a weight.

This is explained by the fact that, in the process of taking off the characteristics, the membrane was so established in its initial position that the rigid center's plane coincided with the seal's plane. With this, the membrane was deformed, and crimps were formed (Fig. 7). As a result, a force Q arose, resulting from the membrane's inherent rigidity, which counteracted the weight G applied to the membrane.

An experiment was specially carried out to determine the inherent rigidity of conical and corrugated membranes, in which the free membrane was gradually loaded, and the translation S of its rigid center under the action of the applied weight Q was recorded. The corresponding graphs are shown on Fig. 8. Curves C and D on this figure correspond to different samples of glass cloth conical membranes.

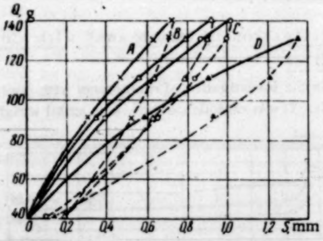

Fig. 8. Characteristics of inherent membrane rigidity.

It is clear from these graphs that, for small weights, the force Q becomes commensurable with the magnitude of the weight G, so that the computation of the effective area in this case can be carried out with the formula $F_e = (G-Q)/\Delta p$.

All the fundamental regularities observed in the testing of plane membranes, both with respect to the behavior of the characteristics $F_e = f(S)$ and $F_e = f(\Delta p)$ for different weights and for different diameters of the rigid center, and with respect to hysteresis, turned out to be valid as well for membranes with conical profiles.

Investigation of Crimped UAS Membranes

For d = 45 mm and D = 62 mm, the characteristics of these membranes are shown in Fig. 9, from which it is clear that the hysteresis and the variation of effective area as a function of travel are, for small weights, very large.

However, for large weights (starting with G = 4.62 kg), i.e., for large pressure drops, the amount of hysteresis sharply decreases, and there is a simultaneous change in the character of the behavior of characteristic $F_e = f(S)$. These characteristics, starting with a travel of about S = 0.45 mm, become practically linear and, what is particularly important, steep.

The magnitude of a UAS membrane's effective area strongly depends on the position of the rigid center with respect to the plane of the membrane's seal. This is particularly apparent for small weights. Figure (10) shows the characteristics of a UAS membrane for d = 45 mm and D = 62 mm, taken off for weights of G = 0.540 kg and G = 17.32 kg, and for various distances h of the membrane's rigid center from the seal plane. Characteristics A correspond to the neutral position, when h = 0; characteristics B correspond to h = -2 mm, i.e., to a position of the membrane below the neutral position, and characteristics C correspond to the position when h = 2 mm, i.e., the membrane is above the neutral position.

For UAS membranes we investigated the hysteresis as a function of the travel (Fig. 11). This confirmed the conclusion, given in [3], that the hysteresis decreases with decreasing travel.

In Fig. 8, given earlier, the characteristics Q = f (S) were given, from which the inherent membrane rigidity can be determined.

Characteristic A corresponds to the case when the UAS membrane is loaded on the side of crimp concavity, and characteristic B to the case when the load is on the convex side.

From a comparison of these characteristics it is clear that the membrane possesses different rigidity, depending on which side of the crimp the force is acting, specifically, the rigidity is greater in the case when the force acts on the crimp's concave side.

SUMMARY

From the experimental results, we may draw the following conclusions:

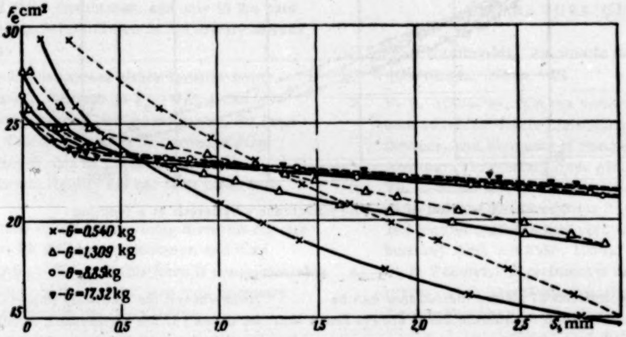

Fig. 9. Characteristics of UAS membranes, taken off for various weights. D = 62 mm, d = 45 mm.

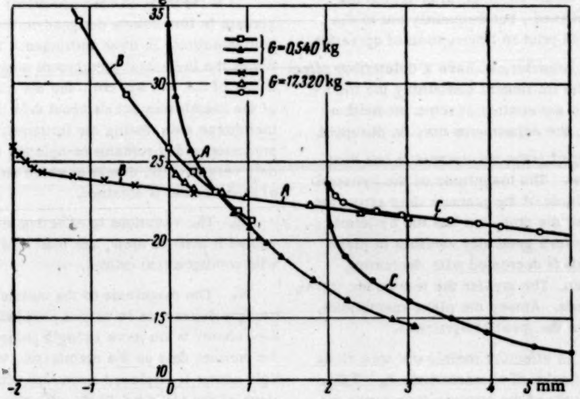

Fig. 10. UAS membrane characteristics, taken off for various positions of the UAS membrane with respect to the plane of the seal.

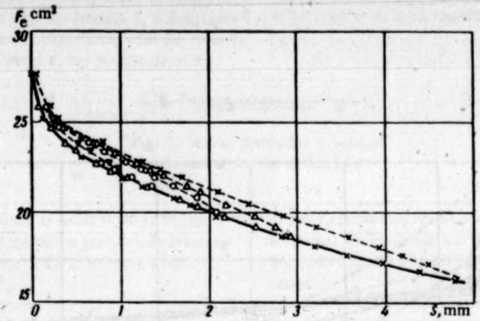

Fig. 11. Variation of the UAS membrane's hysteresis as a function of the travel.

1. The characteristics of all the membranes can be stable only in the case when the membrane is always found under pressure. With large pressure drops, the characteristics are more stable than with small ones. Interruptions in membrane operation lead to a confusion of its characteristics which are then, after protracted operation, again stabilized, but frequently not to the same value which held prior to interruption of operation.

Such membrane behavior can have a deleterious effect on the operation of the instrument containing the membrane and used for the automation of some productive process: for example, the adjustments may be disrupted.

2. The hysteresis of plane membranes is less than that of corrugated ones. The magnitude of the hysteresis depends on the magnitude of the pressure drop across the membrane: the greater the drop, the less the hysteresis; with large drops, hysteresis generally vanishes in plane membranes. Hysteresis is decreased with decreasing membrane rigid center. The greater the membrane travel, the greater its hysteresis. Among the plane membranes, those of TD cloth have the greatest hysteresis.

3. The variation in effective membrane area along its travel, i.e., the behavior of characteristic $F_e = f(S)$, depends on the magnitude of the pressure drop across the membrane. For a given membrane travel, the greater the drop, the less the variation in the membrane's effective area.

4. The effective membrane area varies as a function of the drop; the less the drop, the greater this variation. However, starting with a drop of about 0.15 kg/cm², further increases in it lead to virtually no changes in effective area, i.e., it may be considered constant. This last statement is valid both for plane and for conical and corrugated membranes.

From whence the following important conclusion may be drawn: if the membrane's travel is limited, then its effective area will be constant for all practical purposes for variations of the pressure drop on it within the limits of 0.15 to 1 kg/cm².

It is precisely in such conditions that membranes operate in instruments designed on the principle of force compensation. In these instruments, the pressure drop across the individual membranes might vary within the limits of 0.2 to 1 kg/cm², and the static translation of the membranes equals about 0.05 mm. The effective membrane area, during the instrument's operating processes, either remains completely unchanged or changes only very slightly, thanks to which an increased accuracy of such devices is obtained.

5. The variations in effective area, both with travel and with pressure drop, are least of all in UAS membranes with semispherical crimps.

6. The magnitude of the membrane's effective area strongly depends on its initial establishment; this dependency is the more strongly pronounced, the less the pressure drop on the membrane. When the membrane's rigid center is displaced downward with respect to the plane of the seal (h< 0) the effective area increases in comparison with the case when the membrane is in the neutral position (h = 0) and, when the displacement is upward (h > 0), it decreases.

In connection with this, the accuracy of the initial placement of the membranes in UAS instruments plays an important role, since by it one determines the deviation of the effective area of one membrane from another. In isodrome regulators, for example, this is inadmissible, since it might lead to the appearance of residual nonuniformities.

7. Experiment showed that the formula usually given in the literature for calculating effective membrane area,

$$F_e = \frac{\pi}{12}(D^2 + Dd + d^2),$$

which does not take into account the variation in area as a function of travel and pressure drop, can be used only for determining the value of F_e for zero or very small travels of plane membranes, and only in the case when the membrane is established in the strictly neutral position (h = 0).

8. Calculating membrane characteristics from experimental data by the formula $F_e = G/\Delta p$ can be done only for large weights and, consequently, for large pressure drops. Calculations for small pressure drops give incorrect results, due to the fact that the membrane's inherent rigidity has not been taken into account.

The magnitude of the force arising from this rigidity is not a constant for different membranes, and may reach a magnitude of 300_g. If this force is commensurable with the magnitude of the weight, it is then necessary to take it into account in the calculations.

9. In certain devices of pneumoautomation as, for example, lead blocks, where there are not very stringent requirements on the invariance of membrane effective area, doubled corrugated membranes can be replaced by doubled plane membranes with supply pressure between them.

OPTIMAL FREQUENCY CONTROL OF ASYNCHRONOUS ELECTRIC MOTORS

Yu. P. Petrov

(Leningrad)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 3, pp. 333-339, March, 1960
Original article submitted November 25, 1959

The question is investigated as to which law should be followed in controlling voltage and frequency in asynchronous electric motors so as to provide optimal transient responses. The optimal control laws are derived for various requirements on the character of the transient response for the case when the impedance moment depends linearly on the rotational velocity*.

For those stands where it is possible arbitrarily to vary the frequency of the voltage supplying the executive asynchronous electric motors, the problem arises as to which law the frequency should be varied by so as to provide optimal motor operation in the transient states. Electric drives can be divided into two basic groups as a function of the requirements imposed on the character of their transient responses.

Electric drives of the first group must provide maximum translation of the executive mechanism in a given time for given values of initial and final rotational velocities. Electric drives of the second group must provide maximum change of rotational velocity of the executive mechanism in a given time.

As examples of the first group of electric drives, one may take traction motors while, as examples of the second group, one can adduce electric starting motors.

Optimal control laws, as we shall see below, will be different for the different groups of electric drives.

We shall start from the basic equation of electric drive dynamics:

$$M_{\mathrm{mo}} - M_{\mathrm{i}} = J\,\frac{dn}{dt}, \qquad (1)$$

where M_{mo} is the motor's rotational torque, M_l is the impedance torque, depending on rotational velocity, and J is the moment of inertia about the motor shaft of the motor and drive.

We now introduce relative units. As the unit rotational torque we take the maximum (tilting) torque M_{max}, corresponding to critical slipping; as the unit of rotational speed we take n_s, the synchronous velocity for the supply line's maximum frequency; as the time unit we take T_M, the mechanical time constant, numerically equal to the time for accelerating the drive zero up to the synchronous velocity for a constant rotational torque equal to the maximum; as the unit of current frequency in the rotor, we take f_{cr}, the critical frequency corresponding to tilting slipping; for the unit of current we take I_{cr}, the rotor current for critical slipping.

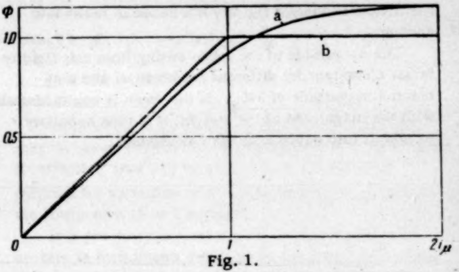

Fig. 1.

The relative units will be : for motor rotational torque, $M = M_{\mathrm{mo}}/M_{\mathrm{max}}$, for impedance moment, $\mu = M_l/M_{\mathrm{max}}$, for time $\tau = t/T_M$, for rotor rotational speed, $\nu = n/n_s$, for rotor current frequency, $\omega = f_{\mathrm{rot}}/f_{\mathrm{cr}}$, for current $i = I/I_{\mathrm{cr}}$ and, for stator frequency, $f = f_{\mathrm{st}}/f_{\mathrm{max}}$.

We make the following assumptions:

1. We shall replace the true motor magnetization curve a by the piecewise-linear curve b, consisting of two segments (Fig. 1).

2. We shall not take into account the electromagnetic transient response (the free component in the rotor current).

In relative units, the dynamics equation (1) takes the following form:

$$M - \mu = \frac{d\nu}{d\tau}. \qquad (2)$$

The rotational torque M and the heat dissipation in the rotor Q will be expressed by the formulas

$$M = \frac{2\Phi^2\omega}{1+\omega^2}, \qquad (3)$$

$$Q = \int_0^\tau \frac{2\Phi^2\omega^2}{1+\omega^2}\,d\tau \qquad (4)$$

---

* The basic propositions of this paper were presented on Sept. 29, 1958 at the All-Union Conference on the Theory and Applications of Discrete Automatic Systems (Section on Optimal System Theory).

where Φ is the motor's magnetic flux in relative units :

$$\Phi = \frac{\Phi_{\text{mo}}}{\Phi_{\text{max}}}.$$

The yield of electric drives of the first group will be proportional to the integral

$$\Delta\alpha = \int_0^\tau \nu d\tau, \tag{5}$$

and that of the second group to the integral

$$\Delta\nu = \int_{\nu_1}^{\nu_2} d\nu = \int_0^\tau \nu' d\tau. \tag{6}$$

In seeking an optimal control law, we should take into account the limitations imposed by the properties of the electric motors. The most important of these is the limitation of heating : the temperature of the winding must not exceed a limiting admissible value. Since the thermal transient responses in a motor flow much more slowly than the mechanical transient responses (heating time constants are measured in minutes [2]), one can ignore the heat emission during the start-up and braking times. With heat emission ignored, the heating limitation on the quantity of heat which can be generated in the rotor in a given time, i.e.,

$$\int_0^\tau \frac{2\Phi^2\omega^2}{1+\omega^2} d\tau \leqslant Q_0. \tag{7}$$

With complete use of motor heating, (7) goes over into an equality. Steel saturation introduces a limitation on magnetic flux. With the assumptions we have made, this limitation, in relative units, is written in the form

$$0 \leqslant \Phi \leqslant 1. \tag{8}$$

Finally, the motor's rotational speed is limited by the supply line's maximum frequency

$$\nu \leqslant \nu_{\text{max}} \tag{9}$$

and, for $\mu = 0$,

$$\nu_{\text{max}} = 1.$$

Optimal Control Law for Electric Drives of the First Group

The optimal control problem for electric drives of the first group is formulated mathematically as follows : to find $\omega = \omega(\tau)$ and $\Phi^2 = \Phi^2(\tau)$ which maximize (5) for a given value of (4), for given relational equations (2) and (3) and given limitations (8) and (9). This is the general Lagrange problem of variational calculus, complicated by the fact that only one-sided variation is admissible here. Consequently [1], the functions sought, $\omega(\tau)$ and $\Phi^2(\tau)$, must :

1) either be extremal, i.e., satisfy the Euler equations

$$\frac{\partial F}{\partial \nu} - \frac{d}{d\tau}\frac{\partial F}{\partial \nu'} = 0, \quad \frac{\partial F}{\partial \omega} - \frac{d}{d\tau}\frac{\partial F}{\partial \omega'} = 0, \quad \frac{\partial F}{\partial \Phi^2} - \frac{d}{d\tau}\frac{\partial F}{\partial \Phi^{2\prime}} = 0$$

for the auxiliary function F :

$$F = \frac{2\Phi^2\omega^2}{1+\omega^2} - \lambda_0\nu + \lambda\left(\nu' + \mu - \frac{2\Phi^2\omega}{1+\omega^2}\right), \tag{10}$$

where λ_0 and λ are Lagrange multipliers, with λ_0 constant and λ a function of τ ;

2) or be boundary curves, i.e., satisfy (8) or (9) with the equality signs;

3) or, finally, may consist of extremal segments plus segments of boundary curves.

We turn now to the search for extremals.

The first Euler equation leads to the expression

$$\lambda\frac{d\mu}{d\nu} - \lambda_0 = \frac{d\lambda}{d\tau}, \tag{11}$$

from which, for $\mu = \mu_0 + k\nu$, we will have

$$\lambda = \frac{\lambda_0}{k} - C_1 e^{k\tau}, \tag{12}$$

and, for the most important case when $\mu = \mu_0 = \text{const}$,

$$\lambda = C_2 - \lambda_0\tau. \tag{13}$$

The second Euler equation, after some transformation, is written in the form

$$\frac{2\omega}{1-\omega^2} = \lambda. \tag{14}$$

We note particularly that (14) does not contain Φ and is valid for any magnetic flux (in addition to the trivial case $\Phi = 0$).

To find the control law for magnetic flux, we use the third Euler equation.

By differentiation of F with respect to Φ^2, we get

$$\frac{\partial F}{\partial \Phi^2} = \frac{2\omega^2}{1+\omega^2} - \lambda\frac{2\omega}{1+\omega^2}. \tag{15}$$

By substituting the value of λ from (14) in (15) , we convince ourselves that $\partial F / \partial \Phi^2$ can not vanish and, consequently, $\Phi^2(\tau)$ which maximizes integral (5) can not be extremal, but is a boundary curve, i.e., $\Phi = 1$.

The optimal voltage control law is a control such that, with account taken of the voltage drop in the stator winding, the magnetic flux will be maintained constant.

The optimal laws of current frequency variation in the rotor will be :

for $\mu = \text{const}$,

$$\frac{2\omega}{1-\omega^2} = C_2 - \lambda_0\tau; \tag{16}$$

for $\mu = \mu_0 + k\nu$

$$\frac{2\omega}{1-\omega^2} = \frac{\lambda_0}{k} - C_1 e^{k\tau}. \tag{17}$$

For constant magnetic flux, the law of rotor frequency variation also determines the optimal law of variation of the motor's rotational torque as a function of time. By knowing the motor's torque and its mechanical time constant, we determine the rotor's speed of rotation and, thereby, the optimal law for supply frequency variation.

This law will be valid until the rotor's speed of rotation reaches its limiting value, bounded by (9). After reaching this limiting speed, one must transfer

Since the extremals must, at the junction point, coincide with the boundary curves tangent to them [1], then the equalitites $M = \mu$ and $d\nu/d\tau = 0$ must hold for the transition points.

Optimal Control Law for Electric Drives of the Second Group

The problem of optimal control for electric drives of the second group is formulated mathematically as follows: to find $\omega(\tau)$ and $\Phi^2(\tau)$ which maximize (6) for a given value of (4), for given relational equations (2) and (3) and given limitation (8). Thus, the optimal control problem for electric drives of the second group is analogous to that for those of the first group, with the sole difference that the auxiliary function will now have the form

$$F_1 = \frac{2\Phi^2\omega}{1+\omega^2} - \lambda_0 \nu' + \lambda\left(\nu' + \mu - \frac{2\Phi^2\omega}{1+\omega^2}\right). \quad (18)$$

The first Euler equation is now written in the form

$$\lambda \frac{d\mu}{d\nu} = \frac{d\lambda}{d\tau}. \quad (19)$$

The second Euler equation will be

$$\frac{1}{1-\omega^2} = \lambda.$$

From the third Euler equation, with account taken of (8), we get, just as for electric drives of the first group, that the magnetic flux, for optimal control, must be maintained constant ($\Phi = 1$). For $\mu = \mu_0 + k\nu$ we obtain, from (19) and (14), the expression for the optimal control law for the current frequency in the rotor:

$$\frac{2\omega}{1-\omega^2} = C_3 e^{k\tau}. \quad (20)$$

It follows from this that the rotational torque must increase as the drive starts up. For k = 0, i.e., for μ = const, it follows from (20) that ω = const. Thus, we arrive at the important conclusion that, for constant impedance torque, the optimal control law for electric drives of the second group amounts to maintaining constant current frequency in the rotor, and consequently, constancy of the rotational torque. With this, the drives rotational speed will vary linearly and, consequently, the supply frequency must also vary as a linear function of time [6].

On the basis of the duality principle of variational calculus [1], all the optimal laws derived by us from the assumptions that the quantity of heat was given, and that it was required to provide the greatest translation (or change of speed), will also remain valid for the case when the translation and the time are given, and it is required to provide minimum dissipation. The same laws also remain valid when the time of translation and the heat dissipation are given, and it is required to provide the minimum time of translation.

The optimal control laws for asynchronous electric motors have great similarity to the optimal laws for dc motors [3-5]. If we compare the dependence of rotational torque on time for optimal control, then the optimal control law for dc motors turns out to be the limiting case of the optimal law for asynchronous motors with the condition that the latter's maximum torque tends to infinity. In an optimally controlled asynchronous motor, the frequency in the rotor is always less than critical, and the rotational torque is less than maximal.

It should also be mentioned that the maximum torque of an optimally controlled asynchronous motor is larger than the maximum torque of a motor with a constant voltage on its terminal, since for critical slipping, due to the voltage drop in the stator winding, the motor's magnetic flux is less than the nominal value. With optimal control, when the magnetic flux is maintained constant, the maximum torque is 1.5 to 2 times greater than what is stated in the catalogs.

Figure 2 shows an example of optimal control for a motor in which critical slipping equals 0.2, the maximum torque multiplicity (for complete magnetic flux) equals 5, the mechanical time constant is $T_M = 1.82$ seconds, the impedance torque is constant and equal to the nominal value, and the electric drive falls in the first group.

Determination of the Coefficients in the Extremal Equations

We had found the extremal equations in a general form. For practical use of the optimal control laws found, it is necessary to know, in each concrete case, the coefficients in the extremal equations as functions of the given electric-drive parameters.

We consider electric drives of the first group, with constant impedance torques. Extremal (16) is known,

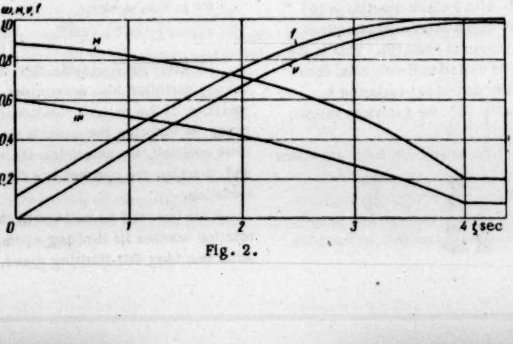

Fig. 2.

from control by extremals (16) or (17) to control by boundary curves, i.e., it is necessary to maintain $\nu = \nu_{max}$ and $M = \mu$ and, consequently, ω = const. and we now derive useful auxiliary formulas. By carrying out a change of variables in (2), (3), and (4) on the basis of (16), and then integrating, we get

$$\nu_2 - \nu_1 = \frac{2}{\lambda_0}\left[\frac{1}{1-\omega^2}\right]_{\omega_2}^{\omega_1} - \mu\tau, \tag{21}$$

$$Q = \frac{2}{\lambda_n}\left[\frac{\omega}{1-\omega^2} - \operatorname{arc\,tanh}\omega\right]_{\omega_2}^{\omega_1}. \tag{22}$$

We recall the self-evident formula

$$\nu = f - s_{cr}\,\omega, \tag{23}$$

where f is the stator frequency in relative units and s_{cr} is the critical slipping.

By using these formulas one can, on the basis of the given parameters of the electric drive and the characteristics of the transient response, find the coefficients in the extremal equations. For the example given, let it be required that the electric motor with critical slipping s_{cr} and impedance torque μ_0 start the drive, within time T_0, from initial speed $\nu_1 = 0$ to speed ν_2, corresponding to stator frequency $f = 1$. The dissipation during starting time T_0 must not exceed Q_0. The electric drive falls in the first group and, consequently, the optimal control problem is to provide maximum translation in time T_0. We know extremal (16). We determine the coefficients C_2 and λ_0 which appear in (16). We start by determining rotor frequency ω_2, corresponding to the end of the start-up period. From the equation

$$\frac{2\omega_2}{1+\omega_2^2} = \mu_0$$

we find ω_2, after which, from (23), we find $\nu_2 = 1 - s_{cr}\omega_2$.

Now, (21) and (22) give us a system of two equations for determining the two unknowns ω_1 and λ_0:

$$\nu_2 = \frac{2}{\lambda_0}\left[\frac{1}{1-\omega^2}\right]_{\omega_2}^{\omega_1} - \mu_0 T_0,$$

$$Q_0 = \frac{2}{\lambda_0}\left[\frac{\omega}{1-\omega^2} - \operatorname{arc\,tanh}\omega\right]_{\omega_2}^{\omega_1}.$$

Knowing ω_1, we determine the coefficient $C_2 = 2\omega_1/(1-\omega_1^2)$ in (16).

SUMMARY

1. For the frequency control of asynchronous motors, there exists an optimal control law of frequency as a function of time which provides maximum yield of the electric drive for given limitations on heating.

2. The optimal control law depends on the conditions imposed on the electric drive, and on the law of variation of the impedance torque. For electric drives of the first group, the optimal control law will be given by (17) and, for those in the second group, by (20). The voltage control law is the same for both groups, and amounts to maintaining the constancy of the motor's magnetic flux.

ON A DRIVE SCHEME WITH A GIVEN EQUATION OF MOTION*

I. A. Boguslavskii

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 3, pp. 340-343, March, 1960

Original article submitted May 15, 1959

A method is presented for the construction of a drive scheme with a given equation of motion wherein operational amplifiers are not employed.

In designing an automatic control system controlled by disturbances (cf. [1]) and also in various modelling schemes, it is frequently necessary to have a drive with a given equation of motion. This means that the drive's output coordinate x(t) (angular velocity, or angular displacement of the drive's output axis) must be related to the input coordinate f(t) (for example, with the arbitrarily varying angle of rotation of a potentiometer slider) by a given differential equation of the form

$$\sum_{k=0}^{n} a_k \frac{d^k x(t)}{dt^k} = \sum_{k=0}^{m} b_k \frac{d^k f(t)}{dt^k}. \qquad (1)$$

The problem just formulated is easily solved under the following conditions:

1) if the drive is shunted by a total feedback path for angle or for angular velocity such that the servosystem thus obtained follows, with high static and dynamic accuracy, the output coordinate x(t) by some input voltage u(t) and, consequently,

$$x(t) = ku(t), \qquad (2)$$

where k is a scale factor;

2) if, using operational amplifiers, one constructs an electronic scheme in which the output voltage u(t)** is related to the input f(t) by the equation obtained by replacing x(t) by ku(t) in (1).

However, in certain conditions of industrial usage, an electronic scheme may turn out to be inapplicable due to its complex voltage supply, zero drift of the operational amplifiers, etc. It is therefore advantageous to consider the possibility of replacing an electronic operational circuit by one composed of passive R and C elements (resistors and capacitors) which is free from the disadvantages mentioned above. However, a circuit of passive elements can be used directly only in solving certain special types of differential equations. For example, even for an equation which describes a simple oscillatory link, an RC circuit, as is well known, does not permit an accurate solution. In addition, the direct use of a circuit of passive elements (even in those cases where this is theoretically possible) is inconvenient in that a change in the coefficients of (1) requires, as a rule, a change in the parameters of all the passive elements. We shall show that a circuit with passive elements can be freed of the disadvantages cited if a voltage proportional to x(t) is applied to certain of its links. In this case, the drive, together with the basic direct negative feedback, is shunted by several indirect feedback paths (Fig. 1), and thus participates directly in the solution of (1). The servo amplifier which directly controls drive operation does not fall into the category of operational amplifiers due, for example, to the completely different requirements on gain stability.

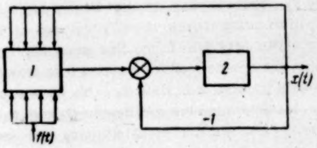

Fig. 1. 1 is the circuit of passive elements, 2) is the drive.

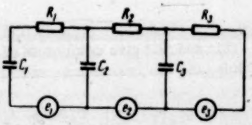

Fig. 2.

For simplicity, we present the proposed principle for drive design in the case when (1) has the form

$$(p^3 + a_2p^2 + a_1p + a_0)\,x(t) = \\ = (b_2p^2 + b_1p + b_0)\,f(t), \qquad (3)$$

where the a_i and b_i are given constant coefficients and p = d/dt.

---

*The material in this paper is contained in the author's paper at the Second All-Union Conference on Automatic Control Theory.

**Note that "u(t)" is used for both input and output voltage [translator's note].

In the general case, the circuit design is carried out analogously.

We consider the electric circuit (Fig. 2) in which the R_i and C_i are constant resistors and capacitors, chosen from technical considerations, and the e_i are certain voltage sources with zero internal impedance. In analyzing the circuit, for example, by the method of loop currents, we find that u, the voltage taken off capacitor C_1, satisfies the equation

$$(p^3 + A_2p^2 + A_1p + A_0)u = (B_2p^2 + = \tag{4}$$
$$= B_1p + B_0)e_1 + (D_1p + D_0)e_2 + C_0e_3,$$

where the A_i, B_i, D_i, and C_0 are constants, easily expressed in terms of the circuit parameters.

We require the holding of (2) and of the conditions

$$e_1 = \frac{1}{k}[k_{x1}x(t) + k_{f1}f(t)], \tag{5}$$

$$e_2 = \frac{1}{k}[k_{x2}x(t) + k_{f2}f(t)], \tag{6}$$

$$e_3 = \frac{1}{k}[k_{x3}x(t) + k_{f3}f(t)], \tag{7}$$

where the k_{xi} and k_{fi} are certain positive or negative constants, defined successively by the relationships

$$A_2 - B_2k_{x1} = a_2, \tag{8}$$
$$A_1 - B_1k_{x1} - D_1k_{x2} = a_1, \tag{9}$$
$$A_0 - B_0k_{x1} - D_0k_{x2} - C_0k_{x3} = a_0, \tag{10}$$

$$B_2k_{f1} = b_2, \tag{11}$$
$$B_1k_{f_1} + D_1k_{f_2} = b_1, \tag{12}$$

$$B_0k_{f_1} + D_0k_{f_2} + C_0k_{f_3} = b_0. \tag{13}$$

By a direct substitution of e_1, e_2, and e_3 in (4), we easily convince ourselves that, if (5)-(13) hold, x(t) and f(t) satisfy the original (3) and, consequently, the construction just described solves the problem posed. As was previously stated, (2) holds as the result of constructing a high-quality system for following x(t) by the voltage u(t). If x(t) is the angular velocity of the output shaft's rotation then, to realize (5), (6), and (7), with the shaft, in addition to the tachometer generator of the direct feedback path, there must be connected three dc tachometer generators whose output voltages are divided by special potentiometers in accordance with the coefficients k_{xi} and then introduced into the proper places in the circuit (Fig. 3). In addition, to the axis rotating to the angle f(t) there must be attached the sliders of three potentiometers with insulated voltage supplies and output voltage dividers operating in correspondence with coefficients k_{fi}. The practical values of R_1, R_2, and R_3 in Fig. 3 are not less than the order of the large divider impedances shunted by the internal impedances of the tachometer generators. Therefore, A_i, B_i, and C_i can be determined without the internal impedances of the voltage supplies being taken into account.

If x(t) is the angular rotation of the output shaft, then to it, in addition to the potentiometer of the direct feedback path, there are connected the sliders of three potentiometers with insulated voltage supplies and with the corresponding dividers. We emphasize that, for any change in the coefficients of (3), the parameters of the passive circuit (the quantities R_i and C_i) are not changed. When there are new values of the k_{xi} and the k_{fi}, only the positions of the divider sliders are subject to change. In an analogous manner, by the use of a passive circuit composed of n series-connected RC networks, n + 1 mutually insulated voltage supplies proportional to x (t), n insulated voltage sources proportional to f(t), and the corresponding number of dividers, one can construct a drive with equation of motion (1) for n > m. By having several circuits of passive elements and several drives with the corresponding number of insulated voltage sources proportional to their output coordinates, one can, by applying portions of these voltages to various points of the circuit, construct a system of drives with given

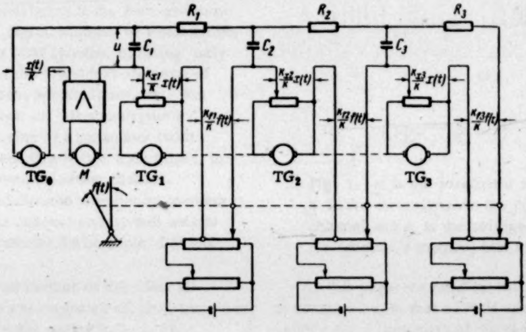

Fig. 3.

interrelationships of the equations of motion. The method described also applies, in an uncomplicated way, to the case when coefficients a_i and b_i of (1) are given functions of time, differentiable a definite number of times. For example, in (3) let $a_0 = a_0(t)$, $a_1 = a_1(t)$, and $a_2 = a_2(t)$.

Then, coefficients k_{xi} in (5)-(7) should be considered as unknown functions of time. As a simple verification, we show that x(t) will satisfy (1) for variable a_i if the functions $k_{xi}(t)$ are successively determined from the following relationships :

$$A_2 - B_2 k_{x1} = a_2(t),$$

$$A_1 - B_1 k_{x1} - 2B_2 \frac{dk_{x1}}{dt} - D_1 k_{x2} = a_1(t),$$

$$A_0 - B_0 k_{x1} - B_1 \frac{dk_{x1}}{dt} - B_2 \frac{d^2 k_{x1}}{dt^2} - D_0 k_{x2} - D_0 \frac{dk_{x2}}{dt} - C_0 k_{x3} = a_0(t).$$

If we , by using the proper elements, move the sliders of the dividers in accordance with the laws $k_{x1}(t)$, $k_{x2}(t)$, and $k_{x3}(t)$, we can implement the realization of a drive with equation of motion (3) for variable $a_0(t)$, $a_1(t)$ and $a_2(t)$.

The static accuracy of the solution of (1) by the drive is determined by the stability of the coefficient $\underline{k}$ in (2), the stability of the values of the R_i and C_i, and by the accuracy of positioning the dividers' sliders for the formation of coefficients k_{xi} and k_{fi}. The dynamic accuracy of the solution of (1) by the drive will be the higher, the wider is the frequency passband of the drive's servosystem, providing for the holding of (2), as compared with the bandwidth of the fundamental frequencies of the solution of Eq. (1).

ON THE NOISE IMMUNITY OF THE DISCRETE-INCREMENTAL METHOD OF INFORMATION TRANSMISSION

V. M. Baikovskii

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 3, pp. 344-358, March, 1960
Original article submitted August 28, 1959

The potential noise immunity (noise stability) of discrete-incremental modulation (DIM) with fluctuation noise is determined. Comparisons are made of the noise immunity of pulse-code modulation (PCM), deltamodulation(DM) and DIM. It is shown that, in a number of cases, the noise immunity of DIM is higher than of PCM and DM.

INTRODUCTION

In remote action telemetry systems, the communications channel is the most essential element, and determines the entire construction and, often, the accuracy of the system. This is true of telemetering apparatus in energy systems and gas and oil pipelines where it is necessary to transmit a series of parameters over distances of up to hundreds of kilometers. This is also characteristic of radiotelemetric systems, widely used in aviation for controlling various moving objects (including those used in space explorations), etc.

In designing such telemetry systems, the form of signal and the type of modulation are selected, not only from considerations of the best construction of the transforming devices, but also as a function of the channel's noise level and other characteristics.

Recently, many designers have been turning to discrete methods of transmitting data which, distinguished by their high equipment accuracy, permit high noise immunity to be attained. These methods acquire particular value from the broad development of digital technology.

Certain forms of discrete modulation had already been frequently considered as applied to communications problems. Pulse-code modulation is the first, and most highly developed, of the digital methods of transmission. There are many different PCM systems, differing only by the implementation of the individual elements of the apparatus: transformers, accumulators, etc. But there is one thing common to all these systems: the complete instantaneous value of a parameter (with account being taken of quantization) is transmitted, in coded form, along the communication channel.

There later appeared discrete modulation methods in which the signal in the channel corresponds only to the increment of the parameter, for example, DM and delta-PCM.

Recently, still another method of this class for transmitting information was suggested—digital-incremental modulation ("incremental coding") [1, 2, 3]. Incremental coding arose in connection with the desire to increase the efficiency of transmitting data along a channel by exploiting the statistical properties of the information to be transmitted. If the assumption in PCM is that each successive parameter value is not related to the previous one, in DIM the design is based on the assumption that there is a comparatively peaked (at least, nonflat) correlation function for the information.

The DIM operating principle is clearly elucidated in Fig. 1. The basic difference between this modulation method and those of PCM and DM is that here a signal is sent through the channel only at the moments when the measured quantity passes through a quantization level. If it stays within the limits of one quantization step, then no signal appears. Thus, transmission occurs irregularly: the more slowly the information changes, the more rarely are pulses sent through the channel.

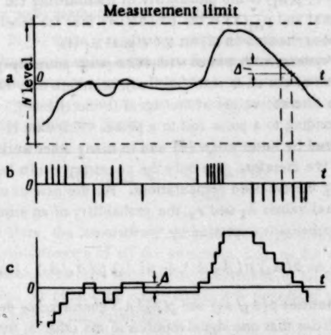

Fig. 1. a is the parameter to be transmitted b is the error signal in the communications channel, and c is the voltage at the output of the receiver's memory block.

In this paper we consider the noise immunity of DIM as compared with that of PCM and DM. As criteria for judging noise immunity of discrete telemetry systems, we adopt here the mathematical expectation of the error (the mean error) and the dispersion of the error (the squared mean-square error). We have obviously made the assumption that the error's probability distribution function is sufficiently completely characterized by its first two moments.

Potential DIM Noise Immunity for One Particular Case

To estimate the effect of fluctuation noise on a discrete system for information transmission, it is convenient to use V. A. Kotel'nikov's theory of potential noise immunity. It consists essentially of the following:

Let the set of signals $\{A(t)\}$ be used for transmission. When signal $A_i(t)$ is sent, then, due to the action of noise, the following total quantity is applied to the receiver:

$$X(t) = A_i(t) + W(t), \qquad (1)$$

where W(t) is a normal fluctuation oscillation. Depending on the value of X(t), the receiver identifies it with (or assimilates it to) one of the possible signals $A_j(t)$ of $\{A(t)\}$ with some probability of error. The potential noise immunity defines the probability of signal distortion as the result of the action of noise, for reception by an ideal receiver.

An ideal receiver is characterized as one for which this probability of incorrect reproduction will be the least for a given form of signal (given energy) and a definite specific energy (per unit bandwidth) of the fluctuation noise. In other words, the ideal receiver reproduces the information, corresponding to that signal, which maximizes the expression

$$p(A_i)\, p_{A_i}(X). \qquad (2)$$

Here, $p(A_i)$ is the probability of transmitting the ith signal and $p_{A_i}(X)$ is the probability that the receiver reproduces the sum in (1) as the signal $A_i(t)$.

In systems with DM or with PCM (with pulse-by-pulse reception of the code combinations), there are only two possible discrete values of the signal in the channel, corresponding to a pulse and to a pause. This case is considered by Kotel'nikov [4] and in many other works [5, 6]. We therefore give only the necessary results here, omitting the detailed computations. For the case of only two signal values A_1 and A_2, the probability of an error in transmission is expressed by the formula

$$p_{\text{dis}} = p(A_1)\, p(A_2/A_1) + p(A_2)\, p(A_1/A_2). \qquad (3)$$

The quantities $p(A_1/A_2)$ and $p(A_2/A_1)$ characterize the probabilities that one signal transfers to the other as the result of the action of fluctuation noise. In correspondence with [4], they equal

$$p(A_2/A_1) = V(\alpha_{21}), \quad p(A_1/A_2) = V(\alpha_{12}), \qquad (4)$$

where

$$V(x) = \frac{1}{\sqrt{2\pi}} \int_x^{\infty} e^{-\frac{z^2}{2}}\, dz,$$

and

$$\alpha_{21} = \alpha + \frac{1}{2\alpha} \ln \frac{p(A_1)}{p(A_2)}, \quad \alpha_{12} = \alpha + \frac{1}{2\alpha} \ln \frac{p(A_2)}{p(A_1)}.$$

Thus, the potential noise immunity is defined by the two quantities :$p(A_1)/p(A_2)$ —the ratio of the a priori probabilities of the two signals—and the quantity α, which characterizes the ratio of the mean energy difference of these signals to the specific energy of the noise, i.e.,

$$\alpha = \sqrt{\frac{1}{2\sigma^2} \int_{-\frac{T}{2}}^{+\frac{T}{2}} [A_1(t) - A_2(t)]^2\, dt}. \qquad (5)$$

Here, T is the signal duration and σ is the specific energy of the noise (intensity), which is defined so that

$$\overline{W^2(t)} = \int_0^{\infty} \sigma^2(\omega)\, d\omega. \qquad (6)$$

Since the quantity to be transmitted in telemetry is always bounded by definite limits, then, on the average, over a sufficiently long interval of its variation, one can consider the appearances of pulses and pauses for DM and PCM to be equiprobable.

Consequently,

$$p(A_1) = p(A_2) = \frac{1}{2}, \qquad (7)$$

$$\alpha_{12} = \alpha_{21} = \alpha.$$

As a result, we obtain

$$p(A_1/A_2) = p(A_2/A_1) = V(\alpha). \qquad (8)$$

Discrete-incremental modulation differs from the foregoing in that the signal can assume three values. In the channel appear the values +1 or −1 when the measured quantity goes through a quantization level and the value 0, if the quantity does not go beyond the bounds of one quantization step. Thus, there are the signals $A_1(t) = +1$, $A_2(t) = 0$ amd $A_3(t) = -1$, with probabilities $p(A_1)$, $p(A_2)$ and $p(A_3)$. With this, and for the same reasons as for (7), we can assume that $p(A_1) = p(A_3)$ and, moreover, that $p(A_2) > p(A_1) = p(A_3)$, since only in this case is DIM meaningful.

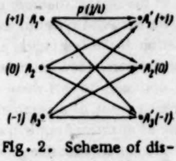

Fig. 2. Scheme of discrete channel (DIM).

The scheme for a channel with discrete-incremental modulation is shown in Fig. 2. According to this scheme, the probability of error for DIM may be found from the formula

$$p_{\text{er}} = \sum_{i=1}^{3} \sum_{j=1}^{3} p(A_i)\, p(A_j/A_i) \quad (i \neq j). \qquad (9)$$

The values of the probabilities $p(A_j/A_i)$ depend on which pulse signs are used for transmission.

In its general form, the problem is difficult to solve even with three signals. It is impossible to find an expression for the probability of distortion in a simple and graphic form, convenient for computations and for comparisons with the analogous expressions for other systems. We therefore consider one simple special case of signal transmission by DIM, and we then show that the results obtained can be used for an approximate estimate of noise immunity in a number of other cases.

We assume that to signals $A_1(t)$ and $A_3(t)$ there correspond identical video pulses of different polarity. Let their transmission be implemented by the so-called synchronous method, i.e., the pulses can be applied to the channel only at regular time intervals, or multiples thereof. Therefore, the intervals between pulses are multiples of some quantity T_{min} chosen, just as in DM, from the condition that there be reproduced the portion of the information with the greatest steepness (the overshoot). In this case, the analysis of noise immunity (cf. the Appendix) allows us to construct, for the ternary channel characterized by the scheme of Fig. 2), the matrix of transition probabilities:

$$\begin{array}{c|ccc|} & A_1' & A_2' & A_3' \\ A_1 & 1-V(\alpha') & V(\alpha')[1-V(\alpha''')] & V(\alpha')V(\alpha''') \\ A_2 & V(\alpha'') & 1-2V(\alpha'') & V(\alpha'') \\ A_3 & V(\alpha')V(\alpha''') & V(\alpha')[1-V(\alpha''')] & 1-V(\alpha') \end{array} \qquad (10)$$

To determine the mathematical expectation and the dispersion of the error, it is necessary to find the "value" or the weight of each individual error ξ_{ij}. The "value" of an error for discrete-incremental modulation is easily determined if we turn back to Fig. 1.

When, under the action of noise, signal A_2 goes over to A_1, or A_3 goes over to A_2, the step function voltage in the receiver will be changed by quantity Δ, i.e., for $(A_2 \to A_1)$ and $(A_3 \to A_2)$, $\xi = +1$ and, analogously, for $(A_2 \to A_3)$ and $(A_1 \to A_2)$, $\xi = -1$. If $(A_3 \to A_1)$ or $(A_1 \to A_3)$, then $\xi = \pm 2$.

Since it was accepted that signals A_1 and A_3 are equiprobable, the system of signals is symmetric, and the average of the error equals zero:

$$MU_{er} = \sum_{i=1}^{3}\sum_{j=1}^{3} p(A_i)\,p(A_j/A_i)\,\xi_{ij} = 0 \qquad (i \neq j). \qquad (11)$$

According to probability theory,

$$D\xi = M(\xi - M\xi)^2.$$

Thus, taking into account that $M\xi = 0$, we find that

$$DU_{er} = \Delta^2 D\xi = \Delta^2 M\xi^2. \qquad (12)$$

By using (9), we find that

$$DU_{er} = \Delta^2\{2p(A_2)V(\alpha'') + 2p(A_1)V(\alpha')[1 - V(\alpha''')] + 8p(A_1)V(\alpha')V(\alpha''')\}. \qquad (13)$$

We now introduce the concept of the probability p_n of a transition of the quantity to be transmitted through a quantization level. Obviously, this quantity depends on the character of the variation of the parameter to be transmitted. The steeper the correlation function, the smaller is the value of p_n. From what was said above, it follows that $p_n = 2p(A_1)$. By keeping in mind that $p(A_2) = 1 - 2p(A_1)$, and by denoting $p(A_2)/p(A_1) = K$, we obtain the final expression for the dispersion of the error for DIM:

$$DU_{er} = \Delta^2 p_n[KV(\alpha'') + V(\alpha') + 3V(\alpha')V(\alpha''')]. \qquad (14)$$

It follows from (14) that the noise immunity of this type of modulation is connected with the statistical properties of the ensemble of possible communications. An analysis of this dependence was given in [2].

On the Approximate Estimate of Noise Immunity of DIM in the General Case

It is obvious that, in addition to the one considered other methods of DIM transmission can be used. However, of all the possible methods, the only interesting ones from the practical point of view are those which are characterized by small values of the probabilities $p(A_1/A_3)$ and $p(A_3/A_1)$.

The determination of an exact analytical expression for noise immunity for each case in even this limited class poses mathematical difficulties.

In [4] there was given a method for the approximate estimation of noise immunity for the transmission of several discrete signals. It is based on the theorem that the probability P of at least one of m possible outcomes B_i lies within the limits

$$p(B_i)_{\max} \leqslant P \leqslant \sum_{k=1}^{m} p(B_i). \qquad (15)$$

Here, the lower limit corresponds to the complete interrelationship of all the outcomes, i.e., to the case when one outcome implies the occurrence of all the others. To obtain the upper limit, it is necessary that the outcomes be incompatible.

As applied to DIM, this inequality takes the form

$$\sum_{i=1}^{3} p(A_i)\,p^*(A_j/A_i)_{\max} \leqslant p_{dis} \leqslant \sum_{i=1}^{3}\sum_{j=1}^{3} p(A_i)\,p^*(A_j/A_i), \qquad (16)$$

where each $p^*(A_j/A_i)$ is determined, in accordance with (4), for each pair of signals without taking account of the others.

We considered several methods of transmission: for example, sending, for the signals $A_1(t)$ and $A_3(t)$, radio pulses with orthogonal frequencies, unipolar orthogonal video pulse, etc. Analysis showed that, for identical p pulse energy, the bounds on the error given by (16) for many methods of DIM transmission virtually coincided with those obtained in the case considered above. With this, the upper and lower bounds are so close that the region of error has the form of a very narrow ribbon (Fig. 3). By keeping this in mind, we can assume that the value of the error found for synchronous transmission of different polarity pulses characterizes, with adequate accuracy, the noise immunity of a number of other forms of DIM transmission. Therefore, in making our subsequent comparisons of noise immunity for the three forms of modulation, we shall use (14) to define the error with DIM (the dashed line on Fig. 3).

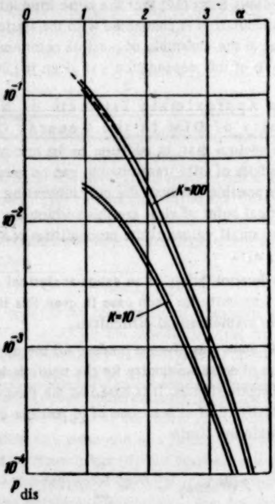

Fig. 3.

It was previously noted that the noise immunity of DIM is determined on the basis of the probabilities of suppression or of formation of false signals $A_1(t)$ and $A_3(t)$ (since $A_2(t) = 0$).

If we therefore replace the "ternary" ideal receiver by two, one of which receives $A_1(t)$ and $A_2(t)$ while the other receives $A_3(t)$ and $A_2(t)$, then the noise immunity will differ very little from the potential value. Computations show that the error arising with this is negligibly small. By taking this into account, we have the possibility, in making approximate estimates of noise immunity for DIM in many cases, to consider two identical binary channels separately. It is obvious that such an approach simplifies the selection of the most efficient methods of transmitting and receiving, and eases system design.

Comparison of Systems' Noise Immunity

For the comparisons, it is necessary to obtain expressions for the dispersion and mathematical expectation of the error for DM and PCM. With deltamodulation, the transition of one signal to the other in the channel (suppression of a pulse or the emergence of a false one) gives rise to a variation in the step function voltage in the receiver by the amount 2Δ. The error voltage with this can be expressed in the form $U_{er} = 2\Delta\xi$, where ξ is a random variable which assumes the values + 1 and − 1. Since these values are equiprobable, the mathematical expectation of the error equals zero:

$$MU_{\text{er}} = 2\Delta M\xi = 0 \qquad (17)$$

The dispersion of the error may be determined as

$$DU_{\text{er}} = 4\Delta^2 D\xi; \qquad (18)$$

since $M\xi = 0$, then $D\xi = M\xi^2$.

For deltamodulation,

$$M\xi^2 = 1\frac{1}{2}p(A_1/A_2) + 1\frac{1}{2}p(A_2/A_1). \qquad (19)$$

By taking (8) into account, we obtain

$$D\xi = V(\alpha). \qquad (20)$$

Thus, for DM

$$DU_{\text{er}} = 4\Delta^2 V(\alpha). \qquad (21)$$

In the case of code modulation, the value of the error depends on which pulse in the code group will be distorted. The value of each individual pulse with ordinal number k in a code group of n pulses is found from the formula

$$N_k = 2^{k-1}\Delta. \qquad (22)$$

Therefore, the error voltage is determined as

$$U_{\text{er}} = \sum_{k=1}^{n} 2^{k-1}\Delta\xi. \qquad (23)$$

Here the random variable, when noise acts, takes the values + 1 and − 1 and, otherwise, the value zero.

Exactly as in the previous case, we find that $MU_{\text{er}} = 0$ and

$$DU_{\text{er}} = D\sum_{k=1}^{n} 2^{k-1}\Delta\xi = \sum_{k=1}^{n} (2^{k-1})^2\Delta^2 D\xi. \qquad (24)$$

After some transformation, we find the formula for the dispersion of the error in the case of PCM:

$$DU_{\text{er}} = \frac{2^{2k}-1}{3}\Delta^2 V(\alpha). \qquad (25)$$

A) The case of a given average transmitter power. We now consider the conditions under which the systems' noise immunity should be compared.

1. We assume that there is no filtering of the signal in the receiver, but simply its recording by a sufficiently

fast-acting reproducing device. We therefore carry out the comparison by using (14), (21), and (25).

2. We assume that all the systems are designed for transmitting information with identical upper-frequency bounds F_u.

3. We assume that the quality of transmission is identical for identical numbers of levels of partitioning, i.e., that the discreteness errors Δ are equal.

4. We assume that the mean transmitter power P_{av} and noise level σ are the same for all cases.

5. We assume that the bandwidth and, consequently the duration of the pulses in the channel, is identical for all the systems.

For simplicity, we shall assume that the pulses are rectangular. With this, the signal energy entering into Formula (6) will equal $P_p\tau$ (here, P_p is the transmitter's pulse power).

Then, for the quantity α we obtain the expression

$$\alpha = \frac{1}{\sigma}\sqrt{\frac{P_p}{2}}\,\tau = \frac{1}{\sigma}\sqrt{\frac{P_{av}}{2}}\,T_t \tag{26}$$

for code and deltamodulation, and the expression

$$\alpha = \frac{1}{\sigma}\sqrt{\frac{P_p}{2}}\,\tau = \frac{1}{\sigma}\sqrt{\frac{P_{av}}{2}}\,T_{av} \tag{27}$$

for discrete-incremental modulation.

Here, the quantity T_{av} is the average duration of the time interval between neighboring pulses. It depends on the statistics of the information to be transmitted and, obviously, is related to p_n. Finding this relationship analytically in the general case entails mathematical difficulties, so that the magnitude of T_{av} is determined from the corresponding distribution, taken off experimentally from recordings of information typical of the given telemetry system.

The implementation of this investigation for several parameters subject to telemetering in industry, in energetics in particular [2], showed that the distribution of the intervals between moments when the parameter changed levels is close to a Poisson distribution. Indeed, if it be assumed that the transition probability p_n on the time segment $\Delta t = T_{min}$ depends on the length of this segment, i.e., $p_n = p_0\Delta t$, and is unrelated to the behavior of the process on the remaining segments, then this distribution will be described by the expression

$$H(t) = p_0 e^{-p_0 t}\Delta t, \tag{28}$$

and the magnitude of T_{av} can be found from the formula

$$T_{av} = \int_0^\infty t p_0 e^{-p_0 t}\,dt = \frac{1}{p_0}. \tag{29}$$

Since we have agreed that $p_n = p_0 T_{min}$, then

$$T_{av} = \frac{T_{min}}{p_n}. \tag{30}$$

In order to express the repetition period in terms of the quantity F_u for code modulation, we use the well-known relationship

$$f_t = 2F_u. \tag{31}$$

The pulse repetition frequency, in the case of delta-modulation, is chosen, as was mentioned earlier, from considerations of reproducing the maximum slope in the information to be transmitted $|dS(t)/dt|_{max}$. Just as in (7) and (8), we use the simplified expression

$$|\Delta| \approx \left|\frac{dS(t)}{dt}\right|_{max} T_t = \Omega_u T_t. \tag{32}$$

Thus, the repetition period for DM, or T_{min} for DIM, will equal

$$T_{IDM} = T_{min} = \frac{\Delta}{2\pi F_u}. \tag{33}$$

On the basis of what has been said earlier, we can write the expressions defining the quantity α for all three forms of modulation:

$$\alpha_{DM} = \frac{1}{\sigma}\sqrt{\frac{P_{av}}{2F_u}}\sqrt{\frac{\Delta}{\pi}}, \tag{34}$$

$$\alpha_{PCM} = \frac{1}{\sigma}\sqrt{\frac{P_{av}}{2F_u}}\sqrt{\frac{1}{2\lg_2\frac{1+\Delta}{\Delta}}}, \tag{35}$$

where $\lg_2[(1+\Delta)/\Delta] = n$ is an integer;

$$\alpha_{DIM} = \frac{1}{\sigma}\sqrt{\frac{P_{av}}{2F_u}}\sqrt{\frac{\Delta}{2\pi}(k+2)}. \tag{36}$$

Figure 4 shows the curves which characterize the potential noise immunity of the three forms of modulation considered, for two different values of Δ. It is clear from the figure that, for a given mean transmitter power,

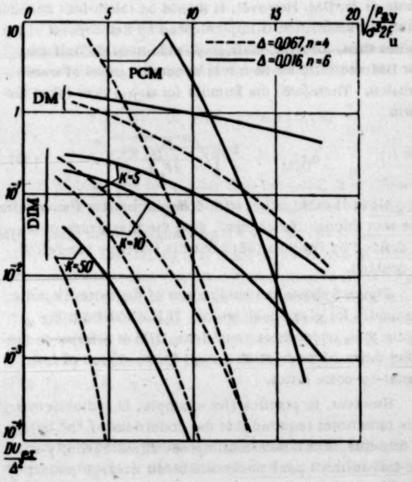

Fig. 4.

the noise immunity of a system with discrete-incremental modulation is always better than in a system with delta-modulation, and only sometimes worse than the noise immunity of a system with PCM. With this, pulse-code modulation turns out to have higher noise immunity than DIM for large numbers of levels to be transmitted and high transmitter power. For small signal-to-noise ratios, conversely, the dispersion of the error is less when DIM is used.

B) The case of given peak pulse power. We now compare the modulation forms we have been considering when the transmitter's peak power is given, retaining all the other conditions assumed under paragraph A.

In this case, (26) and (27) are changed. If we denote by q the mark-space ratio of the pulses, then these expressions will have the form:

$$\alpha_{\text{PCM}} = \frac{1}{\sigma}\sqrt{\frac{P_{\text{p}}}{2F_{\text{u}}\,q^2\lg\dfrac{1+\Delta}{\Delta}}}, \qquad (37)$$

$$\alpha_{\text{DM}} = \frac{1}{\sigma}\sqrt{\frac{P_{\text{p}}\Delta}{2F_{\text{u}}\,q\pi}}. \qquad (38)$$

As for the value of α_{DIM}, we must consider two cases:

a) when the duration of the pulses and the interval $T_{\min}$ are rigidly related to the quantity q ;

b) when the following conditions are imposed on the pulse duration:

$$\tau \leqslant \frac{T'_{\text{av}}}{q} \text{ and } \tau \leqslant T_{\min}$$

In the first case, the magnitude of τ will be the same as for DM. However, it should be taken into account that, if transmission is implemented by heteropolar video pulses then, for DIM, their amplitude must be half that for DM and PCM for identical dynamic ranges of transmission. Therefore, the formula for α_{DIM} now takes the form

$$\alpha_{\text{DIM}} = \frac{1}{\sigma}\sqrt{\frac{P_{\text{p}}}{2F_{\text{u}}q}\,\frac{\Delta}{4\pi}}. \qquad (39)$$

Now, if radio pulses with different carrier frequencies are sent through the channel, then the magnitude of α_{DIM} is defined by Formula (38), but the system's bandwidth is doubled.

Figure 5 shows the comparison of the system's noise immunity for given peak power. It is clear from the figure that, under these conditions, DIM is inferior to the other forms of modulation except in the region of low signal-to-noise ratios.

However, in practice (for example, in radiotelemetry) it is sometimes required that the conditions of "b" hold. In this case, limitations are imposed simultaneously on the transmitter's peak power and on its average power, but the pulse duration is not strictly given (except that $\tau \leq T_{\min}$). With this, the magnitude of α_{DIM} can be found from the formula

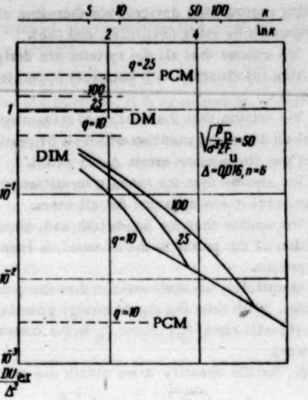

Fig. 5.

$$\alpha_{\text{DIM}} = \frac{1}{\sigma}\sqrt{\frac{P_{\text{p}}}{2F_{\text{u}}}\,\frac{\Delta}{4\pi}\,\frac{(K+2)}{2q}}. \qquad (40)$$

Thus, by increasing the duration of the pulses, one can improve the noise immunity of transmission and, simultaneously, reduce the required channel bandwidth. Broadening of the pulses is possible up to the point when the quantity (K + 2)/2q becomes equal to unity, after which the magnitude of α_{DIM} must remain constant. The improvement of the noise immunity of DIM as a function of K for various admissible mark-space ratios is shown in Fig. 6 .

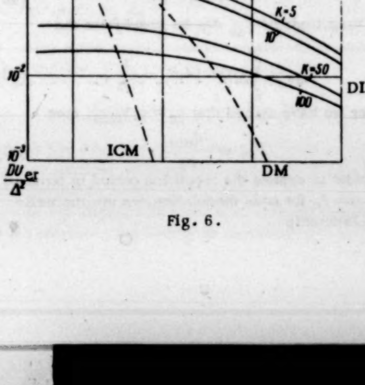

Fig. 6.

SUMMARY

1. The theory of potential noise immunity allows one to estimate the telemetering error with fluctuation noise for the discrete-incremental method of information transmission. An accurate and, at the same time, sufficiently simple expression for the probability of distortion with DIM could be found for only one special case—synchronous transmission of heteropolar pulses. However, this expression can be used for an approximate estimate of the error in a number of other cases.

2. If the signal-to-noise ratio is not very small and the probabilities $p(A_1/A_3)$ and $p(A_3/A_1)$ are much less than the remaining transition probabilities, then a communications channel with DIM may be considered as two individual binary channels, and transmission and reception methods can be chosen in correspondence with this.

3. Noise immunity of DIM is immediately related to the statistics of the messages to be transmitted: the greater the slope of the correlation function, the smaller the probability of error

4. The comparison of the noise immunity of the discrete systems* showed that, for given average power, DIM is always better than DM, and is inferior to PCM only for high signal-to-noise ratios and large numbers of quantization levels.

5. For given peak power and pulse duration, DIM has a practical noise immunity which is comparable to that of DM and significantly worse than for PCM.

For a given mark-space ratio, a gain can be achieved only at the cost of widening the pulses.

APPENDIX

Computation of the Transition Probability Matrix for DIM with Synchronous Transmission of Heteropolar Pulses

We determine the noise immunity for the given particular case of transmission with three discrete signals. For this we return to the basic propositions of the theory of potential noise immunity and to the definition of the ideal receiver which was given previously. We recall that, by Kotel'nikov's theorem, a signal which is limited to the time T and whose energy is lumped into some frequency band F may be completely characterized by a finite number 2FT of its values. These values are considered as the coordinates of the signal vector in a multidimensional space. The length of the vector is determined by the signal's average power, and equals

$$\sqrt{\sum_{r=1}^{2FT} a_r^2} = \sqrt{\overline{A^2(t)}}. \qquad (A.1)$$

Here, the a_r are the signal values at 2FT points uniformly distributed in time. Analogously, the fluctuation noise is represented by a random vector of length

$$\sqrt{\frac{\sigma^2}{2T}\sum_{l=1}^{2FT} \theta_l}, \qquad (A.2)$$

where θ_l is a normal random variable for which

$$p(z < \theta < z + dz) = \frac{dz}{\sqrt{2\pi}} e^{-\frac{z^2}{2}} \qquad (A.3)$$

The terminus of the total vector, corresponding to the oscillation X(t) can, with some probability, fall at various points of space. Therefore, the problem of the receiver is the correct identification of the received signal X(t) with that one of the signals which was transmitted during time T. Thus, the receiver's design principle is characterized by some division or other of the entire signal space into regions of correct reception of each of the signals $A_i(t)$.

In particular, for an ideal receiver, the configuration of the regions is so determined that it must reproduce the signal with the maximum value of the probability described by (2). With transmission of $A_i(t)$, the probability that signal X(t) falls in region dv of the 2FT-dimensional space equals

$$p_{A_i}(X) = \frac{dv}{\left(\sqrt{\frac{\pi}{T}}\sigma\right)^{2FT}} \times$$

$$\times \exp\left(-\frac{T}{\sigma^2}\overline{[X(t) - A_i(t)]^2}\right). \qquad (A.4)$$

Therefore, the ideal signal, in receiving oscillation X(t), will reproduce that signal for which the quantity

$$\frac{T}{\sigma^2}\overline{[X(t) - A_j(t)]^2} - \ln p(A_j) \qquad (A.5)$$

will be minimal.

Thus, when signal $A_i(t)$ of n possible signals is sent, the ideal receiver correctly reproduces the information corresponding to this signal if n-1 inequalities of the following form hold:

$$T\,\overline{[X(t) - A_i(t)]^2} - \sigma^2 \ln p(A_i) \leqslant$$

$$\leqslant T\,\overline{[X(t) - A_j(t)]^2} - \sigma^2 \ln p(A_j). \qquad (A.6)$$

If at least one inequality does not hold, then distortion arises. Analogous conditions are valid for all n signals.

There are the signals $A_1(t) = +1$, $A_2(t) = 0$ and $A_3(t) = -1$. Signal $A_2(t)$ is found at the origin of coordinates, and the radius vectors corresponding to signals $A_1(t)$ and $A_3(t)$ are equal in modulus and oppositely directed. The boundaries between the signal regions are two parallel planes, perpendicular to these radius vectors and symmetrically located with respect to the origin of coordinates (Fig. 7).

---

* We recall that the comparisons made were valid for messages in which the distribution of the intervals between pulses in the channel was close to a Poisson distribution.

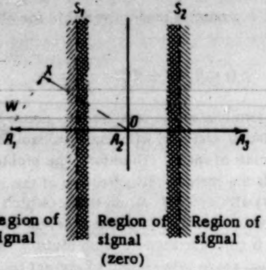

Fig. 7.

It is easily seen that, for distortion of signal $A_1(t)$, it suffices to violate just the one inequality

$$T\,\overline{[X(t)-A_1(t)]^2}-\sigma^2\ln p(A_1)<$$
$$\leqslant T\,\overline{[X(t)-A_2(t)]^2}-\sigma^2\ln p(A_2), \qquad (A.7)$$

since it is only possible to pass from the region of signal $A_3(t)$ to that of $A_1(t)$ by going through the region of signal $A_2(t)$.

We consider the inequality inverse to that of (A.7). By using (1), we may write

$$T\,\overline{[W(t)+A_1(t)-A_1(t)]^2}-\sigma^2\ln p(A_1)\geqslant$$
$$\geqslant T\,\overline{[W(t)+A_1(t)-A_2(t)]^2}-\sigma^2\ln p(A_2) \qquad (A.8)$$

or

$$T\,\overline{W^2(t)}\geqslant T\,\overline{W^2(t)}+2T\,\overline{W(t)\,[A_1(t)-A_2(t)]}+$$
$$+T\,\overline{[A_1(t)-A_2(t)]^2}-\sigma^2\ln\frac{p(A_2)}{p(A_1)}. \qquad (A.9)$$

By then taking into account that, in our case, $A_2(t)=0$, we use (2.60) of [1]:

$$\overline{W(t)\,A(t)}=\frac{\sigma}{\sqrt{2T}}\sqrt{\overline{A^2(t)}}\;\theta. \qquad (A.10)$$

Here, θ is the normal random variable of (A.3). After some transformation we obtain

$$0\geqslant\sigma\sqrt{2T}\sqrt{\overline{A^2(t)}}\;\theta_1+T\,\overline{A_1^2(t)}-\sigma^2\ln\frac{p(A_2)}{p(A_1)}. \qquad (A.11)$$

The probability that this inequality holds is $V(\alpha')$, so that

$$P_{\text{dis}}(A_1)=V(\alpha'). \qquad (A.12)$$

It is obvious here that

$$\alpha'=\frac{\sqrt{T\,\overline{A_1^2(t)}}}{\sigma\sqrt{2}}-\frac{\sigma}{\sqrt{2}\sqrt{T\,\overline{A_1^2(t)}}}\ln\frac{p(A_2)}{p(A_1)} \qquad (A.13)$$

By substituting $\alpha=\dfrac{\sqrt{T\,\overline{A_1^2(t)}}}{\sigma\sqrt{2}}$ and $\dfrac{p(A_2)}{p(A_1)}=K$,

we find

$$\alpha'=\alpha-\frac{1}{2\alpha}\ln K. \qquad (A.14)$$

Distortion of signal $A_2(t)$ corresponds to the holding of the inequalities

$$T\,\overline{[X(t)-A_2(t)]^2}-\sigma^2\ln p(A_2)\geqslant$$
$$\geqslant T\,\overline{[X(t)-A_1(t)]^2}-\sigma^2\ln p(A_1),$$
$$T\,\overline{[X(t)-A_2(t)]^2}-\sigma^2\ln p(A_2)\geqslant$$
$$\geqslant T\,\overline{[X(t)-A_3(t)]^2}-\sigma^2\ln p(A_3). \qquad (A.15)$$

It is easily shown that the probability of each inequality holding is the same for all, and equals

$$p(A_3/A_2)=p(A_1/A_2)=V(\alpha''), \qquad (A.16)$$

where

$$\alpha''=\alpha+\frac{1}{2\alpha}\ln K, \qquad (A.17)$$

and the probability

$$P_{\text{dis}}(A_2)=2V(\alpha''). \qquad (A.18)$$

Due to the symmetry of the system of three signals, we have

$$P_{\text{dis}}(A_3)=P_{\text{dis}}(A_1).$$

We can thus obtain the expression for the probability of error with discrete-incremental modulation in this particular case.

Since

$$P_{\text{er}}=\sum_{i=1}^{3}p(A_i)\,P_{\text{dis}}(A_i), \qquad (A.19)$$

then

$$P_{\text{er}}=2p(A_1)\,V(\alpha')+2p(A_2)\,V(\alpha''). \qquad (A.20)$$

Equation (A.20) characterizes the probability of distortion as a whole. For us to compute the errors, it is necessary to know the transition probabilities of each signal to the two others separately. For this, we consider in more detail the transmission of signals $A_2(t)$ and $A_3(t)$. Let signal $A_2(t)$ be transmitted. The probability that the ideal receiver reproduces precisely signal $A_2(t)$ at its output equals the probability of the simultaneous holding of the inequalities

$$p(A_1)\exp\left(-\frac{T}{\sigma^2}\,\overline{[X(t)-A_1(t)]^2}\right)\leqslant$$
$$\leqslant p(A_2)\exp\left(-\frac{T}{\sigma^2}\,\overline{[X(t)-A_2(t)]^2}\right),$$
$$p(A_3)\exp\left(-\frac{T}{\sigma^2}\,\overline{[X(t)-A_2(t)]^2}\right)\leqslant$$
$$\leqslant p(A_3)\exp\left(-\frac{T}{\sigma^2}\,\overline{[X(t)-A_3(t)]^2}\right). \qquad (A.21)$$

The probability that the first of these hold was already found earlier (A.12).

We consider the second inequality. We rewrite it in the form

$$T\,\overline{[X(t)-A_2(t)]^2}-\sigma^2\ln p(A_2)\leqslant$$
$$\leqslant T\,\overline{[X(t)-A_3(t)]^2}-\sigma^2\ln p(A_3). \qquad (A.22)$$

After multiplying out the parentheses and cancelling, we have

$$2T\,\overline{W(t)\,A_1(t)}+\overline{T\,A_1^2(t)}-\sigma^2\ln\frac{p(A_3)}{p(A_1)}\leqslant$$
$$\leqslant 2T\,\overline{W(t)\,[A_1(t)-A_3(t)]}+T\,\overline{[A_1(t)-A_3(t)]^2}. \qquad (A.23)$$

By taking into account that $|A_1(t)| = |A_3(t)|$ and $p(A_1) = p(A_3)$, we can write

$$2T\,\overline{W(t)\,A_1(t)}\leqslant 2T\,\overline{W(t)\,[A_1(t)-A_3(t)]}+$$
$$+3T\,\overline{A_1^2(t)}+\sigma^2\ln K. \qquad (A.24)$$

We now use Formula (A.10). Then,

$$\sqrt{2T}\sqrt{\overline{A_1^2(t)}}\,\theta_1\leqslant 2\sqrt{2T}\sqrt{\overline{A_1^2(t)}}\,\theta_{13}+$$
$$+3T\,\overline{A_1^2(t)}+\sigma^2\ln K. \qquad (A.25)$$

For the case considered, the quantities θ_1 and θ_{13} are equal, since they are the projections of one and the same vector on one and the same line. With this in mind, we obtain the inequality

$$0\leqslant 2\sqrt{2T}\sqrt{\overline{A_1^2(t)}}\,\theta_1+3T\,\overline{A_1^2(t)}+\sigma^2\ln K. \qquad (A.26)$$

The probability that this holds equals

$$1-V(\alpha'''), \qquad (A.27)$$

where

$$\alpha'''=3\alpha+\frac{1}{2\alpha}\ln K. \qquad (A.28)$$

The probability that the two inequalities in (A.21) hold simultaneously equals the product of the partial probabilities, i.e.,

$$p(A_2/A_1)=V(\alpha')\,[1-V(\alpha''')]. \qquad (A.29)$$

The probability of reproducing signal $A_3(t)$ instead of $A_1(t)$ is defined by the inequalities

$$p(A_1)\exp\left(-\frac{T}{\sigma^2}\overline{[X(t)-A_1(t)]^2}\right)<$$
$$<p(A_3)\exp\left(-\frac{T}{\sigma^2}\overline{[X(t)-A_3(t)]^2}\right),$$
$$p(A_2)\exp\left(-\frac{T}{\sigma^2}\overline{[X(t)-A_2(t)]^2}\right)\leqslant$$
$$\leqslant p(A_3)\exp\left(-\frac{T}{\sigma^2}\overline{[X(t)-A_3(t)]^2}\right). \qquad (A.30)$$

Since the regions of signals $A_3(t)$ and $A_1(t)$ do not have common boundaries, the first inequality should be replaced by the inequality

$$p(A_1)\exp\left(-\frac{T}{\sigma^2}\overline{[X(t)-A_1(t)]^2}\right)\leqslant$$
$$<p(A_3)\exp\left(-\frac{T}{\sigma^2}\overline{[X(t)-A_3(t)]^2}\right). \qquad (A.31)$$

After transformations analogous to those given above, we find† that

$$p(A_3/A_1)=V(\alpha')\,V(\alpha'''). \qquad (A.32)$$

Since $p(A_2/A_3)$ and $p(A_1/A_3)$ have the same value, it is then easy, from the data obtained, to construct the matrix of transition probabilities (10).

† Generally speaking, this can be obtained from simpler considerations, by taking into account (A.29) and that

$$P_{\text{dis}}\ (A_1)=p(A_2/A_1)+p(A_3/A_1).$$

FINITE AUTOMATA.II*

M. A. Aizerman, L. A. Gusev, L. I. Rozonoér,
I. M. Smirnova, and A. A. Tal'
(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 3, pp. 359-368, March, 1960

In the second part of this work we continue the exposition of the authors' point of view on finite automata, the problems in the theory of finite automata, and the interrelationships of this theory with the ordinary theory of switching (in particular, relay contact) circuits. The general problem is posed of constructing automata operating in one time scale (i.e., with one partitioning of the continuous time axis into discrete points) from elements which operate in a different time scale. As examples of this type of system, we consider abstract neurons (neurons of the type proposed by McCulloch and Pitts) and neuron nets. Relay contact and, more generally, switching circuits are then simply one possible technical realization of abstract neuron nets.

6. Realizations of Automata Operating in a Given Time Scale from Automata Operating in a Different One

In the first part of this work it was assumed that both an automaton as a whole and all of the elements of which the automaton was assembled operate in one and the same time scale (the term "sequentiality" was used previously). As applied to the last remarks of section 5, related to technical realization, this meant, for example, that all the delay elements simultaneously received signals denoting the appearance of the next cycle (i.e., next moment of discrete time) from one and the same cycle transducer.

Here we shall be interested in the more general problem of constructing automata which operate in one time scale from automata operating in a different one.

We consider automaton A, defined by the equation

$$\varkappa(p) = F[\varkappa(p-1), \rho(p-1)], \qquad (1)$$

for which there is given partitioning of the time axis into cycles t = 0,1,2,..., p,..., defining the time scale T, and we construct a tape L of the states of this automaton which arise for some initial automaton state $\kappa(0) = \kappa_0$ and for some sequence of inputs $\rho = \rho(t)$. We transform this tape in the following way. From the sequence t = 0, 1, 2,..., p,..., we choose some increasing sequence of values of time $t_0, t_1, t_2, \ldots, t_i, \ldots$, and we pick out from the original tape those columns ρ, κ which correspond to the moments of time $t_0, t_1, \ldots t_i, \ldots$. The sequence of these columns, written in correspondence with the sequence of moments of time $t_0, t_1, \ldots, t_i, \ldots$, forms some new tape L^*. Still one more transformation may be carried out on tape L^* by recoding all the symbols written in row "κ"†. The recoding amounts to this, that all symbols from the $\{\kappa\}$ alphabet which appear on tape L^* are divided into groups, and each group is put into correspondence with some new symbol (which, in particular, may again be a symbol from the $\{\kappa\}$ alphabet). The symbols within any given group are not distinguished from each other, and one and the same new symbol corresponds to each of them. By replacing the symbols in column "κ" of tape L^* by the corresponding new symbols, we obtain tape L'.

It may certainly happen that there are contradictory triads on tapes L^* and L', although there were none on tape L. It is important to note that even if there are contradictory triads on tape L^*, it is possible that, thanks to the recoding, there will be none on tape L'. If there are contradictory triads on tape L', then this tape cannot be the state tape of any finite automaton. But if L' contains no contradictory triads, then it could have been obtained as the result of the operation of some finite automaton, operating in time scale T', defined by the sequence of moments of time $t_0, t_1, \ldots, t_i, \ldots$

We now assume that, for each possible state tape L of automaton A, it is possible to stipulate a sequence of moments of time $t_0, t_1, \ldots, t_i, \ldots$ and a method of recoding‡ such that the transformed tape L' would not contain contradictory triads. With this, let there be no contradictory triads even among the set of all the triads contained in the entire collection of transformed tapes. Then this set of transformed tapes can be considered as the set of state tapes of one and the same new finite automaton A', operating in the new time scale T'[**]. The alphabet $\{\kappa'\}$ of states of automaton A' is defined by the accepted method of recoding and contains, as is readily understandable, a number of symbols less than, or equal to, the number of symbols in alphabet $\{\kappa\}$. The alphabet $\{\rho'\}$ of inputs of automation A' is composed of all or some of the symbols of alphabet $\{\rho\}$. By numbering the moments of time $t = t_0, t_1, \ldots$ by the series of natural numbers $0, 1, \ldots, i, \ldots$ and by introducing the new time variable $t' = 0, 1, 2, \ldots, p', \ldots$, we can present the operation of the new automaton A' by an equation of the form

---

* For the first portion of this work, cf. Avtomatika i Telemekhnika No. 2 (1960).

† The symbols in row "ρ" will not be recoded although, to be sure, this is possible.

‡ For different tapes it is admissible to choose different sequences of time and different methods of coding (for example, the sequence of moments $t_0, t_1, \ldots, t_i, \ldots$ may be determined by the sequence of inputs $\rho(t)$ for which the given tape L was obtained; for an example of this type, see section 7 below). As a particular case, the sequence $t_0, t_1, \ldots, t_i, \ldots$ and the method of coding may be chosen independently of the appearance of any given tape.

$$\varkappa'(p') = F'[\varkappa'(p'-1), \rho'(p'-1)],$$

where $p' = i$ if $p = t_i$.

The problem of constructing a given automaton A', operating in time scale T', from elements operating in time scale T reduces to the realization, based on these elements, of an automaton A which, although operating itself in time scale T, may nonetheless be used, with some coding system and with the proper choice of a "new time", as the automaton A', operating in time scale T'. Automaton A' may be represented as consisting of automaton A and a special "reading" device. This device records, for each state tape L of automaton A, the moments of time $t_0, t_1, \ldots, t_i, \ldots$, reads the symbols for the state and inputs of automaton A at these moments of time, and puts out the notation for these symbols in the adopted coding system[††]. In contradistinction to the cycle transducer which was discussed at the end of section 5, the reading-coding device just described in no way acts on the elements of automaton A.

Automata thus constructed, operating in time scale T', must themselves serve as elements for the construction of nets (section 5), mapping automata operating in the new time scale.

The transition from automaton A to the new automaton A' was implemented by transforming discrete time t to t' and alphabet $\{\kappa\}$ to $\{\kappa'\}$. As was stated earlier, because of the possibility of contradictory triads making an appearance, not each such transformation translates a finite automaton into another finite automaton. The problem arises as to what sort of transformation of discrete time, in conjunction with a recoding of symbols, does not take the device under consideration out of the class of finite automata. Closely related to this question is the question as to which class of device the aforementioned reading-coding device belongs to, and whether it is itself a finite automaton.

We note in conclusion that the contents of sections 5 and 6 reduce to the determination of different structures which are maps of one and the same automaton. What we are saying, essentially, is that different structures, thanks to recoding of states and transformations of time, may be mappings of equivalent automata.

7. Two Methods of Constructing Automata by Transforming Time Scales

Let there be a set of elements, consisting of arbitrary instantaneously acting binary logical transformers and of one-cycle delay element symbols from the alphabet $\{0,1\}$. We assume for simplicity that the cycles are defined by a partition of the continuous time axis into identical intervals of duration τ. It is required to construct, from this set, an automaton forming a given automaton A':

$$\varkappa(p') = F[\varkappa(p'-1), \rho(p'-1)] \qquad (2)$$

with alphabets $\{\kappa\}$ and $\{\rho\}$, operating in a time scale defined by a partitioning of the time axis into identical intervals of length $l\tau$ (l 0– is an integer), i.e., into an l-fold decelerated time scale.

It was shown in section 5 that a net, mapping any given automaton of any time scale T', can be constructed from a set containing any logical transformers and from delay elements of the same time scale T'. We are now given logical transformers and delay elements in time scale T. The problem thus reduces to the construction, from delay elements in time scale T, of delay elements in time scale T'.

Fig. 1.

[**] A time scale is defined, not by giving a concrete partitioning of the time axis into equal or unequal intervals, but by giving a method which permits such a partitioning to be made in each concrete case. Thus, for example, the statement that each change of the input state means the beginning of a new cycle (i.e., defines a new discrete moment of time) thereby also determines the time scale, since for each concrete giving of the sequence of inputs it permits one to carry out a definite partitioning of the time axis into cycles.

Earlier, before there was any discussion of transformations of time scales, this remark would have been meaningless.

[††] Since, for different tapes of automaton A (i.e., for different inputs and states of the automaton), different sequences of moments of time $t_0, t_1, \ldots t_i, \ldots$ and different coding methods are permitted, then this device must, generally speaking, obtain signals as to the inputs and states of automaton A at each moment of time $t = 0, 1, 2, \ldots, p, \ldots$

This device is intended, essentially, for the representation of events. Specifically, it represents some event characterizing the operation of automaton A (for example, each change of state of A's input, the appearance of some state in automaton A itself, etc.) by putting out a reading signal at the moment when the event transpires.

For this purpose, we join l delay elements, operating in time scale T, in series so as to form a delay line (Fig. 1), which is described by the recursion formulas

$$
\begin{aligned}
x_1(p) &= x_2(p-1),\\
x_2(p) &= x_3(p-1),\\
&\cdots\cdots\\
x_l(p) &= u(p-1).
\end{aligned}
$$

By eliminating from these relationships all the x_l except x_1, we obtain, for the delay line as a whole,

$$x_1(p) = u(p-l).$$

The delay line's output at time sl is uniquely determined by the input at time $(s-1)l$. Therefore, if we set $t' = s$ for $t = sl$, then such a delay line may be considered as a delay element operating in time scale T'.

We now construct an automaton by the assembly method (section 5) but now, instead of delay elements in time scale T, we connect, in each instance, a delay line as just described. The automaton thus constructed will operate in time scale T. But if we read the input symbols of this automaton, and the output of each delay line, only every $l\tau$ seconds, then we shall obtain the required automaton, operating in the time scale we require.

The reading-coding device of which we spoke earlier can, in the given case, be a time counter , which gives a reading signal for the automaton inputs and the delay lines' outputs every $l\tau$ seconds; here, coding is implemented automatically since only the delay lines' outputs are read, by virtue of which those states of automaton A which are not differentiated by the states of the terminal elements of all the delay lines are therewith lumped into one group.

We consider one particular case of the problem of realizing an automaton, operating in a given time scale, by means of an automaton operating in another time scale. This case is of interest in its own right, since it plays a basic role in the understanding of certain important technological methods of realizing finite automata in general, and switching circuits in particular.

We consider some automaton A, given by (1). At time t_0, let the input assume the state denoted by symbol ρ^0, and let the input state thereafter remain unchanged until time t_1. During the entire time $t_0 \le t \le t_1$, the automaton operates as an autonomous automaton, and its changes of state occur in correspondence with the equation

$$\varkappa(p) = F[\varkappa(p-1), \rho^0], \qquad t_0 < p \leqslant t_1. \qquad (3)$$

We now assume that, for each ρ^0, there exists a number $\underline{s}$ such that :

a) this autonomous automaton is decremented, i.e., its graph is such that, from any initial state, it can reach one of several possible equilibrium states [i.e., a state which, by virtue of (3), is transformed into itself] within a finite number $\underline{h}$ ($h \le s$) of cycles, and

b) the following change of the automaton's input occurs only after the automaton has reached an equilibrium state, i.e., $t_1 - t_0 \ge s$.

At time $t = t_1$, input state ρ^0 is changed to ρ^1, which then remains unchanged until time $t = t_2$. There is then formed a new autonomous automaton

$$\varkappa(p) = F[\varkappa(p-1), \rho^1], \qquad t_1 < p \leqslant t_2,$$

about which we make the same two assumptions. Once again, after a time less than $t_2 - t_1$, the automaton reaches an equilibrium state, which may differ from the previous one. At time $t = t_2$, input ρ^1 is changed to ρ^2, etc.

We assume that the automaton's inputs and states are read only at the moments $t_0, t_1, t_2, \ldots, t_i, \ldots$, when the input states change. It is not necessary here to recode the states.

Tape L', written by the corresponding "reading" device,

t	t_0	t_1	t_2	...
ρ	ρ^0	ρ^1	ρ^2	...
$\varkappa$	$\varkappa(t_0)$	$\varkappa(t_1)$	$\varkappa(t_2)$	...

does not contain contradictory triads, as is easily seen.

Therefore, tape L' can be considered, for any input sequence $\rho^0, \rho^1, \rho^2, \ldots$, as the result of the operation of the new automaton A', operating in time scale T' which is defined by the moments at which the inputs change. Serving as the states of automaton A' are the equilibrium states of the autonomous automata formed from automaton A for fixed (sustained) inputs.

It is immediately evident that the operation of automaton A' is completely independent of the time scale of automaton A. It is important only that automaton A operate sufficiently rapidly, i.e., that equilibrium is attained in it before a new cycle commences in automaton A'.

8. Abstract Neurons and Neuron Nets

The name "abstract neuron" is given to an element with a finite number of input lines and one output line, the states of which can be denoted by symbols from the alphabet $\{0, 1\}$; the symbol at the output is uniquely defined by the symbols at the inputs τ seconds previously, where τ is a given number.‡‡

Thus, a neuron is a combination of logical transformers and delay elements with lag time τ. The specific feature of neurons is that the logical transformers and delay elements cannot be distinguished from each other.

---

‡‡ The term "neuron" for these abstract elements is used for historical reasons, and is only slightly related to the physiological meaning of the term.

A neuron may be considered as an elementary finite automaton in which only two states are possible whereby, with a fixed input, an equilibrium state is reached in one cycle (the time between cycles is τ seconds).

Neurons are connected to each other, forming neuron nets. For the formation of a net, the states of several or all input lines of the neurons from some set are immediately identified with the output states of some neurons from the same set. In contradistinction to the nets treated in section 5, neuron nets do not contain symbol transformers, and the original elements are not any automata, but automata of a very special form, namely, neurons.

The logical functions which can be realized by one neuron can be most diverse. But in neurons of a given type only a completely concrete set of logical functions may be realized. By setting up a net from neurons of a given type, this net having one output line and several input lines, one can extend the set of realizable logical functions, in the sense that the state at the output of such a net will be a logical function of the input states, but with a delay, not of τ, but of $l\tau$ seconds, where l is an integer. We now assume that, for any logical function whatever, one can, from neurons of a given type, construct a net which realizes this function in not more than $\zeta\tau$ seconds. The least value of ζ which satisfies this condition will be called the index of the neuron. The number ζ depends on the logical capabilities of the neurons from which the net was set up. •••

It follows from what has been presented that, from neurons with a finite index ζ, one can construct any logical transformer but, in contradistinction to the transformers studied in previous sections, these will not be instantaneously acting: up to $\zeta\tau$ seconds will be required to implement a logical transformation.

A neuron net is a particular case of a net in the sense of section 5, so that any neuron net is therefore a finite automaton. The time scale of this finite automaton is determined by the partitioning of the continuous time axis into equal intervals of duration τ. Obviously, if one is considering the operation of an automaton in such a time scale, then neurons with index $\zeta > 1$ do not constitute a complete set. Indeed, in such a time scale it is impossible to construct from neurons even the simplest automaton.

$$\varkappa(p) = L[\varkappa(p-1), u(p-1)],$$

where L is a logical function for the realization of which more than one cycle is required (if $\zeta > 1$ then, by definition, such a function L exists).

Now, if the time scale is defined by a partitioning of the time axis into identical intervals equal or greater than $\zeta\tau$, then any automaton may be constructed from neurons with index ζ. In fact, any logical function is realized within $\zeta\tau$ seconds, as well as (by the use of feedback paths) a system of equations of the form

$$\varkappa_i(p') = L_i[\varkappa_1(p'-1), \dots, \varkappa_n(p'-1);$$
$$u_1(p'-1), \dots, u_s(p'-1)] \quad (i=1, \dots, n),$$

where $p' = s$ if $p = s\zeta$, i.e., an abstract structure which is the mapping, as was shown in section 5, of any finite automaton of time scale p'.

By using automata operating in such a "uniform" time scale $\zeta\tau$, we can construct, from neurons, automata operating in other time scales. On the basis of the arguments given in sections 5-7, we can now give at least two methods for realizing such automata.

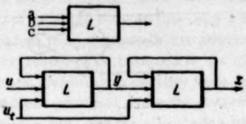

Fig. 2.

First method. From neurons with finite index ζ we can construct delay elements for the time defined by the externally supplied special cycle signals u_t. Figure 2 shows an example of a circuit of such elements, with input u and output x. The transformers L shown on the circuit realize the following logical function with a delay $l\tau$ (where $l \leq \zeta$):

$$z = (a \,\&\, \bar{c}) \vee (b \,\&\, c).$$

In correspondence with this, the equations which describe the delay elements have the form

$$x(p) = [y(p-l) \,\&\, u_t(p-l)] \vee [x(p-l) \,\&\, \bar{u}_t(p-l)],$$
$$y(p) = [u(p-l) \,\&\, u_t(p-l)] \vee [y(p-l) \,\&\, \bar{u}_t(p-l)],$$

Correct operation of the scheme shown can be guaranteed in the case when the new cycle signal u_t lasts for l old cycles and, moreover, if input u does not change before signal u_t is applied. Figure 3 shows the changes in time of all the net coordinates for certain given changes in u and u_t. Figure 4 shows an example of a McCulloch-Pitts neuron net which realizes a delay element for a time defined by synchronizing input u_t.

From such delay elements and from logical transformers which, as was shown above, are constructed from the same neurons, one may construct any finite automaton, operating at a tempo defined by synchronizing input u_t.

••• It is certainly possible that $\zeta = \infty$, or that there exist logical functions which, in general, cannot be realized by neurons of the given type.

The McCulloch-Pitts neuron has index 2, since no more than 2τ seconds is required to realize any complete normal form in a net constructed of McCulloch-Pitts neurons.

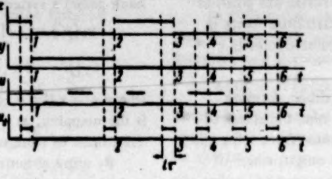

Fig. 3.

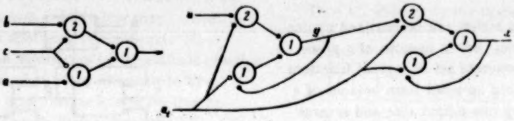

Fig. 4.

Second method . If it is necessary to construct an automaton whose time scale is defined by the changes in the input states, then one may use, in neuron circuits, the method of constructing automata from the equilibrium states of the corresponding autonomous automata (cf. section 7). Certainly, the first method is the more general; it is also valid in the given case, when the signals u_t are engendered by each change of input states in the automaton.

9. Relay Contact Circuits as Finite Automata

In the consideration of relay contact circuits there arise many important technological and scientific problems related to the peculiar features of this branch of technology. The problems alluded to will be briefly stated at the end of the present section. We, however, will not be interested here in these problems, however important they may be for the construction of actual relay contact circuits.

Here, we consider relay contact circuits only from the point of view of their special features which permit their assimilation to finite automata and which permit the use of the methods of the theory of finite automata in the construction of relay contact circuits. Therefore, we shall henceforth in this section consider an idealized model of a relay circuit.

By a relay we understand a device with a finite number of input lines and one output †††, and which satisfies the following two requirements :

a) each of the input lines and the output may have only two states, denoted by zero or unity;

b) the output state is some logical function of the states of the input lines with some time lag τ .

For example, in ordinary electromechanical relays with one winding, each relay has one input (the presence or absence of current in the winding) and realizes a logical function of one variable of the type " yes" (normally open relay contacts) or "no" (normally closed relay contacts). The lag of τ seconds is due to the relay's operating time.

In using relays with several windings, each relay has several inputs, and the character of the logical functions realized (with a delay of τ seconds) in the relays is determined by the special characteristics of the windings.

Individual relays are combined in a relay circuit by means of electrical circuits (contact circuits). These circuits define all or several inputs to relays as logical functions of the states of relay contacts and of contacts whose states depend on external stimuli . These logical functions are realized virtually instantaneously in practice. Therefore, the contact circuits play the role of the instantaneously acting logical transformers.

From what has been presented it follows that a relay is an ordinary neuron, the value of whose index ζ depends on which logic can be realized by means of one relay. A relay circuit differs from a neuron net only in its capability of being used as an instantaneously acting transformer. This difference is inessential, since the essential fact for a neuron net is that its time scale, as an automaton, is predetermined by the time τ — the neurons' lag.

Therefore, relay circuits are finite automata of the "neuron net" type, and everything presented in sections 6 and 7 applies to relay circuits as well. In particular, the two methods given in section 7 for constructing finite automata which operate in time scales different from the neurons' natural time scale, also define two possible ways of constructing relay circuits which map an arbitrary finite automaton whose time scale differs from the natural time scale of the relay circuit, as defined by the relays' time lag. Both these methods are used for synthesizing relay circuits. The first of these (with the construction of delay elements) is used most frequently in the construction of the so-called cyclical circuits. However, it is clear from section 7 that this method is a general one, valid for the relay realization of any finite automaton. As an example, Fig. 5 shows the schematic realization of a delay element for the time defined by synchronizing signal u_t, constructed from ordinary electromechanical relays. The second method, using the equilibrium states of the corresponding autonomous automata, is actually used in almost all sequential circuits.

---

††† Or two outputs, one of which is the negation of the other.

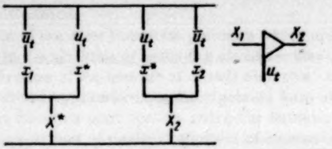

Fig. 5.

Although relay circuits are one of the possible methods of technically realizing finite automata, specific analytical and synthesizing techniques are applied to them. This specificity is due, in particular, to the fact that the lag times in different relays of one circuit are not identical. Therefore, the time axis cannot be partitioned beforehand into equal cycles, thanks to which the analysis and synthesis of relay circuits requires that one obtain additional information which is not forthcoming from finite automata theory. Moreover, the differences in relay operating times might lead to relay competitions.

Also specific are the minimization problems which arise in the synthesis of relay contact circuits (for example, minimization of the number of contacts, windings, etc. Thus, relay circuits pose their own problems which do not arise in the general theory of finite automata. To our way of thinking, the aim of relay circuit theory consists of studying such types of specific problems and of general methods for the technical realization of finite automata by relay circuits of some type or other.

Since finite automata theory began to be crystallized as an independent scientific discipline only very recently, it is natural that part of the general questions which are important for the understanding of finite automata in general were developed within the purview of relay circuit theory. Due to this, there is ordinarily no distinction made between the general questions bearing on finite automata theory and the questions specific to relay realizations.

The development of the theory of logical devices naturally led to the introduction into consideration of abstract "finite automata" and to the splitting off of finite automata theory as an independent scientific discipline.

10. Concluding Remarks

In designing concrete automatic devices, it is necessary to distinguish several independent steps.

Design begins with the analysis and idealization of the operations which the automatic device must execute. If this idealization leads to a formulation of the operating conditions in terms of discrete time and a finite set of variables, each of which may assume only a finite number of values, then the possibility arises of seeking the automatic device to be designed in the class of finite automata. With this possibility there is closely related a problem subsumed under the general problem of representing events, and the elucidation of what may and may not be implemented by finite automata.

If this question is answered in the affirmative, there arises the second problem, namely, by which equation of type (1) may one describe the finite automaton which satisfies the conditions posed , i.e., what are the tapes of this automaton and of what triads do they consist. This problem relates to the problem of the abstract synthesis of a finite automaton from its given operating conditions.

Even within boundaries of abstract consideration, one may cite a number of ways of realizing automata. One and the same automaton may be made, for example, from elements implementing functional transformations of two-valued or of multi-valued logic, with the use of special delay devices for externally given cycles or without their use if the equilibrium states in abstract neuron nets are employed, etc. The choice among the theoretically different ways of realizing an automation is related to the choice of the automaton's structure, to its abstract assembly.

This entire group of questions comprises the contents of the general theory of finite automata.

Each technical realization of a finite automaton gives rise to its own scientific problems, requires its own methods of analysis and synthesis, the taking into account of the technical special features of the actual apparatus, the economic and other requirements on the design or the circuit.

The application of finite automata theory ends as soon as one has chosen the structure or the net, i.e., as soon as one has written the equations of type (6) of the first part of the present work .

For the problem of the technical realization, the equations of type (6), or any of their equivalents, are the initial data, and the aim here is the engineering choice of design or circuit which is optimal in some sense (technical or economical).

Certainly, the boundaries between the problems of finite automata theory and the problems of technical realization are not well-defined.

Even in the choice of an abstract structure, one has to take into account the requirements and the special features of the technical realization. But this "infiltration" of technical requirements into the abstract considerations does not impede the detachment of the general theory from the very important, but specific, problems.

A VISUAL-MATRIX METHOD FOR MINIMIZING BOOLEAN FUNCTIONS

A. D. Zakrevskii

(Tomsk)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 3, pp. 369-373, March, 1960
Original article submitted April 25, 1959

A semiintuitive method is presented for the minimization of Boolean functions which is based on the use of certain properties of visually perceived information. The method is applicable to the minimization of arbitrary Boolean functions with up to 10 to 12 variables, and is particularly effective for the minimization of incompletely defined functions.

One of the most important problems which must be solved in the synthesis of switching circuits— the minimization of the number of circuit elements – is ordinarily solved by transforming the algebraic form of Boolean functions until one has arrived at formulas which are superpositions of minimal numbers of elementary functions.

The difficulties which arise in minimizing arbitrary Boolean functions increase catastrophically fast as the number n of arguments increases, so that a number of methods become inapplicable in practice even for $n > 6$.

The increase in the number of arguments of the function to be minimized may be compensated for either by restricting the class of functions to be considered or by increasing the speed of solution of the minimization problem by using modern computing technology. The realization of these possibilities is the main subject of a large number of published works [1-17].

A common characteristic feature of the contents of a large part of these works is the algorithmization of the process of minimizing Boolean functions. Significantly less attention has been given to the development of methods based on the use of certain properties of the human perception of information which are difficult to translate into algorithms. Despite this, just such methods are necessary for manual minimization of Boolean functions.

The original information on Boolean functions must be presented in compact and readily perceivable form. Since the basic "memory device" for manual minimization is the two-dimensional sheet of paper, the most compact form of representing information in this case will be a two-dimensional—matrix—form. Matrix forms for presenting Boolean functions were used by O. Plekhl' [10], A. Svoboda [18], M. Karnaugh [19] and others.

In these methods, the elements of information concerning the Boolean functions are the functions' values given by sets of elements in two-dimensional space, placed into a single-valued correspondence with the sets of values of the variables. The order of the mutual spatial arrangement of the elements, a matter of indifference in an algorithmic approach, plays an essential role for the visual perception of the matrix by a human being. An advantageous choice of such a mutual spatial disposition of elements, i.e., such a method of coding the spatial elements by sets of values of the variables, is one for which the properties of the Boolean functions which are of interest to us in trying to carry out minimization, would be readily eye-catching.

In the method suggested by A. Svoboda for minimizing Boolean functions, the potential possibilities for minimizing a Boolean function, as represented by a matrix, are expressed by the periodicity properties of that representation. With large numbers of variables, one has to do with the superposition of periodic representations with different periods which is difficult to preceive visually as a whole. In connection with this, A. Svoboda uses lattices (grids), corresponding to the individual variables, by means of which one successively isolates the portions of the matrix which correspond to definite values of these variables.

In the author's opinion, it is easier to perceive visually the symmetry properties of the representation, which gives the possibility of using the superiority of Gestalt perception of the original information, thus dispensing with cards and leading to the successive analysis of the individual portions of the representation.

The visual matrix method of minimizing Boolean functions which the author proposes is semialgorithmic, semiintuitive, so that its practical implementation is required in order to elucidate its superiorities over other methods.

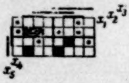
It should be remembered that, for a large number of arguments, due to the complexity of the problem, the minimization of a Boolean function in the general case is considered to be successfully implemented if it has led to a sufficiently minimal algebraic form (i.e., strictly speaking, to a form which is sufficiently close to the absolutely minimal one).

An arbitrary Boolean function $f(x_1, x_2, \ldots x_n)$ can be given by a matrix (α_{ik}) whose binary elements α_{ik} are the function values, while the subscripts i, k are its arguments. The pairs of values of i, k are put into a one-to-one correspondence with the sets of values of the arguments $x_1, x_2, \ldots x_n$, whereby the arguments are, for convenience, divided into two sets of as close to equal size as possible. Values of the arguments which enter into one of these parts code the values of $\underline{i}$, the values of the remaining arguments code the values of $\underline{k}$. O. Plekhl' and A. Svoboda coded the natural number $i, \bar{k}$ by a positional binary code with weight 2^j for the $\underline{j}$th place (bit).

For coding the rows and columns of the matrix which represents the Boolean function to be minimized, we shall use a symmetric Gray code which, as will be shown, has certain superiorities over other codes.

Unit ("1") values of a Boolean function will be represented by dots in the corresponding matrix elements, blank elements will correspond to zero function values, and blackened matrix elements will attest that the function is not defined on the sets of argument values corresponding to these elements. The set of all elements thus marked will be called the representation of the function.

TABLE 1



Example 1. Table 1 represents the Boolean function which takes the value "1" on the sets* 00000, 00010, 11011, 01110, 10100, 10110, 00111, is not defined on the sets 10010, 11010, 10001, 01101, 11111 and takes the value "0" on the remaining sets. One may consider that Table 1 represents all $2^5 = 32$ Boolean functions which are defined on all the sets but differ in their values on the sets 10010, 11010, 10001, 01101, and 11111.

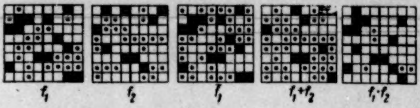
We note that when the number of variables does not exceed four, the method suggested here coincides with the method of M. Karnaugh [19] (cf. also [8, 20]), but loses its similarity as the number of variables increases (in Karnaugh's method functions of six variables are represented in three-dimensional space while, for the representation of functions of five variables, Richards [8] suggests carrying out a diagonal decomposition of the elements in the tables representing functions of four variables, etc.).

Let $y = f(f_1, f_2, \ldots, f_m)$ be a Boolean function whose arguments are functions of the binary variables $x_1, x_2, \ldots, x_n$. In order to express $\underline{y}$ as a function of $x_1, x_2, \ldots, x_n$, it suffices to find, for each set of values of $x_1, x_2, x_3, \ldots, x_n$, the corresponding values of $f_1, f_2, \ldots, f_m$ and then to determine the value of $\underline{y}$ corresponding to these latter values.

This permits the easy implementation of operations on Boolean functions by means of their matrix forms, represented by tables on tracing paper. The sheets of tracing paper are laid on each other, the function values in the corresponding elements are compared and, in the corresponding element of the result matrix, the resulting value is noted.

The given method is not only applicable to manual computations; by using bit-wise logical operations, one can easily program it for computers.

TABLE 2



Example 2. Table 2 gives the matrix representations of the incompletely defined functions f_1 and f_2 of six variables, as well as the results of certain operations on them.

Note 1. The character of the representation matrices does not depend on the method of coding their elements if this method is the same for all the interacting matrices, so that the coding was not given here.

Note 2. In obtaining the matrix for f_1 it was supposed that the inverse (negation) of an undefined value of a binary variable is also an undefined value.

We begin the consideration of the method of minimizing Boolean functions with a comparatively simple case—obtaining the minimal disjunctive form (m.d.f.), while assuming that, in the general case, the function to be minimized is not defined on all the sets of argument values.

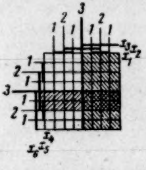
In general, obtaining the m.d.f. makes it easier to find other minimal forms, although it may turn out that, in making the transition from the m.d.f. to another form, this latter will not be absolutely minimal.

An algorithm which solves completely the problem posed was described by Yu. I. Zhuravlev [7], but it entails scanning variants, which leads to a very lengthy computational procedure, that hinders its practical employment.

Using the terminology of [7], we shall denote by an interval of the $\underline{k}$th rank a set of matrix elements corresponding to the conjunction of $\underline{k}$ variables, some of which may enter with a negation sign.

We now define the rules for isolating intervals.

TABLE 3



---

* By a set we mean a conjunction of argument values, for example the set 01000 corresponds to the values $x_1 = 0, x_2 = 1, x_3 = x_4 = x_5 = 0$.

1. Vertical lines in the table which separate elements corresponding to different values of x_1 we shall call axes of symmetry of the first rank; lines separating elements corresponding to different values of x_2 we shall call axes of symmetry of the 2nd rank, etc. We apply an analogous nomenclature to the table's horizontal lines (cf. Table 3).

2. A set of elements which form a band of elements of width 2^r , the central line of which is axis of symmetry of the rth rank, shall be called a zone of symmetry of this axis. (The hatched boxes on Table 3 indicate zones for the first rank horizontal axis and second rank vertical axis.)

3. Each element in the table for a Boolean function of n variables is an nth-rank interval.

A set of two kth-rank intervals is an interval of the (k-1)th rank if the intervals are symmetric with respect to some axis of symmetry and are found completely within its zone of symmetry.

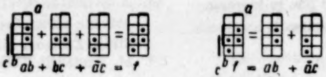
We remark that, since the minimum width of a band of symmetry equals two, it follows that two series of elements forming a rectangle are always intervals; analogously, four series of elements forming a square are always intervals.

The task of obtaining the minimal disjunctive form of a Boolean function reduces to finding such a decomposition of the function representative into intervals for which the sum of the ranks of all the intervals will be minimal. The decomposition is obtained by such a covering by intervals of all the table elements corresponding to unit function values for which interval intersections are admitted, and covering by intervals of elements on which the function is undefined, but not admitting the covering of elements which correspond to zero function values.

Example 3. To find the m.d.f. of the function

$$f(a, b, c) = ab + bc + \bar{a}c.$$

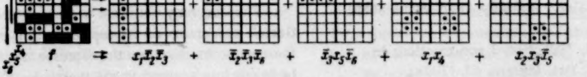
TABLE 4



a

b

TABLE 5



By successively marking with dots the elements of the intervals which correspond to the conjunctions ab, bc, and $\bar{a}c$, we obtain the representation of the function (cf. Table 4, a).

From the visual perception of the representation it becomes obvious that the advantageous decomposition of the representation is into the two intervals corresponding to the conjunctions ab and $\bar{a}c$ (Table 4, b). Thus easily do we obtain the m.d.f. of the original function $f(a, b, c) = ab + \bar{a}c$.

The special convenience of the visual method comes to the fore in the minimization of incompletely defined functions.

Example 4. To find the m.d.f. of the function whose representation is shown in Table 5.

The series of coverings of the representation by intervals is shown in Table 5, given only to elucidate the decomposition principle, since in practice one of the original matrices can be avoided by successively covering the representation by intervals and by blackening the elements which fall in intervals. With a little practice, one can carry out the decomposition of the representation mentally.

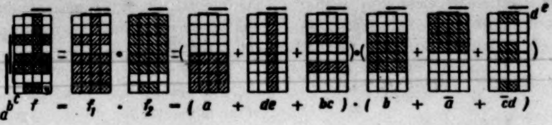
The result of the decomposition gives the m.d.f. of the function to be minimized.

$$f = x_1\bar{x}_2\bar{x}_3 + \bar{x}_2\bar{x}_3\bar{x}_6 + \bar{x}_3x_5\bar{x}_6 + x_1x_4 + x_2x_3\bar{x}_5.$$

As this example shows, the visual estimate of the representation permits one to find the optimal variant of the incompletely defined function more rapidly than may be done with algebraic methods [6].

In certain cases, the algebraic form of the original Boolean function which contains a minimal number of variable symbols may be obtained in the form of a product of two disjunctive forms.

TABLE 6



d
b
c
e
$f = f_1 \cdot f_2 = (a + de + bc) \cdot (b + \bar{a} + \bar{c}d)$

Example 5. (Taken from R. K. Richards' book [8], page 70.) To find the minimal algebraic form of the Boolean function $f = ab + a\bar{c}d + bc + bde + a\bar{d}e + \bar{c}de$. The function's representation is given as the intersection of two other representations, f_1 and f_2, easily decomposed into intervals (Table 6). The final result, $f = (a + bc + de)(b + a + cd)$, contains nine variable symbols.†

The material herein presented allows the following conclusions to be drawn:

1. The matrix representation of Boolean functions in which the matrix rows and columns are coded by the variables' values in a Gray code has the convenience of immediate visual perception of certain properties of the function represented, the correct estimate of which is necessary in the finding of the optimal way to minimize. Visual analysis of the representation allows one to estimate the possibilities of minimization presented by the representation by degrees of regularity of the representation's elements, the criterion for which is the symmetry of the elements' mutual positioning.

2. Being intuitive to a certain extent, the visual matrix method of minimizing Boolean functions was designed for using certain properties, difficult to render in algorithmic form, of visual perception, thus allowing, without recourse to computing technology, the implementation of complicated transformations of the original function for its minimization. With a little practice, the minimization of Boolean functions of five or six variables may easily be done mentally (if the representation of the function is in front of one's eyes), while making notes on the representation elements during the minimization process allows one to increase the number of variables up to ten or twelve.

† This is one symbol fewer than in Richards' result, attesting to the fact that the solution of this problem is indeed a puzzle.

The economy obtained is a consequence of the Gestalt perception of the representation which allows the connection between the representation elements to be taken into account in the search for the optimal variant of its decomposition.

GENERALIZED PROPORTIONALITY CONDITIONS OF ELECTROMAGNETIC SYSTEMS

(GEOMETRY OF ELECTROMAGNETIC SYSTEMS)

A. S. Tulin

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 3, pp. 374-383, March, 1960
Original article submitted November 5 , 1959

Questions of proportionality of electromagnetic devices are propounded. Geometric regularities, related to the conditions of rational use of electromagnetic energy, are used. As a result, there are found many optimal configurations from which, in correspondence with the technical and economic requirements, the actual configuration is chosen in each specific instance.

In devices which use electromagnetic energy, the basic design element is the electromagnetic system, which is a ferromagnetic magnetic circuit with one or several windings.

The electromagnetic system of an electromagnetic device is a function of the device's purpose. Thus, for example, there are electromagnetic systems for transformers, chokes, magnetic amplifiers, relays, and other electromagnetic mechanisms, among which can be included electrical machines.

Despite the variety of the physical forms taken by electromagnetic systems, they have something in common, which speaks for the efficacy of a generalized consideration of the fundamental regularities which are valid for all electromagnetic devices.

For this generalized consideration of electromagnetic systems, we use the fact that any electromagnetic system is some geometric figure whose absolute and relative dimensions are determined by the physical laws concerning the use of electromagnetic energy.

We are justified in calling the set of questions as to the geometry and physics of electromagnetic systems the "geometry of electromagnetic systems ."

Basic Postulates of the Geometry of Electromagnetic Systems

Questions as to the geometry of electromagnetic systems in their generalized form have not yet been treated in the literature, so that it is necessary to first consider certain postulates and, for convenience of exposition, to introduce some terms from electromagnetic system theory.

First of all, it is necessary to introduce the concept of the absolute magnitude of an electromagnetic system.

The necessity for this arises in all cases when it is required to compare different electromagnetic systems among themselves. Such comparisons can be made with sufficient simplicity if the electromagnetic systems to be compared are completely similar. In all other cases, this comparison gives rise to well-known difficulties.

We shall henceforth take, as the absolute magnitude of an electromagnetic system, the sum of the volumes of its active materials, i.e., the sum of the volumes of its windings and magnetic circuit. With this, any change in the dimensions of the electromagnetic system without any concomitant change in the sum of the volumes of its active materials will be considered as a change of its relative dimensions with retention of its absolute magnitude. Conversely, we shall consider that a change in an electromagnetic system's absolute magnitude corresponds to a change wherein all linear dimensions change while the conditions of geometric similarity are retained. Finally, if a change in the dimensions of an electromagnetic system is not accompanied by a retention of the conditions of geometric similarity and, simultaneously, the sum of the volumes does not remain a constant, we shall then consider that, in this case, both the absolute magnitude and the relative dimensions of the electromagnetic system have changed.

As the relative linear dimensions of an electromagnetic system, we take its linear dimensions divided by a fixed one of them.

Corresponding to the concepts of absolute magnitude and relative dimensions of an electromagnetic system are the concepts of the absolute and relative parameters of this system. As the relative (or reduced) parameters we take the absolute parameters divided by the absolute magnitude of the electromagnetic system. With this, if the parameters which interest us are proportional to the first powers of linear dimensions, then their reduction will be implemented by a division by the cube root of the sum of the first powers of the active materials' volumes. For a quadratic dependency, the aforementioned sum will be raised to the second power , etc.

By using the fact that the parameters of electromagnetic devices can be reduced to an arbitrary number of turns of their windings, we shall consider their windings to be reduced to the one-turn form. In this case, instead of the cross section and length of a circuit's winding, we shall consider its mean length and total cross section, with account taken of the corresponding space factor.

Naturally, all parameters of electromagnetic systems are the corresponding functions of the geometric dimensions of these systems and of the properties of the active materials. For convenience of exposition, we shall henceforth, instead of such expressions as "a geometric function of the magnetic circuit's magnetic conductance," use "the magnetic circuit's geometric conductance," "the geometric impedance of the winding," and also "geometric coefficient. . ." or "geometric constant. . .," etc.

The nonlinearity of ferromagnetic materials ordinarily introduces significant complication into the theory of elemectromagnetic devices, but it is not mandatory to take these nonlinearities into account in the theory of the geometry of electromagnetic systems. The explanation of this is that the geometry of electromagnetic systems is concerned with the regularities imposed on the relative (or reduced) parameters, in the aforementioned sense, of electromagnetic systems, and these reduced parameters do not depend on the properties of any material. As will become clear in the sequel, the materials' properties, while having no infleunce on the choice of relative dimensions of electromagnetic systems, influence completely its absolute dimensions.

We should make particular mention of the questions in our generalized consideration of electromagnetic systems which deal with the classification of systems into those with closed or with open magnetic circuits. Thus, for example, a transformer has a closed, and an electromagnetic relay an open, magnetic circuit.

The author initially will consider all electromagnetic systems in the closed magnetic circuit mode (the mode of a short-circuited magnetic circuit). The transition from closed to open magnetic circuits does not render it necessary to change the optimal geometric relationships obtained when considering closed magnetic circuit modes. The proof of this assumption in particular cases of electromagnetic system employment engenders no particular difficulty, and is in good agreement with experience.

The consideration of proportionality of electromagnetic systems with closed magnetic circuits eliminates the necessity of taking magnetic flux leakage into account, which also simplifies the problem.

The reduction of windings to one turn and the ignoring of flux leakage lead to an equivalence between current and ampere-turns, and also between magnetic flux and flux linkages.

Energetic Bases of Electromagnetic Systems

The use of electromagnetic energy in any electromagnetic device is related to the property of the electromagnetic system of accumulating energy obtained from a source of electric current. This energy is then partially or completely utilized, and is partially converted to a source of supply or is lost in the form of various energy dissipations.

As the characteristic of this property of electromagnetic systems, we can use the quantity of accumulated energy divided by the power used in maintaining the static state of the energy stored in the system. To find this parameter we shall use regularities which exist for dc circuits, but it should be kept in mind with this that the parameter in which we are interested does not depend on the nature of the current.

As is well-known, when the windings of an electromagnetic system are connected to a dc source, a transient response ensues for which the following equation is valid:

$$ui\,dt = i^2 r\,dt + i\,d\psi. \tag{1}$$

Equation (1) shows that all the energy from the source consists of two parts, one of which is consumed in thermal losses in the windings, while the other serves to change the system's magnetic state. At the termination of the transient response, the current and the magnetic flux assume constant values. The energy which continues to be supplied from the source is now consumed solely by the thermal losses in the windings. These losses determine the power which goes to maintain the static state of electromagnetic energy accumulated in the electromagnetic system during the transient response. This power, defined in terms of the steady-state value of current I and the electric conductance g_M of the windings, equals

$$P = \frac{I^2}{g_M}. \tag{2}$$

The quantity of electromagnetic energy stored in the electromagnetic system during the transient response is defined by the expression

$$W_L = \int_0^I i\,d\psi. \tag{3}$$

To find the differential magnetic flux which appears in Expression (3), we use the well-known dependency which exists between the magnetizing force of magnetic flux and magnetic conductance. With this, and also using (2), we obtain

$$W_L = \frac{1}{2} P g_M g_c, \tag{4}$$

from whence

$$\frac{W_L}{P} = \frac{1}{2} g_M g_c = kG_M G_c, \tag{5}$$

where G_M and G_c are the geometric conductances of, respectively, the windings and the closed magnetic circuit, and k is a proportionality factor which takes into account the adopted units of measurement, the space factors of the winding cross section and the magnetic circuit, the specific conductance and permeability of the materials of the windings and the magnetic circuit, and other quantities relating the windings' electric conductance and the magnetic circuit's magnetic conductance with the geometric dimensions of the electromagnetic system.

By dropping the factor k from (5), we obtain a function of the electromagnetic system's geometric dimensions which characterizes this system's property of accumulating electromagnetic energy. With this, we obtain

$$\gamma = G_{\text{м}} G_{\text{c}} = \frac{S_{\text{м}} S_{\text{c}}}{L_{\text{м}} L_{\text{c}}}. \tag{6}$$

Here, S_M and S_c are the cross sections of the winding and of the magnetic circuit, and L_M and L_c are their mean lengths.

As is clear from (6), to improve the properties of electromagnetic systems, it is necessary, in choosing their geometric dimensions, to attempt to increase the product of the cross sections of the winding and magnetic circuit, and to decrease the product of their lengths. This is the basic law of the theory of electromagnetic systems. However, (6) cannot be used for comparing different electromagnetic systems among themselves, since the quantity defined by this formula depends not only on the relative, but also on the absolute, dimensions of the electromagnetic systems. To eliminate the dependence on absolute quantities, we use the relative value of the parameter of interest to us. We obtain with this

$$\xi = \frac{1}{\sqrt[3]{Q^3}} \frac{S_{\text{м}} S_{\text{c}}}{L_{\text{м}} L_{\text{c}}}, \tag{7}$$

where Q is the sum of the volumes of the active materials, i.e., the absolute magnitude of the electromagnetic system.

In the theory of the geometry of electromagnetic systems, (7) is one of the fundamentals. In the sequel, this formula will be used for the analysis of the proportionalities of the geometric forms of electromagnetic systems. The parameter defined by (7) is called the "geometric constant" of the electromagnetic system.

The introduction of the concept of the geometric constant into the analysis of proportionality of electromagnetic systems allows geometric function (6) of any electromagnetic device to be presented in the form of two factors, one of which is determined by relative, the other by absolute, dimensions of the electromagnetic

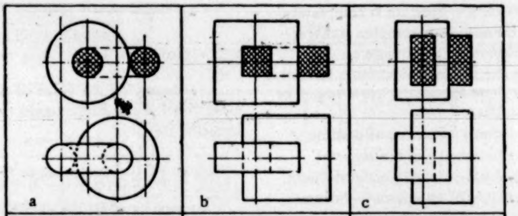

Fig. 1. Certain possible geometric forms of electromagnetic systems.

system, i.e., in the case of the geometric function given by (6), we shall have

$$\gamma = \xi \sqrt[3]{Q^2}. \tag{8}$$

As is obvious, for a given magnitude of the electromagnetic system's geometric function γ, to decrease the expenditure of active materials, i.e., to decrease the quantity Q, it is necessary to try to maximize the geometric constant ξ.

However, it should be taken into account with this that the prices of the materials of the windings and of the magnetic circuit are different, so that it is necessary to attempt to realize, not an absolute decrease in the sum of the volumes of the windings and the magnetic circuit, but a reduction of the total cost of the electromagnetic system's active materials.

Linkages of Geometric Dimensions of Electromagnetic Systems

Electromagnetic systems, in their geometric aspect, are complicated figures which consist of linkages of simpler figures of windings and magnetic circuits.

Linkage between windings and magnetic circuits may be simple or complex. In a simple linkage, the entire aperture of the magnetic circuit is filled by the winding's cross section, and the winding's aperture is completely filled by the magnetic circuit. In a complex linkage, between winding and magnetic circuit there remain certain spaces, filled by the surfaces of winding insulation or by other windings, or these spaces, for some reason or another, may remain unfilled.

As examples, Fig. 1 shows a number of possible geometric forms of simply-linked electromagnetic systems. Certainly, any simply-linked geometric form, with any permissible unfilling of an aperture, becomes a figure with a complex linkage.

For this purpose, as an example, we consider the geometric form of an electromagnetic system as shown in Fig. 2.

As is clear, the given form has four dimensions, the absolute values of which are denoted by a, b, d, and e.

To obtain relative dimensions, we relate all the remaining dimensions to one selected absolute dimension. For example, as such a fundamental dimension, we take the width a of the magnetic circuit's aperture. In this case, the relative dimensions of height, width of core section, and magnetic circuit thickness will equal, respectively,

$$\frac{b}{a} = c, \qquad \frac{d}{a} = m, \qquad \frac{e}{a} = k.$$

With the notation chosen the cross sections and lengths of the windings and magnetic circuit will equal

$$S_{\text{M}} = a^2 c, \quad S_{\text{c}} = a^2 mk, \tag{9}$$

$$L_{\text{M}} = 2a(m + k + 2), \quad L_{\text{c}} = 2a(m + c + 1). \tag{10}$$

Knowing the cross sections and the lengths, we determine the volumes of the windings and magnetic circuits and then, by adding these volumes, we find the quantity which we have called the absolute magnitude of the electromagnetic system. For this, we get

$$Q = 2a^3 [c(m + k + 2) + mk(m + c + 1)]. \tag{11}$$

To determine the value of the parameter which we have taken as the fundamental one, we solve the last equation for a:

$$a = \sqrt[3]{\frac{Q}{2[c(m + k + 2) + mk(m + c + 1)]}}. \tag{12}$$

We now have all the data necessary for determining, by (7), the geometric constant of the electromagnetic system under consideration. This constant equals

$$\xi = \frac{mck}{(m + k + 2)(m + c + 1)\sqrt[3]{16^2 [c(m + k + 2) + mk(m + c + 1)]^2}}. \tag{13}$$

In our task here, we do not enter into an analysis of all the possible geometric forms of electromagnetic systems. We limit ourselves just to a consideration of a method of analysis which is applicable, with the proper specifications being made, to the analysis of any form and of any type of linkage.

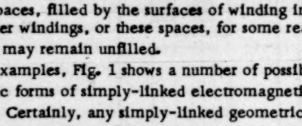

Fig. 2. Geometric form of a three-core electromagnetic system.

The problem of finding the optimal proportions of electromagnetic systems does not have a unique solution. In each particular case it is necessary to take into account the concrete conditions of use of electromagnetic energy and the economic requirements. This bears first of all on the ratio of the volumes of the electromagnetic system's active materials. By bearing this fact in mind, we should seek, not the general case of the maximum of the geometric constant of (13), but its particular cases, each of which corresponds to some previously given ratio of the aforementioned volumes. With the notation we have adopted, the ratio of the volume of the magnetic circuit to that of the windings equals

$$\frac{Q_{\text{c}}}{Q_{\text{M}}} = \frac{mk(m + c + 1)}{c(m + k + 2)}. \tag{14}$$

By solving this last equation for one of the relative dimensions, and then substituting the value obtained in (13), we would have the capability, by computing the partial derivatives with respect to the relative dimensions, to determine the optimal values of these dimensions, which would correspond to the maximum geometric constant for the previously given constant ratio of the volumes of the active materials. However, this path to a solution leads to significant complexity, so that we shall solve this problem by finding the maximum of the

TABLE 1

m	0.0	0.25	0.5	1.0	1.5	2.0	3.0	10.0	15.0
k	3.0	3.0	2.84	3.0	3.16	3.45	3.9	6.95	10.0

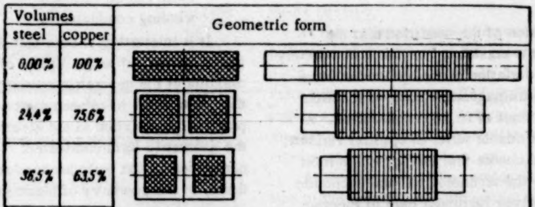

Fig. 3. Series of optimal geometric forms of three-core electromagnetic systems for various ratios of winding and magnetic circuit volumes.

geometric constant of interest to us for a constant value of one of the relative dimensions, which is equivalent to the condition that the ratio of the volumes be constant, although the magnitude of this ratio itself is not given explicitly in this case. As the constant quantity, we take the relative dimension m, since the ratio of the winding and magnetic circuit volumes depends most heavily on this dimension.

By analyzing (13) for an extremum by the method of partial derivatives, we obtain the following optimal values of the relative dimensions k and c for a constant value of dimension m:

$$k=\frac{m+2}{4}\left[1+\sqrt{1+\frac{24c}{m(m+c+1)+c}}\right], \quad (15)$$

$$c=\frac{m+1}{4}\left[1+\sqrt{1+\frac{24mk}{m+k+2+mk}}\right]. \quad (16)$$

Joint solution of (15) and (16) leads to cumbersome computation, so that we solve this problem by the method of successive approximations. The results are given in Table 1, where we also give the volume of the magnetic circuit as a percentage of the total volume of active material plus the corresponding maximum of the geometric constant for the electromagnetic system of the form under consideration.

Thus, the imposition of the condition that the geometric constant be a maximum leads to a completely definite regularity of variation of the optimal relative dimensions of the electromagnetic system as functions of the ratio of the volumes of its active materials. As a result, we obtain a continuous series of optimal variants, from which one should choose that variant which most completely answers to the technological and economic requirements of each given particular case of electromagnetic system usage.

As an illustration of the regularities obtained, Fig. 3 shows a series of forms of the type of electromagnetic system considered. All the sketches on the figure are drawn to scale and are in accordance with the condition that the geometric constant be a maximum. The order in which the sketches are placed on the figure takes into account the ratio of the volumes of active materials for a constant value of their sum. The limits of the series show the sketches with limiting ratios of their dimensions. On the top are shown the sketches corresponding to zero magnetic circuit volume and, on the bottom, those corresponding to zero winding volume.

Knowing the optimal ratios of the dimensions, there is no difficulty in determining all the parameters of electromagnetic systems for any ratio of the volumes of the active materials. Thus, for example, the curves of Fig. 4 show, as functions of the ratio of the volumes of active materials, the relative geometric conductances of the windings and magnetic circuit as well as their product, i.e., the geometric constant of the electromagnetic system under consideration.

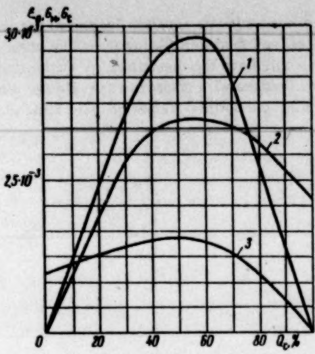

Fig. 4. Geometric conductance of windings and magnetic circuit plus the geometric constant of a three-core electromagnetic system as functions of the ratio of winding and magnetic circuit volumes. 1 is the geometric constant, 2 is the magnetic circuit conductance, and 3 is the winding conductance.

It is interesting to note that the geometric ratios which correspond to the regions of the maximum of the maxima of the geometric constant (Figs. 3 and 4) are the ratios which have been most widely used in the practical application of the electromagnetic systems of the geometric form considered. This substantiates the correctness of the basic assumptions we have made for the theory of the geometry of electromagnetic systems.

TABLE 2

Sketch on figure	Form coefficient $\times 10^3$	Sketch on figure	Form coefficient $\times 10^3$
1. a	3.40	1. e	6.70
1. b	2.46	1. f	5.00
1. c	3.62	1. g	8.00
1. d	4.85	1. h	6.40

The method presented here for the analysis of optimal geometric proportions is applicable to any geometric form of electromagnetic systems. Thus, for example, the author carried out the corresponding analysis of all the sketches given in Fig. 1. Omitting similarities, we give only the value of the maximum of the maxima of the geometric constant for each of these sketches. The results appear in Table 2. The maximum of the maxima of the geometric constant may serve as the characteristic of the form of an electromagnetic system, for which reason we call this parameter the "form coefficient" of an electromagnetic system.

Economics of Electromagnetic Systems

In choosing some variant from the series of optimal design variants of an electromagnetic system (cf., for example, Fig. 3) for some particular case, one must take into account, not only technological, but also economic requirements.

Thus, economic considerations, while having no effect on the general regularities of the geometry of electromagnetic systems, have an effect, in each particular case, on the system's geometric proportions. It should be kept in mind with this, that the basis of the economic influence is the difference in prices of the winding and of the magnetic circuit materials of the electromagnetic system. With identical prices per unit volume of these materials, the economic requirements would cease to be operative.

The cost of an electromagnetic system, defined by the costs of its active materials, equals

$$A = Q_M t_M + Q_c t_c, \tag{17}$$

where Q_M and Q_c are the winding and magnetic circuit volumes, and t_M and t_c are the unit volume costs of, respectively, the windings and the magnetic circuit.

The ratio of unit volume cost of winding to that of magnetic circuit equals

$$t_0 = \frac{t_M}{t_c}. \tag{18}$$

By introducing the coefficient

$$n = \frac{Q_M}{Q_M + Q_c} = \frac{Q_M}{Q}, \tag{19}$$

and by taking (18) into account, we transform Expression (17) to the form

$$A = Qt_c[n(t_0 - 1) + 1]. \tag{20}$$

By dividing (20) by Qt_c, we obtain the relative cost of the electromagnetic system, i.e.,

$$A_0 = \frac{A}{Qt_c} = n(t_0 - 1) + 1. \tag{21}$$

As is clear, the relative cost when the prices of the active materials are equal (i.e., for $t_0 = 1$) is unity, and does not depend on the ratio of the volumes of these materials. In this case, the optimum variant of the electromagnetic system to use is that one which corresponds to the maximum geometric constant. When these prices are not equal, a change in the ratio of the volumes of active materials changes both the geometric constant of the electromagnetic system and its cost. In this case, to choose the optimum variant of electromagnetic system to be used, one should aim at the minimum ratio of the relative cost to the geometric constant, i.e.,

$$A_\xi = \frac{A_0}{\xi} = \frac{n(t_0 - 1) + 1}{\xi}. \tag{22}$$

Thus, for example, from the data of Table 1, if no account is taken of differences in active material costs, i.e., for $t_0 = 1$, the optimal variant of the electromagnetic system to use is the one for which the winding volume is 42 % of the total volume of active materials. If the price of the winding material is, for example, 20 times as high as the magnetic circuit material, then from the data of Table 1 and from (22), we find that the optimal variant for this case is the one where the winding volume is 24% of the total volume of active material in the electromagnetic system.

What has already been said sufficiently adumbrates the principal interrelationships which exist between geometric proportions and the economics of electromagnetic systems.

Conclusion

In this paper we touched on only the most general postulates of the theory of the geometry of electromagnetic systems. In the future, by basing ourselves on these regularities, we can find optimal relationships for standard electromagnetic devices: transformers, electromagnetic relays, magnetic amplifiers, induction relays, chokes, electrical machines, etc.

As the final goal, the consideration of any configuration of the electromagnetic system of any electromagnetic device should allow one to obtain a continuous series of optimal variants of the configuration considered, the sequence of these variants being determined by the ratio of the volumes of windings and magnetic circuit. The study of such a series provides the capability of establishing the interdependencies of the relative dimensions and the technical-economic parameters which are of decisive value in choosing the physical design of the electromagnetic device from this series in each specific case.

RELAY WINDING OVERHEATING AND HEAT TRANSMISSION COEFFICIENT AS FUNCTIONS OF AMBIENT AIR TEMPERATURE

M. I. Vitenberg

(Leningrad)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 3, pp. 384-392, March, 1960
Original article submitted November 30, 1959

The paper deals with relay winding overheating and heat transmission coefficient as functions of ambient air temperature. Empirical formulas are derived for determining the magnitude of relay winding overheating and relay heat transmission coefficient.

1. Winding Overheating

The excess of relay winding temperature over the ambient medium's temperature is ordinarily determined under normal conditions for an air temperature of +20°C. However, relays are frequently used under conditions where there are large oscillations of the ambient temperature – from -60 to +60°C – and special types of relays are used at temperatures up to +125°C and higher.

As is well known, with a raising of the winding temperature the heat transmission coefficient (specific heat transmission) increases, since heat transmission by convection depends on a fractional power of the overheating temperature, while heat transmission by radiation is proportional to the difference of the fourth powers of the absolute temperatures of the winding and of the ambient air. Therefore, with identical magnitudes of power dissipation, overheating of a relay winding is decreased as the ambient air temperature increases.

The working life of relay insulation is determined by the greatest magnitude of the working temperature. Consequently, it is necessary to know, as accurately as possible, the relay winding overheating for the highest ambient air temperature. Measurement of relay winding overheating with increased temperature is ordinarily carried out experimentally in a thermostat, for which a great deal of time is required. Moreover, these measurements are usually distinguished by their low accuracy, due to the significant relative errors in

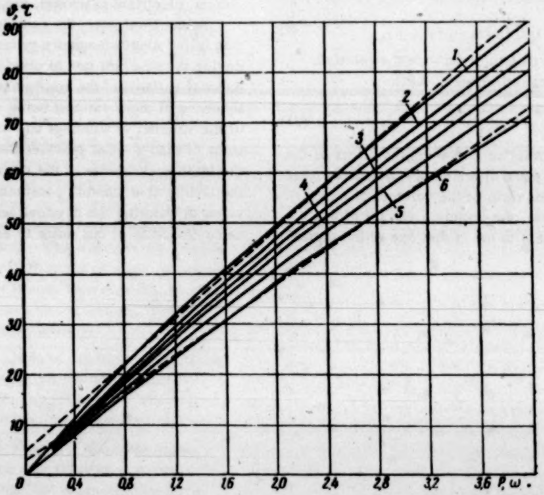

Fig. 1. 1 — θ_0 = 21° C, 2 — θ_0 = 44°C, 3 — θ_0 = 65° C, 4 — θ_0 = 84° C. 5 — θ_0 = 105° C, 6 — θ_0 = 141° C.

determining the winding overheating temperature for an increased temperature of the ambient air.

Thus , for example, with ambient temperature of 100°C and winding overheating temperature of 30°C, an error of 2% (2°C) , in measuring the temperatures of winding and air gives a relative error of about 13% in determining the temperature of the relay winding overheating.

Relay winding overheating temperature can be found more accurately by analytical means.

Figure 1 gives curves showing excess of relay winding temperature over ambient temperature as a function of the power applied for small-size-type RMU relay, taken off experimentally for various ambient temperatures up to +141°C .

The measurements were carried out in a 500-watt dessicator with automatic temperature regulation within the limits of +30 to +200°C with an error no greater than ± 3 % . The working chamber of the dessicator had a diameter of 300 mm and a length of 290 mm.

The dimensions of the relay types tested were: for type RMU, 24.7 x 38.5 x 41 mm, for type RÉS10, 11.1 x x 16.5 x 26 mm and, for type RKN, 25.6 x 56.5 x 97 mm.

The relay weights were: for type RÉS10, 6 g, for type RMU, 70 g and, for type RKN, 290 g.

The relay specimens had wire windings with brand PÉTKM heat-resistant insulation. The winding temperatures were measured by a copper-constantan thermocouple. To eliminate heat leakage at the relay supports, the relays were suspended by a fine wire in the center of the dessicator.

The ventilation apertures of the dessicator were tightly covered by asbestos plugs, and were used for the outlet of the conductors and the thermocouple.

The air temperature in the dessicator was also measured by a thermocouple, which was placed at the level of the specimen relay at a distance of about 30 mm from it. As protection against direct radiation, the thermocouple's junction on the relay's side was shielded by a small fragment of white paper. For each value of supplied power, the relay was immersed for not less than an hour in the given ambient temperature. The actual temperature oscillations in the dessicator did not exceed 2 %. It is clear from Fig. 1 that, in the limits of overheating temperature from 20 to 70°C, the curves differ very little from the straight lines drawn with dashes (the error does not exceed ± 1°C). In Fig. 1, the dashed straight lines are shown only for the extreme curves, so as not to complicate the figure.

In the aforementioned limits, the relay winding overheating curves can be approximated by the formula

$$\vartheta = a + bP, \tag{1}$$

where a is the amount of overheating intercepted by the straight line on the axis of ordinates, and b is the tangent of the slope of this line.

TABLE 1

Ambient temperature θ_0 °C	a, °C	b, °C/ω
21	4.7	21.7
44	4.3	20.9
65	3.8	20.4
84	3.6	19.3
105	3.2	18.6
141	2.8	17.2

The values of the quantities a and b for relay type RMU for different values of ambient air temperature, determined graphically from Fig. 1, are given in Table 1.

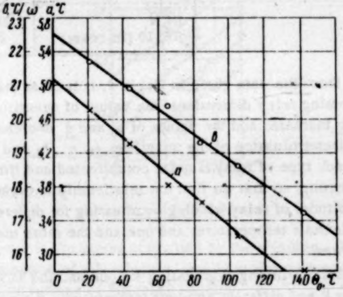

Fig. 2.

From the data of this table, the dependencies of a and b on the ambient temperature were constructed, as shown in Fig. 2. These dependencies are straight lines, which can be expressed by the formulas

$$a = a_0 - c\theta_0, \tag{2}$$

$$b = b_0 - d\theta_0, \tag{3}$$

where a_0 and b_0 are the values of a and b for an ambient temperature of 0°C , and c and d are the tangents of the slopes of these lines.

By substituting in (1) the values of a and b from (2) and (3), we obtain a general expression for determining the relay winding overheating temperature as a function of the supplied power and the ambient temperature :

$$\vartheta = a_0 - c\theta_0 + (b_0 - d\theta_0) P. \tag{4}$$

This formula gives sufficient accuracy only in the limits of overheating values from 20 to 70°C, which are the ones most frequently occurring .

The largest errors are obtained at the initial portion of the curve, for overheating temperatures less than 20°C. The accurate determination of such overheating temperatures ordinarily has no practical value.

From Fig. 2 we find the values of quantities a_0, c , b_0, and d for relay type RMU : a_0 = 50.7°C, c= 0.0175 , b_0 = 22.54°C/watt and d = 0.038.

Consequently, for type RMU relay, winding overheating is expressed by the following formula:

$$\vartheta = 5{,}07 - 0{,}0175\,\theta_0 + (22{,}54 - 0{,}038\,\theta_0)\,P. \tag{4a}$$

By an analogous procedure, we found the values of the quantities a_0, c, b_0, and d for miniaturized type RÉS10 relay (without cover) and normal type RKN relay.

The values of these quantities are given in Table 2.

TABLE 2

Relay type	S_k, cm²	a_0, °C	c	b_0, °C/cm	d
RÉS10 (without cover)	3.2	6,3	0.0171	71.6	0.126
RMU	22.6	5,07	0.0175	22.54	0.038
RKN	60.2	8,36	0.0238	8.85	0.0167
RÉS10 (in cover)	3.2	3,52	—0.006	91.5	0.103

From the data given in Table 2, it is clear that, with increasing relay dimensions, the values of quantities b_0 and c increase, and the values of b_0 and d decrease.

Determination of the quantities a_0, c, b_0, and d for each type of relay is quite complicated and time-consuming, so that we find the relationship between the magnitudes of relay winding overheating for different ambient air temperatures and one and the same magnitude of power.

Relay winding overheating for one and the same power P and different ambient temperatures θ_{01} and θ_{02} will equal

$$\vartheta_1 = a_0 - c\theta_{01} + (b_0 - d\theta_{01})\,P \text{ and}$$

$$\vartheta_2 = a_0 - c\theta_{02} + (b_0 - d\theta_{02})\,P,$$

from which we find the following expression for relay winding overheating for ambient temperature θ_{02}:

$$\vartheta_2 = \vartheta_1 - (c + Pd)(\theta_{02} - \theta_{01}) = \vartheta_1\,[1 - \beta\,(\theta_{02} - \theta_{01})], \tag{5}$$

where

$$\beta = \frac{c + Pd}{\vartheta_1}.$$

Table 3 gives the values of the temperature overheating coefficient β for various values of power in the winding, and the corresponding relay winding overheating temperatures of relay types RMU, RÉS10 and RKN for these values of power and for ambient temperature +20°C, computed by means of (4) and (6).

Figure 3 shows the curves, constructed from the data of Table 3, of the temperature overheating coefficient β as a function of the winding overheating temperature of these types of relays for $\theta_0 = +20°$C. For comparative purposes, the dashed line of Fig. 3 shows the approximate curve for type RÉS10 relay (with cover). It follows from Fig. 3 that the curves for the coefficient β for relay types RMU and RÉS10 (without cover) virtually coincide, and the value of coefficient β for type RKN relay is about 10 % larger.

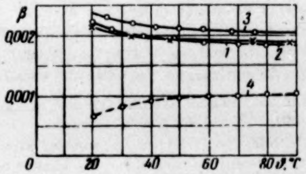

Fig. 3. 1) Relay type RMU; 2) relay type RÉS10 without cover; 3) relay type RKN, 4) relay type RÉS10 in cover.

Type RÉS10 relay, protected by a thin aluminum cover, has a coefficient β of about half the size, due to the poor thermal contact between the relay's magnetic

TABLE 3

Relay type								
RMU			RÉS10 (without cover)			RKN		
P, ω	β	ϑ, °C	P, ω	β	ϑ, °C	P, ω	β	ϑ, °C
0.7	0.00219	19.86	0.2	0.00214	19.77	2	0.00229	24.92
1.0	0.00209	26.5	0.4	0.002005	33.58	3	0.00221	33.43
1.5	0.00199	37.4	0.6	0.001955	47.4	4	0.00216	41.95
2.0	0.00194	48.29	0.8	0.00193	61.22	5	0.00213	50.46
2.5	0.00190	59.22	1.0	0.001905	75.03	6	0.0021	59.0
3.0	0.00188	70.1	1.2	0.001895	88.86	7	0.00208	67.5
						8	0.00207	76.01

circuit and the cover (the relay's pedestal is made of plastic). With air-tight relays having thick steel covers and fastened to a metallic base (pedestal), the magnitude of coefficient β is about the same as for relays unprotected by covers, since the winding of an air-tight relay generally has good thermal contact with the magnetic circuit and with the cover. As the relay winding overheating temperature varies within the limits of 20 to 70°C [the limits of applicability of (4)], the size of coefficient β varies comparatively little (by not more than ± 10 %).

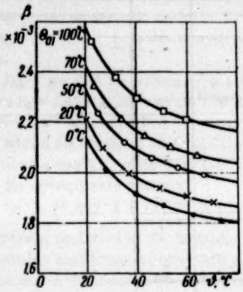

Fig. 4.

The magnitude of coefficient β depends on the initial temperature of the ambient air. Figure 4 gives the curves for the coefficient β as a function of winding overheating for various ambient air temperatures for type RMU relay. By means of these curves, the curves shown on Fig. 5 of coefficient β as a function of ambient air temperature for various heating temperatures were constructed. The curves of Fig. 5, for β within the limits of 0 to 100°C, are practically straight lines, so that coefficient β as a function of initial ambient air temperature with average overheating temperature ($\vartheta = 40°C$) can, for small-size relays (without covers), be expressed by the formula

$$\beta = (1.91 + 0.0036\theta_{01})\,10^{-3}. \qquad (6)$$

Consequently, with a constant magnitude of power, if one knows the winding overheating temperature of small-size relays (without covers) for the ambient temperature θ_{01}, one can, with an accuracy sufficient for practical purposes, determine the overheating of these relays' windings for another ambient temperature θ_{02} by means of the formula

$$\vartheta_2 \approx \vartheta_1\,[1 - (1.91 + 0.0036\,\theta_{01})\,10^{-3}\,(\theta_{02} - \theta_{01})]. \qquad (7)$$

If the initial ambient temperature is θ_{01} = 20°C, then

$$\vartheta_2 \approx \vartheta_1\,[1 - 0.00198\,(\theta_{02} - 20)]. \qquad (7a)$$

Thus, with an increase of ambient air temperature by 10°C (within the limits of 0 to 100°C), the winding overheating of the relay (without cover), for one and the same value of power, is decreased by about 2%.

Measurements carried out on different types of relays showed that this formula is also valid for higher temperatures of the ambient air (up to 140°C).

2. Heat Transmission Coefficient

The magnitude of the average (nominal) heat transmission coefficient of windings of electromagnetic relays and dc apparatus can be determined from the experimental data by means of the formula [1]

$$q_1 = \frac{P}{\vartheta S_k}, \qquad (8)$$

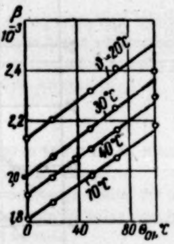

Fig. 5.

where P is the power consumed by the winding, ϑ is the overheating of this winding, and S_k is the computed cooling surface of the relay winding.

Figure 6 gives the experimental curves which show the mean heat transmission coefficient of the winding of a type RMU relay as a function of its overheating for various ambient temperatures. Within the limits of an overheating temperature of 20 to 70°C, these curves differ very little from straight lines. The large scattering of points for overheating values less than 20°C is explained by the inaccuracy of measurements of small temperature drops.

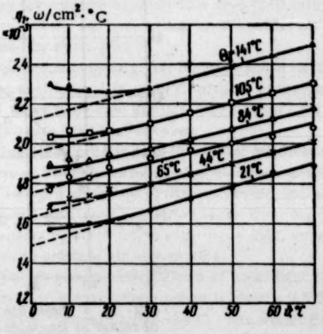

Fig. 6.

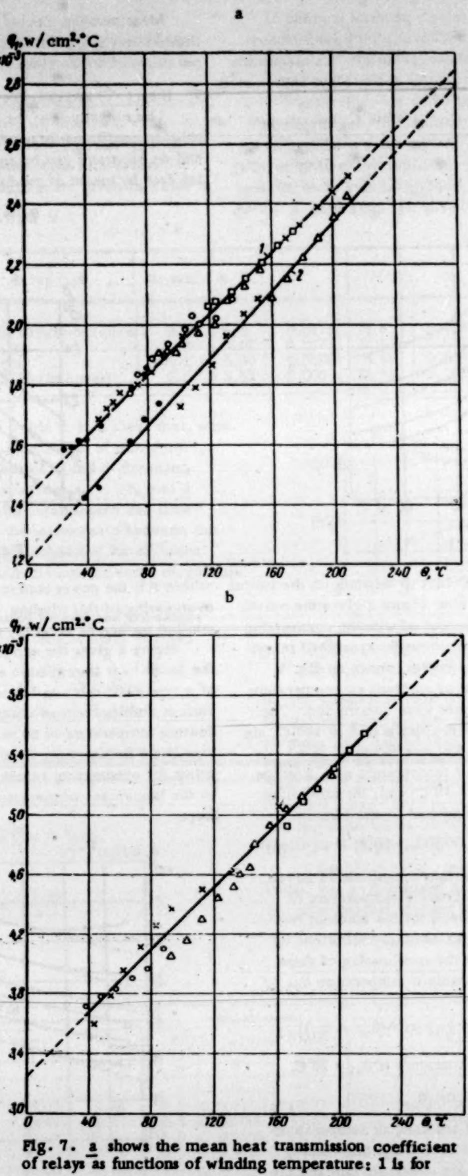

Fig. 7. a shows the mean heat transmission coefficient of relays as functions of winding temperature; 1 is for relay type RMU and 2 is for relay type RKN; b shows the same thing for relay type RÉS10 (without cover).

To elucidate the relationship between relay winding heat transmission and temperature, Fig. 7 shows the constructed relationship of the average heat transmission coefficient of relay windings and the temperature of these windings. Within the limits of 30 to 210°C, this relationship is virtually a linear one which may be expressed by the formula

$$q_1 = q_0 + e\theta = q_0 + e(\theta_0 + \vartheta), \qquad (9)$$

where q_0 is the magnitude of the heat transmission coefficient, intercepted on the axis ordinates by the extension of the straight line, and $\underline{e}$ is the tangent of the slope of this line.

From Fig. 7 we find the values of q_0 and $\underline{e}$ for type RMU relay : $q_0 = 1.422 \times 10^{-3}$ w/cm²/°C and $e = 0.00507 \times 10^{-3}$ w/cm²/°C².

Thus, within the limits of 30 to 210°C, the mean heat transmission coefficient for type RMU relay is expressed by the approximate formula

$$q_1 = (1.422 + 0.00507\,\theta)\,10^{-3}. \qquad (9a)$$

The greatest deviation of the individual values of heat transmission coefficient of type RMU relay from the straight line does not exceed 2.2%. The values of q_0 and $\underline{e}$ for relay types RMU, RÉS10, and RKN are given in Table 4.

TABLE 4

Relay type	q_0, w/cm²·°C	e, w/cm²·°C
RÉS10 (without cover)	$3.24 \cdot 10^{-3}$	$0.01965 \cdot 10^{-3}$
RMU	$1.422 \cdot 10^{-3}$	$0.00507 \cdot 10^{-3}$
RKN	$1.198 \cdot 10^{-3}$	$0.00567 \cdot 10^{-3}$
RÉS10 (in cover)	$2.77 \cdot 10^{-3}$	$0.0045 \cdot 10^{-3}$

The magnitude of the mean heat tramission coefficient for different temperatures θ_1 and θ_2 of the relay winding will be $q_1' = q_0 + e\theta_1$ and $q_1'' = q_0 + e\theta_2$, from which we find the following expression for the mean heat transmission coefficient of the relay winding for temperature θ_2:

$$q_1'' = q_1' + e(\theta_2 - \theta_1) = q_1'[1 + \gamma(\theta_2 - \theta_1)], \qquad (10)$$

where

$$\gamma = \frac{e}{q_1'}. \qquad (11)$$

Figure 8 shows the curves of the transmission coefficient of the mean heat transmission coefficient γ as a function of winding temperature for relay types RMU, RÉS10 , and RKN, computed by means of Formulas (9a) and (11).

It follows from Fig. 8 that the curves of $\gamma = \gamma(\theta)$ for small-size relay types RMU and RÉS10 (without cover) differ very little from each other, and that the value of coefficient γ for type RKN relay is about 25% larger. Type RÉS10 relay, protected by an aluminum cover, has a value of coefficient γ which is about half the size.

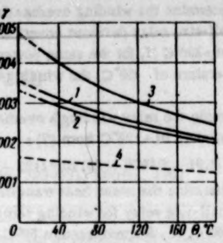

Fig. 8. 1) Relay type RMU; 2) relay type RÉS10 without cover; 3) relay type RKN; 4) relay type RÉS10 in cover.

In the limits of 20 to 160°C for θ, these curves differ very little from straight lines.

In the aforementioned limits, the coefficient as a function of temperature for relay type RMU may be expressed by the formula[1]

$$\gamma = (3.45 - 0.0079\,\theta_1)\,10^{-3}. \qquad (12)$$

Thus, if we know the magnitude of the heat transmission coefficient of small-size type RMU relays (without cover) for winding temperature θ_1, we can, with an accuracy sufficient for practical purposes, determine the heat transmission coefficients of these relays for other winding temperatures θ_2 (in the limits of 20 to 160°C) from the following approximate formula :

$$q_2 \approx q_1\,[1 + (3.45 - 0.0079\,\theta_1)\,10^{-3}\,(\theta_2 - \theta_1)]. \qquad (13)$$

If the initial winding temperature is $\theta_1 = 50$°C, then

$$q_2 \approx q_1\,[1 + 0.00306\,(\theta_2 - 50)]. \qquad (13a)$$

Formula (13a) shows that with a 10°C increase in winding temperature of small-size type RMU relays (without cover), the heat transmission coefficient is increased by about 3%.

We find analogously that the increase in heat transmission coefficient with a 10°C increase in temperature is 2.87 % for relay type RÉS10 (without cover) and 1.5% for relay type RÉS10 in its cover.

Thus, our work has established that overheating temperature of windings of small-size electromagnetic relays (weights up to 300 g) without covers, and also airtight relays with good heat elimination from the windings, is decreased by about 0.2 % with $\theta_{01} = 20$°C for a 1°C increase in ambient air temperature.

The temperature coefficients of mean heat transmission coefficient of these relays is about + 0.3 %/°C for winding temperatures of +50°C. The winding overheating temperature of relays protected by thin covers having poor thermal contact with the windings, is decreased by about a 1%/°C rise in ambient temperature.

Examples

1. We determine the winding overheating temperature of a small-size relay (without cover) for ambient temperature of +125°C if, for the same power and for ambient temperature of +25°C, the winding overheating was 50°C.

We determine the relay winding's overheating with ambient temperature of +125°C from (7):

$$\vartheta_{125} \approx 50\,[1-(1.91+0.0036\times 25)\,10^{-3}\,(125-25)] = 40°\mathrm{C}.$$

2. We determine the mean heat transmission coefficient of a small-size relay for winding temperatures of 40 and of 100°C, if, for temperature 50°C, the heat transmission coefficient equals 1.5×10^{-3} w/cm²/°C.

We determine the relay's heat transmission coefficient by (13):

$$q_{40} \approx 1.5\times 10^{-3}\,[1+(3.45-0.0079\times 40)\,10^{-3}\,(40-50)] = 1.45\times 10^{-3}\ \mathrm{w/cm^2\cdot °C}$$

and

$$q_{100} \approx 1.5\times 10^{-3}\,[1+(3.45-0.0079\times 100)\,10^{-3}\,(100-50)] = 1.7\times 10^{-3}\ \mathrm{w/cm^2\cdot °C}$$

CERTAIN QUESTIONS IN THE THEORY OF MAGNETIC AMPLIFIERS LOADED BY DC DRIVES

L. V. Safris

(Rostov-on-Don)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 3, pp. 393-401, March, 1960

Original article submitted November 2, 1959

Equations are derived which characterize the basic modes and peculiarities of operation of a saturated-reactor magnetic amplifier loaded by a dc drive. A simplified method of designing such an amplifier is given.

Introduction

The operation of a magnetic amplifier loaded by a dc motor (MA-M) has its peculiar features. They stem from the fact that the motor, as an energy consumer, presents itself as an impedance and a variable counter-emf whereby, with amplifier control, there is an action on this emf. The presence of the amplifier leads, naturally, to a change in the drive's characteristics. In [1], individual questions in the analysis of such schemes were touched on for one special case. In [2], certain design approaches were adduced. At the same time, there is interest in establishing general regularities characterizing the operation of an MA-M system when its elements are connected in accordance with the scheme of Fig. 1. In the present paper we attempt to fill this void partially. We note that the analogous problem, as applied to a rotary amplifier, and also for the case when control of asynchronous motors is implemented by means of magnetic amplifiers, received consideration in [3-5].

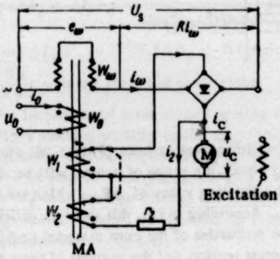

Fig. 1.

As the basis of our investigation, we take the linearization method described in [6, 7]. This method turns out to be particularly effective if one may make the two following assumptions: a) the characteristics of simultaneous core magnetization by constant and variable fields may be approximated by straight line segments ; b) the load curve, expressing the dependency between the variable component of the saturated reactor emf and the load voltage can be replaced by a straight line.

On the strength of the first assumption, we shall suppose that, for amplifier operation, we shall use a linear domain of the magnetization characteristic of the cores, which are made of material of sufficiently high quality. Under these conditions, the increment of the mean value of the working windings' ac current ΔI_ω can be found from the expression [6]

$$\Delta I_\omega = S\Delta I_0 + \frac{\Delta E_\omega}{R_i}. \tag{1}$$

Here, I_0 is the control current, E_ω is the mean value of the ac windings' emf, S is the slope of the characteristic, and R_i is the amplifier's internal impedance. The last two parameters are defined as follows:

$$S = \sigma \frac{W_0}{W_\omega}, \tag{2}$$

$$R_i = \frac{\omega\mu_i W_\omega^2 Q}{l}. \tag{3}$$

W_0 is the number of turns in the control winding, W_ω is the number of turns in the ac winding, Q is the active cross section of the two cores, l is the mean length of the magnetic circuit, $\sigma = \frac{\partial H_\omega}{\partial H_0}$, $\mu_i = \frac{\partial B_\omega}{\partial H_\omega}$, H_0 is the constant (monotonic) component of the magnetic-field strength, H_ω is the "mean" value of the variable component of the magnetic-field strength :

$$H_\omega = \frac{W_\omega I_\omega}{l}, \tag{4}$$

and B_ω is the "mean" value of the variable component of the magnetic induction:

$$B_\omega = \frac{E_\omega}{\omega W_\omega Q}. \tag{5}$$

The second assumption derives from the following considerations. It was established in [8] that, with amplifier operation on the counter-emf, the load curve, as a function of material quality, can deviate from the straight line on both sides.

By taking this circumstance into account, as well as the fact that it is desirable to obtain simple graphic expressions, in the first instance mirroring the qualitative side of the phenomena, we shall assume that $E_\omega = U_s - (E_C + RI_\omega)$ and, consequently,

$$-\Delta E_\omega = \Delta E_C + R\Delta I_\omega. \qquad (6)$$

Here, U_s is the mean value of the supply voltage, E_C is the motor's counter-emf, R is the equivalent active impedance of the ac circuit. Figure 2 gives a geometric interpretation of these assumptions. The family of magnetization curves $H_\omega = f_1(H_0, B_\omega)$ is replaced by the dashed-line parallel segments. The linear domain is marked by the coordinates of points 1 and 2 (B_1, H_1 and B_2, H_2). In correspondence with (6), the increments of voltage and emf drops occurring in the system are represented by segments (ab, bc, ce, etc.) whose projections on the axis of abscissas sum arithmetically to emf E_ω.

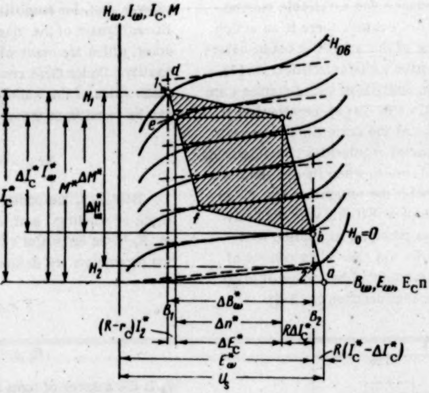

Fig. 2.

Coefficients of Control and Rigidity

We adopt the nomenclature that $K_C = \partial n/\partial I_0$ for M = const is the control coefficient, and $K_r = -\partial M/\partial n$ for I_0 = const is the rigidity coefficient. Here, n is motor speed and M is the torque developed by the motor.

We first consider the case when there is no feedback, and we assume that each conducting arm of the rectifier bridge can be replaced by a constant resistance r / 2. The back impedances will be considered infinite.

If we take into account the generally known expressions for dc motors with independent excitation,

$$M = C_M I_C, \qquad (7)$$

$$E_C = C_E n, \qquad (8)$$

we can write (6) in the following way:

$$-\Delta E_\omega = \Delta n C_E + R\frac{\Delta M}{C_M}. \qquad (9)$$

Here, $I_C = I_\omega$ is the motor armature's current, $R = r_C + r_a + r_1$, r_C is the impedance of the armature winding and motor brushes, r_1 is the impedance of the amplifier's ac winding.

By substituting (7), (8), and (9) in (1), we obtain

$$\Delta n = \frac{k}{C_E}\Delta I_0 - \frac{\Delta M}{C_M C_E}(R_i + R) =$$

$$K_C \Delta I_0 - \frac{1}{K_r}\Delta M, \qquad (10)$$

where

$$k = SR_i.$$

It follows immediately from (9) that, all other things being equal, the range of control will be determined by the limiting value of ΔE_ω, which we denote by ΔE_ω^*. According to (5), this latter quantity depends on the properties of the core material (ΔB_ω^* in Fig. 2), its cross section, and the number of turns of the working winding. Since ΔB_ω^* is a constant for a given material, an increase of ΔE_ω^* may be attained by increasing Q and W_ω. Simultaneously, as is clear from (3), R_i will also be increased, which implies an increase in K_C and a decrease in K_r. In view of these circumstances, it is frequently not possible to create an amplifier which, operating in the scheme under consideration, can satisfactorily provide the necessary values of control range and coefficient, and also the rigidity of the mechanical characteristics. We now show that a system in which the amplifier is used with feedback is free of such a disadvantage.

Effect of Feedback on K_c and K_r

a) Current feedback. Since, in addition to the ampere-turns $W_0 \Delta I_0$, the ampere-turns $W_1 \Delta I_c$ (Fig. 1) also take part in core magnetization, we then obtain, by adding the proper term to (10),

$$\Delta n = \frac{k}{C_E}\left(\Delta I_0 + \frac{W_1}{W_0}\Delta I_c\right) - \frac{\Delta M}{C_M C_E}(R_i + R), \quad (11)$$

where $R = r_c + r_a + r_i + r_1$. By taking (7) into account, we obtain, after some simple transformations,

$$\Delta n = \frac{k}{C_E}\Delta I_0 - \frac{\Delta M}{C_M C_E}[R_i(1 - \beta_1 S) + R]. \quad (12)$$

Here, $\beta_1 = W_1 / W_0$ is the feedback coefficient, W_1 and r_1 are, respectively, the number of turns and the impedance of the current feedback winding.

The expression $R_i(1-\beta_1 S)$ can be considered as the equivalent internal impedance of the amplifier with positive current feedback, the magnitude of which can be varied within broad limits by the proper choice of β_1. This statement is well known from the general theory of amplifiers with feedback [9].

Thanks to this, we can obtain the necessary values for K_r, including the value which provides (at least theoretically) absolute rigidity of the mechanical characteristics. The control coefficient does not depend on the current feedback.

b) Voltage feedback. Change of the control coefficient can be obtained by introducing voltage feedback. For this purpose, we use a winding with number of turns W_2, connected in parallel with the motor via resistor r_2. The increment of feedback current will be $\Delta I_2 = \frac{\Delta E_c + \Delta I_c r_c}{r_2}$. and the corresponding ampere-turns are $\Delta I_2 W_2 = W_0 \beta_2 (\Delta E_c + \Delta I_c r_c)$. Here, $\beta_2 = \frac{W_2}{W_0 r_2}$ — is the feedback coefficient.

The increment of total current passing through the amplifier's working winding equals $\Delta I_\omega = \Delta I_c + \Delta I_2$. Magnetization will be implemented by the positive feedback of ampere-turns $W_0 \Delta I_0 + W_2 \Delta I_2$. Since the current ΔI_2 does not flow through the motor's armature winding, the component $r_c \Delta I_2$ should be subtracted from the right member of (6), i.e.,

$$-\Delta E_\omega = \Delta E_c + R\Delta I_c + (R - r_c)\Delta I_2. \quad (13)$$

By substituting this last expression in (1) and by taking (7) and (8) into account, we find that

$$\Delta n = \frac{k\Delta I_0}{C_E(1 - \beta_2 k + a)} - \frac{\Delta M}{C_E C_M}\frac{[(R_i + R) - (\beta_2 k - a) r_c]}{(1 - \beta_2 k + a)}, \quad (14)$$

where

$$a = \frac{R_i + R - r_c}{r_2}, \qquad R = r_i + r_a + r_c.$$

Frequently, $r_c(\beta_2 k - a) \ll R_i + R$. Then, we can conclude from (14) that the introduction of positive voltage feedback leads to an increase in K_c and a decrease in K_r. The stability of motor speed will be even worse than with the absence of feedback. With negative feedback, the inverse phenomena will be observed. If $|\beta_2| \rightarrow \infty$, then $K_r \rightarrow \frac{1}{r_c}$.

c) Combined Feedback. It is clear from an analysis of the two forms of feedback considered that their properties complement each other to a certain extent, and that their joint use must give the very best results. This is an immediate consequence of the following expression, obtained on the basis of the same considerations and methods which we used previously:

$$\Delta n = \frac{k\Delta I_0}{C_E\left[1 - k\left(\beta_2 + \frac{\beta_1}{r_2}\right) + a\right]} - \frac{\Delta M}{C_E C_M}\frac{\left\{R_i + R - k\left[\beta_1\left(1 + \frac{r_c}{r_2}\right) + \beta_2 r_c\right] + a r_c\right\}^*}{\left[1 - k\left(\beta_2 + \frac{\beta_1}{r_2}\right) + a\right]}. \quad (15)$$

Here, $R = r_i + r_a + r_1 + r_c$. In deriving (15), it was taken into account that the increment of the total constant component of magnetizing force equals $W_0 \Delta I_0 + W_1 \Delta I_c + (W_1 + W_2)\Delta I_2$, and that ΔE_ω is defined by (13).

The relationships $r_c \ll r_2$, $\beta_1 \ll r_2 \beta_2$, $(\beta_2 k - a) r_c \ll R_i + R$ are frequently valid. In this case, (15) can be simplified to

$$\Delta n = \frac{k\Delta I_0}{C_E(1 - \beta_2 k + a)} - \frac{\Delta M}{C_E C_M}\frac{R_i(1 - \beta_1 S) + R}{(1 - \beta_2 k + a)}. \quad (16)$$

By the proper choices of β_1 and β_2, one can attain the necessary values of both the control coefficient and the rigidity coefficient. From this point of view, combined feedback is the most advantageous.

Transient Responses

We first consider the case when there is no feedback. The law of variation of motor speed during the transient response may be found by jointly solving (9) and (10) (written for instantaneous values) and the following equations:

$$\Delta u_0 = r_0 \Delta i_0 + W_0 Q \frac{d(\Delta B_0)}{dt}, \quad (17)$$

---

* The terms β_1/r_2 and r_c/r_2 will be missing if one connects winding W_2 as shown by the dashed line in Fig. 1, which is advantageous for $\beta_2 < 0$.

$$W_0 Q \Delta B_0 = \frac{W_0^2 Q}{l} \mu_c \Delta i_0 - \frac{\nu}{\omega} \frac{W_0}{W_\omega} \Delta e_\omega, \qquad (18)$$

$$\Delta M = \Delta M_0 + m\Delta n + J \frac{d(\Delta n)}{dt}. \qquad (19)$$

Here, u_0 is the voltage applied to the input of the controlling winding, r_0 is the control circuit's impedance, B_0 is the constant (monotonic) component of magnetic induction. Some explanation should be given a propos of the last equations. Expression (17) derives from Kirchhoff's second law for the control circuit; (18) was borrowed from [6, 7]. Henceforth, to simplify the problem, bearing in mind that the cores are of good quality, we shall assume that $\mu_c = 0$, and we shall denote $\nu W_0 / \omega W_\omega$ by T. Equation (19) expresses Newton's law of motion with the assumption that the static impedance torque of the productive mechanism has two components, one of which is constant (ΔM_0) and the second of which is directly proportional to the speed ($m\Delta n$). On the basis of the equations enumerated, we get

$$\tau_{el}\tau_{mec}\delta \frac{d^2(\Delta n)}{dt^2} + \left[\tau_{el}\left(1 + \frac{m\delta}{K_r}\right) + \right. \qquad (20)$$

$$\left. + \tau_{mec}\right] \frac{d(\Delta n)}{dt} + \left(1 + \frac{m}{K_r}\right) \Delta n = K_c \Delta I_0 - \frac{\Delta M_0}{K_r}.$$

Here,

$$\tau_{el} = \frac{K_c T C_E}{r_0}, \quad \tau_{mec} = \frac{J}{K_r},$$

$$\Delta I_0 = \frac{\Delta U_0}{r_0}, \quad \delta = \frac{R K_r}{C_E C_M}.$$

Finding the solution of (20) poses no difficulty. For a qualitative estimate of the possible results, we consider the following particular cases: $\tau_{el} = 0$, $\tau_{mec} \neq 0$, and $\tau_{el} \neq 0$, $\tau_{mec} = 0$. Correspondingly, we obtain the equations

$$\tau_{mec} \frac{d(\Delta n)}{dt} + \left(1 + \frac{m}{K_r}\right) \Delta n = K_c \Delta I_0 - \frac{\Delta M_0}{K_r}$$

and

$$\tau_{el} \left(1 + \frac{m\delta}{K_r}\right) \frac{d(\Delta n)}{dt} +$$

$$+ \left(1 + \frac{m}{K_r}\right) \Delta n = K_c \Delta I_0 - \frac{\Delta M_0}{K_r}.$$

In the first case, the time to establish the number of revolutions is determined by the quantity $\frac{\tau_{mec}}{1 + \frac{m}{K_r}} = \frac{J}{K_r + m}$, which will be quite large, since, in the absence of feedback, K_r is small.

In the second case, the duration of the transient response depends principally on the amplifier lag, and will be characterized by the quantity

$$\frac{K_c T C_E}{r_0} \frac{1 + \frac{mR}{C_M C_E}}{1 + \frac{m}{K_r}}.$$

In investigating transient responses with feedback present, we should, instead of (10), use (16), adding to the latter the terms $W_1 Q d(\Delta B_0)/dt$ and $W_2 Q d(\Delta B_0)/dt$, taking into account the appearance of the corresponding emf, in each of the feedback windings. It was proved in [6] that these emf's can be neglected in the case of current feedback and active load. We assume that this may be done in the present case, bearing in mind the qualitative nature of our estimate. Under these conditions we may, to elucidate the effect of the feedback, use (20), in which the values for K_c and K_r are chosen from (16). It is easily comprehended that an increase in K_r due to positive current feedback or to negative voltage, feedback gives rise to a decrease in τ_{mec} and, consequently, to an acceleration of the transient response. Positive voltage feedback increases K_c and, consequently, τ_{el} as well. However, if r_0 is also simultaneously increased, maintaining the condition $U_0 I_0$ = const, then τ_{el} will be decreased. Thus, with the assumptions we have made, all forms of feedback are advantageous, in the sense of accelerating the transient response.

We note that if $K_r < 0$, then $\tau_{mec} < 0$ and the term with $d(\Delta n)/dt$ may become negative. In this case, the system exhibits a static instability, the assumption of linearity is unrealistic, and autooscillations will arise in the system, as we have observed in experiments.

Several Remarks Regarding Nonlinearity of Mechanical Characteristics

When low-quality cores are used, the two assumptions made will not hold. In this case, it is impossible to consider the coefficients S and R_1 (1) as constants, where their maximum corresponds to a linear domain. With such cores, the load curve cannot be approximated by a straight line, as the second assumption required. In this case, a more suitable approximation is $E_\omega^2 = U_s^2 - (E_c + RI_\omega)^2$, by virtue of which $-dE_\omega = (dE_c + RdI_\omega)(E_c + RI_\omega) / E_\omega$. By denoting $(E_c + RI_\omega) / E_\omega = \alpha$, $R_1 / \alpha = R_{1\alpha}$ and $k/\alpha = k_\alpha$, we can find that

$$dn = \frac{k_\alpha}{C_E} dI_0 - \frac{dM}{C_M C_E} (R_{i\alpha} +$$

$$+ R) = K_c dI_0 - \frac{dM}{K_r}. \qquad (10')$$

Thus, K_c and K_r will depend on the values of α, S, and R_1 which, in their turn, are determined by the choice of the working point. The common structure of (10) and (10') allows the basic propositions of the analysis provided earlier to be extended to the given case also, of course, in the neighborhoods of each working point.

We now explain the influence of S and R_1 on the linearity of the mechanical characteristics: For this purpose, we determine the relative variation of the rigidity coefficient due to the variation of the internal impedance and of the slope, respectively on dR_1 and dS.

Using the expression for K_r from (10), we find that

$$\frac{dK_r}{K_r} \approx -\frac{dR_1}{R_1}.$$

In the absence of feedback, the linearity of the mechanical characteristic will be determined by the constancy of R_1. In the case of positive current feedback

$$\frac{dK_r}{K_r} = -\frac{(1-\beta_1 S)\,dR_1 - \beta_1 R_1 dS}{R_1(1-\beta_1 S)+R}.$$

If

$$|R_1(1-\beta_1 S)+R| - \quad \text{then}$$

$$K_r \to \infty \text{ and } \frac{dK_r}{K_r} \to \infty.$$

Increasing the rigidity by means of current feedback leads to a sharp manifestation of nonlinearity in the mechanical characteristics. Finally, as was shown earlier, with negative voltage feedback, K_r converges monotonically to its limit $1/r_c$ if $|\beta_2| \to \infty$. In this case, dK_r/K_r will converge to zero. Consequently, negative voltage feedback allows the mechanical characteristic to be linearized and, therefore, is frequently used in combination with positive current feedback. This assertion is confirmed, in particular, by the data of the experimental investigation given in [2].

Design Considerations

The order followed in designing amplifiers will be different, depending on the problem posed and the data originally given, which must be sufficient and which must be compatible. The consideration of all the questions related to design goes beyond the limits of the present work. Here, we limit ourselves to illustrating how the expressions given earlier may be employed in design work.

Let there be given the nominal parameters and operating mode of the motor, $M^\bullet$, $I^\bullet_c$, C_M, $n^\bullet$, the voltage on the brushes $U^\bullet_c$, r_c, and C_E, the limiting variation of torque and number of rotations $\Delta M^\bullet$ and $\Delta n^\bullet$, the core parameters $\mu_1, \sigma, B_1, B_2, H_1,$ and H_2 or the corresponding family of magnetization curves from which these parameters may be determined, and the necessary values of the coefficients K_c and K_r.

We now determine the required volume of cores. This will be used in the best way if, in the process of operation, there are attained the largest admissible values (in the limits of the linear domains) of magnetic induction B_2 and magnetic-field strength H_1. By taking this circumstance into account, we find, on the basis of (5) and (13), that

$$\frac{\Delta E^\bullet_c + R\Delta I^\bullet + (R-r_c)\,\Delta I^\bullet_2}{\omega W_\omega \Delta B^\bullet_\omega} = Q, \qquad (21)$$

where $\Delta B^\bullet_\omega = B_2 - B_1$. The components of the voltage drop given in the left member of (21) are represented in Fig. 2 by the following segments: the increase in motor emf $\Delta E^\bullet_c$, by segment ce; the voltage drop across all the active impedances due to the increase in drive current $R\Delta I_c^\bullet$, by segment bc; voltage drop due to the current of the voltage feedback $(R-r_c)\,\Delta I^\bullet_2 \approx (R-r_c)\,I^\bullet_2$ – by segment ed. Since $I^\bullet_\omega = I^\bullet_c + I^\bullet_2$ (Fig. 2) then from (4), we find that

$$\frac{(I^\bullet_c + I^\bullet_2)\,W_\omega}{H_1} = l. \qquad (22)$$

It is assumed for this that the inequality $(I^\bullet_c - \Delta I^\bullet_c)\,W_\omega \geqslant H_2 l$ always holds.

Equations (21) and (22) permit the calculation of the active volume of the cores $V = Ql$ if one knows, in addition to the original data, the values of R and $I^\bullet_2$, i.e., essentially, r_1, r_a, r_1, and r_2. Resistance r_a depends on the rectifier properties and may be found by well-known methods. Amplifier efficiency and volume of copper depend on resistances r_1, r_1, and r_2. Their values can be varied within well-known limits. We assume roughly that $r_i \approx r_1 \approx r_c$, $r_2 \approx (5-10)\frac{U^\bullet_c}{I^\bullet_c}$ and, consequently, $I^\bullet_2 \approx (0{,}2 \text{ to } 0{,}1)\,I^\bullet_c$. We note that the core volume, found in accordance with (21) and (22) is minimal from the point of view of guaranteeing the magnetic mode. The possibilities of spacing the windings must be verified by additional well-known methods.

By knowing the value of V, we can determine Q or l by giving either the cross section or the mean length of the magnetic circuit. For different ratios of Q/l, we obtain different-size apertures and, to a certain degree, different operating conditions for the cores. The question as to the optimal ratio of Q/l requires a special investigation. As a first approximation, it is advantageous to start with the data given in the table below, obtained on the basis of the recommendations found in [10]:

$V/2$, cm^3	1.0	2.0	10	20	30	60	100	300
$Q/2l$, cm	0.02	0.035	0.05	0.075	0.1	0.15	0.2	0.3

By selecting the value of Q, we find from (21) the number of turns W_ω, and from (3) the magnitude of R_1. Then, using (15), we should determine β_1, β_2, and S for the given K_c and K_r. Since there are three unknowns, one of them should be given, since the necessary control coefficient can be obtained by virtue either of the proper value of W_0 or of W_2. When internal feedback is used, $\beta_1 S \approx 1$. Then, β_2 and S are determined uniquely. Finally, we calculate the supply voltage by the formula $U_s = \omega W_\omega Q B_2 + (I^\bullet_c - \Delta I^\bullet_c) R + (U^\bullet_c - \Delta E^\bullet_c)$, the meaning of which is clear from Fig. 2, on which the particular case is shown when $\Delta E^\bullet_c \approx U^\bullet_c$.

SUMMARY

The analysis of the equations obtained for the MA-M system leads to the following conclusions:

1. When there is no feedback, it is not possible to provide a satisfactory operating mode of the MA-M

system. Introduction of current and voltage feedback can have an effect on the rigidity of the mechanical characteristics and on the control coefficient. The best results can be obtained with the concurrent employment of the aforementioned forms of feedback.

2. Feedback permits the acceleration of the transient response and the linearization of the mechanical characteristics.

3. The expressions obtained may be used for a first-approximation design of an amplifier in accordance with the methodology presented.

THE USE OF HALL PICKUPS IN MAGNETIC HEADS

Yu. A. Vasilevskii

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 3, pp. 402-408, March, 1960
Original article submitted March 4, 1959

This paper reports on the development and experimental investigation of magnetic reading heads based on the Hall effect. The heads have the property that their emf is proportional to the residual carrier flux, in contradistinction to the usual induction-type reading heads in which the emf is proportional to the velocity of flux change. The heads can operate both with magnetic tape and with carriers in the form of drums or disks.

In ordinary magnetic heads for reading or reproducing magnetic recording, there occurs a differentiation of the signal stored on a ferromagnetic carrier. With this, there appear distortions in the amplitude and phase frequency characteristics of the reproduction channel which hinder correct transmission of the signal. Exceptions are sinusoidal signals which, in the given case, do not undergo changes in form if the system is linear. However, even for them there are serious limitations in the range of low audio and infraaudio frequencies.

It is not always possible to tolerate this disadvantage of induction heads, despite their great superiority in other respects. Therefore, there were developed a number of designs of the so-called flux-sensitive heads of the servo system type, whose output emf's are proportional, not to the velocity of change, but to the magnitude of the residual carrier flux. The best known of these are the magnetomodulation head whose operating principle is analogous to a magnetic amplifier (sonde) of the second harmonic type, and the electrobeam head, based on a tube with magnetic deflection of the beam.

The flux-sensitive heads to be considered below, based on the Hall effect, are further developments in this direction. Their operating principle amounts to this, that the residual carrier flux, by means of a magnetic circuit, is applied to a Hall pickup, with the result that at the pickup's output there is generated an emf which is proportional to the magnitude of this flux.

One design of such a head is shown schematically on Fig. 1, a; an over-all view of it is shown in Fig. 1, b. Used in it is an ordinary ring-shaped magnetic circuit, for example, from standard head V-01. The dimensions of core 1 are as follows: length of the leading (reading) slit d_1 = 45 microns; length of the trailing slit d_t = 0.28 mm; outside diameter of the core D_0 = 25 mm; inside diameter D_1 = 18 mm. Height of the core assembly is h = 7 mm. The given design is intended to operate with magnetic tape 2 of width 6.35 mm, although it can also operate with a magnetic drum. The Hall pickup 3 is established in the leading slit of the magnetic circuit. Semiconductor pickups of n-type germanium (n-Ge) were used, with dimensions of 6 × 3 × 0.18 mm.

The Hall pickup has a dc supply. The selection of the magnitude of the current turned out to have an essential influence on the head's signal-to-noise ratio. We used the following method to determine the optimum current magnitude. On the carrier there was recorded a sinusoidal signal with a frequency of 125 cps (carrier speed of motion was 38.1 cm/sec) and with a magnitude of residual flux Φ_C = 300 millimaxwells. For the carrier used, this level was about 10 db lower than the saturation level. The pickup's Hall electrodes were supplied directly at the high-ohmic input of the amplifier circuit. Since the pickup's inherent noise is independent, within broad limits, of the magnitude of the signal, the signal-to-noise ratio was determined as the ratio of the indication of

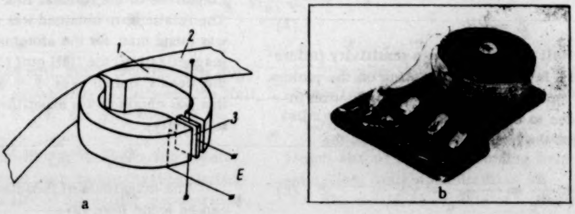

Fig. 1.

the instrument at the output of the amplifier circuit at the time of carrier motion to the instrument's indication for a motionless carrier. This ratio was taken off as a function of the magnitude of the current supplied to the pickup. As a result, it was found that the optimum magnitude of this current for the head under consideration was 8 ma. With such a current, and for an amplifier circuit passband of 20 to 6000 cps, the signal-to-noise ratio was 20.4 db; for a passband of 75 to 150 cps, this ratio was 33.2 db and, for a passband of 25 to 100,000 cps, it equaled 17 db. To eliminate pickup from the constant poles, the current supply circuit for the pickup was carefully screened. A thermal regimen corresponding to the pickup's optimal supply current and to an ambient temperature on the order of 25°C provided prolonged stable operation of the head. For example, the pickup was supplied with current continuously for 48 hours. With this, the operation of the head was periodically verified. No operating changes were observed.

The magnitude of the emf generated by the pickup when it is acted upon by the carrier's magnetic field is related to the head's sensitivity. As a preliminary measure, we found the character of the calculated dependency of the head's sensitivity on the parameters of its magnetic circuit and on the so-called voltage sensitivity of the Hall pickup [1].

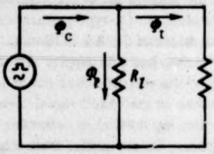

Fig. 2. Simplified equivalent schematic of the head's magnetic circuit. R_l is the reluctance of the leading (reading) slit, R_t is the reluctance of the trailing slit, and Φ_C is the carrier's residual flux.

In a first approximation, the equivalent schematic of the head's magnetic circuit has the form shown in Fig. 2. The emf at the pickup's output may be given as

$$E = \gamma B, \tag{1}$$

where γ is the Hall pickup's voltage sensitivity (microvolts / gauss) and B is the induction acting on the pickup. In our case, B is the average value of the induction in the trailing slit due to the residual carrier flux Φ_C.

We determine the head's sensitivity from the formula

$$\eta = \frac{E}{\Phi_c} = \frac{E}{B}\,\frac{B}{\Phi_c} = \gamma\nu, \tag{2}$$

where ν is a coefficient defined by the parameters of the head's magnetic circuit:

$$\nu = \frac{\Phi_t}{\Phi_c S_t} = \frac{1}{S_t + d/R_l},$$

S_t is the cross section of the flux in the trailing slit, R_l is the reluctance of the leading slit, i.e.,

$$\eta = \frac{\gamma}{S_t + d/R_l}.$$

In the general case, Φ_C is, with certain limitations, an arbitrary function of the space coordinates related to the carrier, and B and E are functions of time corresponding to it.

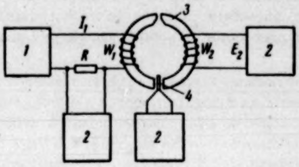

Fig. 3. Scheme for measuring the Hall pickup's sensitivity, with the pickup located in its operating position between the halves of the head's core. 1 is a generator, 2 is a vacuum tube voltmeter, 3 is the head's core, and 4 is the Hall pickup.

The pickup's voltage sensitivity was determined experimentally as shown in Fig. 3. The head's core had two windings: magnetizing winding W_1 and measuring winding W_2. The measure of magnetic induction in the core was taken to be the magnitude of the voltage induced in winding W_2. The ratio of the measured magnitude of the Hall emf E to the corresponding value of induction B gave the mean value of the pickup's voltage sensitivity $\gamma = 116$ microvolts/gauss from whence, for the parameters of the magnetic circuit previously enumerated, we found the computed sensitivity of the head:

$$\eta = 204\ \mu v / \mu sec$$

The experimental value of the head's sensitivity was determined by measuring the emf at the pickup's output and seeking the dependency of the emf on the magnitude of the residual flux for an 8 ma supply current. The relationship obtained was close to a linear one. It was found that, for the aforementioned intensity of magnetization, the Hall emf (the equivalent value) at the head's output was E = 52 microvolts. From this was obtained the experimental value of the head's sensitivity:

$$\eta_{exp} = \frac{52}{0.3} = 173\ \mu v / \mu sec$$

The magnitude of induction B in the trailing slit can be found from (2):

$$B = \frac{\eta}{\gamma}\,\Phi_{\text{н}} = 0.45 \text{ gauss}$$

On the basis of the dynamic range of 20.4 db, found earlier, the head's sensitivity threshold corresponds to a value of induction of

$$B_{\min} = \frac{0.45}{10^{20.4/20}} = 4.3 \cdot 10^{-2} \text{ gauss}$$

The head's frequency characteristic, obviously, is determined by the frequency characteristics of the two factors in (2). The frequency characteristic of the voltage sensitivity γ was measured by the circuit of Fig. 3 for a constant value of induction B = 3 gauss within the frequency limits of 20 to 200,000 cps. It was found that, within these limits, the voltage sensitivity does not depend on frequency.

In a pickup placed in a variable magnetic field, there is induced an induction emf which is added geometrically to the Hall emf. However, the induced emf can be easily compensated by the proper placement on the core of one of the conductors joining the Hall electrodes to the amplifier circuit. The optimum compensation is chosen as that giving the minimum deviation of the instrument in the circuit of the Hall electrodes at the highest operating frequency. On the basis of the system's linearity and the applicability of the principle of superposition, one can use still another method of isolating the Hall emf from the geometric sum of the two emf's : with the current supplying the pickup switched in, one measures (without compensation) the total emf, after which, with the current switched off, one measures the induced emf. Their geometric difference gives the Hall emf. By such a method, results were obtained which coincided closely with the previous ones until the induced emf exceeded the Hall emf by a factor of more than 3 or 4 . This latter method is effective when the Hall pickups are used as pickups for geometric sums or differences of stimuli, one of which is proportional to the frequency.

The frequency characteristic of coefficient ν is determined by the magnetic and geometric parameters of the core such as, for example, the slit and the frequency-dependent losses, and is not characteristic of the given head .

Since, in the range considered, the pickup sensitivity does not depend on frequency, the head's frequency characteristic is simultaneously the frequency characteristic of the induction in the trailing slit.

The head's experimentally obtained frequency characteristic is shown in Fig. 4. The signal was recorded at a constant writing current but at different frequencies, with a speed of carrier motion of 38.1 cm/sec. Some lifting of the characteristic in the low-frequency range is related to the length of the head contact with the carrier. The fall of the characteristic in the high-frequency range is explained both by slit phenomena and by certain other peculiar characteristics of magnetic recording.

On the other hand, since the Hall emf may be defined in practice as the geometric difference of the total emf and the induced emf, this is confirmed by the form of the proportional dependency (1) between the Hall emf E and the induction B, i.e., the head possesses the property of flux sensitivity.

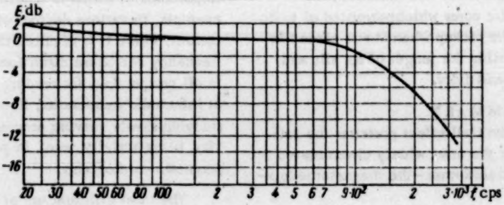

Fig. 4.

This latter was illustrated by the following experiments. Recording was read from an immovable carrier. The magnetization intensity of the carrier corresponded to :

1) a sinusoidal signal with a recording wavelength of 16 mm;

2) a pulse signal with a dipole recording length of 10 mm (recording from zero to saturation; a mark-space ratio of 2);

3) a rectangular signal with a dipole recording length also of 10 mm (recording from saturation to saturation; mark-space ratio of 2).

The carrier, by means of a micrometric device, was drawn past the head for a definite distance and then stopped, after which a sensitive galvanometer measured the voltage on the head's Hall electrodes.

The point of reading initiation coincided with the beginning of the recording, for which the initial portion of the recording was made visible by precipitating on the carrier a powder of carbonyl iron from a heptane suspension. As a result of this, there was shown the synphasing of the carrier's surface residual flux and the voltage on the head's Hall electrodes.

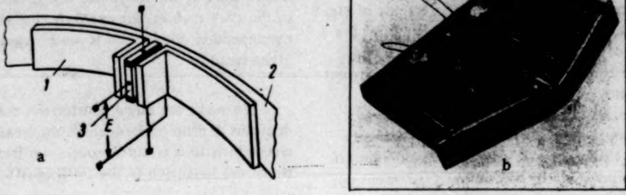

Fig. 5. 1 is the core, 2 is the carrier, 3 is the pickup.

We should mention one further trial head design, shown in Fig. 5, a and b. The head's magnetic circuit is open, and the Hall pickup is placed in the reading slit whose length is about 0.35 mm. The design has extended pole shoes (the length of each shoe is 25 mm) and is intended to read recording of long wavelengths. A simplified equivalent schematic of the head's magnetic circuit can be obtained if, in Fig. 2, one sets $R_t = \infty$. As should be expected, with the same pickup, this design has greater sensitivity and a correspondingly better dynamic range than the first design. At a frequency of 40 cps, the increase in sensitivity is about 4 db.

Other heads based on the Hall effect which were investigated differed from the two types considered here only by the core configurations and materials; for example, we used ferrite cores which permitted us to do without insulation of the pickup when it was placed in the slit, thereby decreasing the length of the slit and increasing the head's sensitivity.

SUMMARY

A head based on the Hall effect possesses the following advantages over the most widely disseminated type of flux-sensitive transformer—the magnetomodulation head.

1. It permits simplification of the electrical reading scheme.

2. It possesses sensitivity to the direction of the carrier field, i.e., to the polarity of the signal.

3. It can operate in a broad frequency range, in particular, for frequencies of the order of 100 kcps and higher. In this case it is advantageous to use a ferrite magnetic circuit.

4. With heads based on the Hall effect, the danger of random erasure or magnetization of the carrier is excluded.

5. Phase distortion of the signal is virtually eliminated.

6. The requirements on head shielding are reduced.

7. Simplicity of design and small dimensions are provided.

This last quality effectively distinguishes the head based on the Hall effect from the other well-known flux-sensitive head—the head of the electron-beam type.

The Hall pickup is an inductionless transformer, which eases the shielding of such a head in comparision with an ordinary induction head of equal sensitivity.

A head based on the Hall effect may be useful in many cases of special uses of magnetic recording, the importance of which is continuously growing; for example, in various devices of automation and remote control, where it is required to read pulses with minimal frequency and phase distortions; in geology, particularly in oil prospecting, for reading processes which change at infraaudio frequencies; in medicine and biology, for studying slowly varying processes related to brain activity, heart activity, etc., in particular, for reading magnetic cardiograms.

The most efficient use of heads based on the Hall effect is in the frequency range from fractions of a cps to about 100 cps, and for carrier speeds up to 4 to 5 cm/sec, i.e., in those cases where induction heads are practically ineffectual. The basic disadvantage of a head with a Hall pickup for sound reproduction is the relatively small dynamic range. There exist the following ways of improving the dynamic range and other indicators of head quality:

1. Improvement of the technology of preparing Hall pickups, the quality of processing the surfaces and contacts.

2. The use of Hall pickups with non-current-carrying contacts.

3. The use, for pickups, of materials with higher Hall constants.

4. Reduction of the length of the slit in which the Hall pickup is established, which introduces the particular requirement to reduce the width of the pickup. There is interest, in this connection, in film pickups of materials with high voltage sensitivity. These latter can be mounted in the form of a thin film of thickness of 10 to 100 micrometers on the face surface of a ferrite core.

5. The use of magnetic recording carriers with high values of residual flux.

6. Operation with high levels of carrier magnetization, for example, with levels corresponding to the magnetic saturation of the carrier, as occurs in the majority of special applications of magnetic recording.

In conjunction with this, it should be mentioned that, in many cases of special uses of magnetic recording, only a twofold increase of signal over noise is sufficient.

A VOLTAGE DEFLECTION PICKUP BASED ON SEMICONDUCTOR ELEMENTS*

S. V. Kulikov

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 3, pp. 409-416, March, 1960
Original article submitted August 19, 1959

A description is given of a voltage deflection pickup implemented by semiconductor elements — silicon base diodes, transistors, and thermoimpedances. A design methodology is proposed, and calculated relationships and experimental results are given.

General Remarks

The voltage deflection pickup considered in this paper is designed for use in systems for stabilizing voltage or any quantity which is transformed to a voltage. The special feature of the voltage deflection pickup, shown in Fig. 1 and 2, is its implementation by semiconductor elements. This provides its small weight and size (Fig. 2), reliability, heightened resistance to vibration and shock, and length of useful life .

Type D 810 silicon base diodes D_1 and D_1', connected in opposite arms of bridge D_1-R_p-R_{11}-D_1'-R_{12}, execute the function of voltage calibration. The voltage to be regulated, E_{reg}, is applied to one of the bridge's diagonals via ballast resistor R_{13}. Connected to the other diagonal of the bridge is a preamplifier of silicon transistors T_1-P102, T_1'-P102, whose output current controls the relay power amplifier, implemented by germanium transistors T_2, T_2'-P13A, T_3 and T_3'-P4D. Thermoimpedances R_{T_1} and R_{T_2} are used to compensate the temperature variations in the scheme.

To obtain, in load impedances R_3 and R_3', a signal whose average value would be a continuous function of the input signal for a limited range of variation of the latter, one should connect, instead of resistors R_5 and R'_5, condensers C_1 and C'_1 (shown by dashed lines in Fig. 1),which would provide self-excitation, i.e., the principle of vibration linearization is used. Pulse-width modulation is used in the scheme for deviations of the controlled voltage.

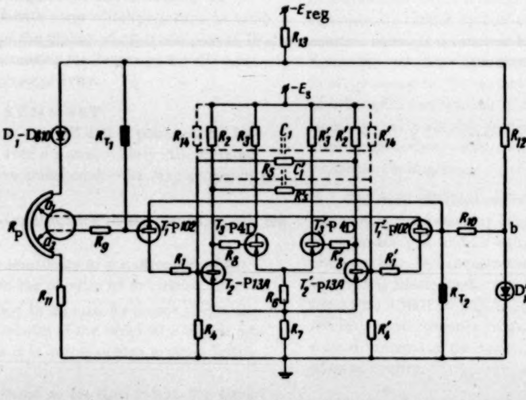

Fig. 1. Simplified schematic of the voltage deflection pickup . $R_1 = R'_1 = 1.2$ kohm; $R_2 = R'_2 = 3.3$ kohm; $R_3 = R'_3 = 100$ ohm; $R_4 = R'_4 = 5.6$ kohm; $R_5 = R'_5 = 15$ kohm; $R_6 = 5$ ohm; $R_7 = 5$ ohm; $R_8 = R'_8 = 1$ kohm; $R_9 = 0$; $R_{10} = 200$ ohm; $R_{11} = 1920$ ohm; $R_{12} = 2100$ ohm; $R_p = 542$ ohm; $R_{a_1-a_2} = 210$ ohm; $R_{a_1} = 40$ ohm ; $R_{13} = 395$ ohm .

---

* The results of the investigation described in this paper were discussed in the April, 1959 seminar of the Laboratory of Automation and Remote Control Elements of the IAT AN SSSR .

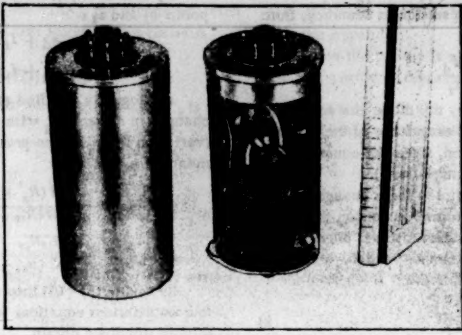

Fig. 2. Outside view of the voltage deflection pickup.

Posing of the Problem

The problem raised in this paper is the presentation of an engineering method of designing the voltage pickup. Relationships are derived which, for given regulated voltage E_{reg}, source voltage E_3 and load resistances R_3 and R'_3, allow one to determine the remaining circuit parameters for which feasibility of the circuit and its stability under temperature variations would be guaranteed.

In addition, a generalized method is propounded for the analysis of transistor switching circuits.

Method of Investigation

Thanks to the fact that silicon transistors in the cutoff region have insignificant current flowing through the base-collector junction ($I_{CO} \leq 1 \mu a$), it is possible to design the bridge together with the thermoimpedances R_{T_1} and R_{T_2}, and to implement the additional impedances R_9 and R_{13} separately.

In designing the bridge, the nonlinear base diodes D_1 and D'_1, after the piecewise-linear approximation of their volt-ampere characteristics, are given as "conditionally autonomous" dipoles with emf's E_d and E'_d and with impedances R_d and R'_d (Fig. 3).

The high-ohmic thermoimpedances R_{T_1} and R_{T_2} are presented as current sources I_{T_1} and I_{T_2}.

As a result, we obtain the replacement scheme, shown in Fig. 4, for the bridge. It is calculated by the methods of the linear theory of electrical circuits.

By considering the outputs of transistors T_1 and T'_1 as current sources (in the equilibrium state the currents virtually equal zero), one can compute the relay stages of transistors T_2, T'_2, T_3 and T'_3 separately. The design of the latter is implemented from the conditions of transistor cutoff and saturation, with account taken of temperature variations.

For the computation of the circuit's sensitivity (cf. the Appendix), we introduce the concept of a "conditionally autonomous three-pole," allowing one to take into account the nonlinear properties of the transistor and, at the same time, to use a generalized method of designing linear electrical circuits.

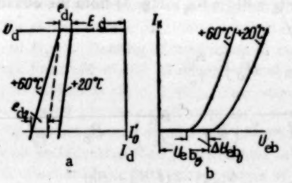

Fig. 3. Volt-ampere characteristics for determining parameters. a is for the silicon base diodes, b is for the silicon transistors.

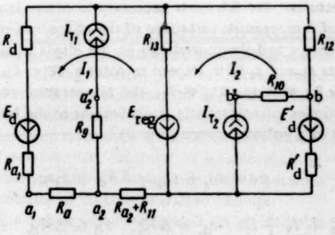

Fig. 4. Equivalent replacement scheme of the nonlinear bridge.

Designing the Nonlinear Bridge

Use of type D808-813 base diodes shows that, for the greatest stability, their operating current I_0 must be of the order of 5 ma.

The magnitude of currents I_{T_1} and I_{T_2} on the circuit of Fig. 4 are determined, with sufficient accuracy, from the equation

$$I_T = \frac{E_d}{R_T}, \tag{1}$$

where E_d is the emf defined by the diode characteristics (Fig. 3), $E_d < E'_d$; R_T is the magnitude of the thermoresistor (the subscript is omitted, since the equation is valid for both diodes and thermoresistors).

The thermoresistors are chosen large enough so that, first of all, operation of the thermoresistors on the linear portion of the volt-ampere characteristic is provided [1] and, secondly, the thermoresistors R_{T_1} and R_{T_2} can be replaced by current sources. This latter is realized for the condition

$$I_0 \geqslant 10 I_T. \tag{2}$$

By neglecting the components of I_T in the bridge, we can find the resistances R_{12}, R_{13} and $R = R_{11} + R_a + R_{a_1} + R_{a_2}$ ($R_p = R_a + R_{a_1} + R_{a_2}$, Fig. 1) from the equations

$$R_{12} = R'_d + \frac{E'_d}{I_0}, \tag{3}$$

$$R = 2\left(R'_d + \frac{E'_d}{I_0}\right) - R_d - \frac{E_d}{I_0}, \tag{4}$$

$$R_{13} = \frac{E_{reg} - 2(I_0 R'_d + E'_d)}{2I_0}, \tag{5}$$

where R'_d is the diode's dynamic impedance.

The remaining unknown resistances, R_a , R_{a_1}, R_{a_9}, and $R_{a_{10}}$, are determined from the conditions of equilibrium of the circuit for normal and for elevated temperatures. For this, it is necessary to determine the effect of temperature variations of the characteristics of the diodes and thermoresistors on the displacement of points a_1 and a_2 with respect to point b (Fig. 4).

For $R_d \ll R$ and $R'_d \ll R_{12}$, the temperature variation of the diodes' characteristic is equivalent to the introduction of a voltage source (Fig. 3)

$$e_d = e_{d_1} + e_{d_2} = \Delta E_d + I'_1 r_d, \tag{6}$$

where

$$I'_0 = I_0 + I_T + i_T, \quad e_{d_1} = \Delta E_d, \quad r_d = \Delta R_d, \quad i_T = \Delta I_T.$$

Using the principle of superposition, we determine the effect of temperature variations of the diodes' characteristic from the matrix equation

$$\begin{bmatrix} i_1 \\ i_2 \end{bmatrix} = \begin{bmatrix} R + R_{13} & -R_{13} \\ -R_{13} & R_{13} + R_{12} \end{bmatrix}^{-1} \begin{bmatrix} -e_d \\ +e_d \end{bmatrix}, \tag{7}$$

where i_1 and i_2 are the increments of currents I_1 and I_2 (Fig. 4).

Solving (7), we get

$$i_1 = \Delta I_1 = \frac{(R_{12} + R_{13})\, e_d - R_{13} \dot{e}_d}{R(R_{12} + R_{13}) + R_{12} R_{13}}. \tag{8}$$

By means of (8), we determine the displacements of points a_1 and a_2 :

$$\Delta U'_{ba_2} = \dot{e}'_d + i_1 (R - R_a - R_{a_1}),$$
$$\Delta U'_{ba_1} = \dot{e}'_d + i_1 (R - R_{a_1}). \tag{9}$$

Analogously, we find the displacements due to changes in current I_{T_1} with the condition that $R \gg R_p$ (variation in I_{T_2} has no practical effect on the displacements of a_1 and a_2) :

$$\Delta \dot{U}_{ba_2} = -\frac{R(R_a + R_{a_1})(R_{12} + R_{13})}{R(R_{12} + R_{13}) + R_{12} R_{13}} i_{T_1};$$

$$\Delta \dot{U}_{ba_1} = \frac{R_a R_{12} R_{13} - R_{a_1} R (R_{12} + R_{13})}{R(R_{12} + R_{13}) + R_{12} R_{13}} i_{T_1}. \tag{10}$$

By taking (8)-(10) into account, one can set up the four equilibrium equations for the two temperatures, by solving which we obtain

$$R_8 = \frac{I_{T_1}(\Delta U_{eb_0} + \Delta U'_{eb_0}) + i_{T_1}(U_{eb_0} + U'_{eb_0})}{I_{T_1} i_1 + I_0 i_{T_1}},$$

$$R_9 = \frac{(I_0 - I_{T_1})(\Delta U_{eb_0} + \Delta U'_{eb_0}) - (i_1 + i_{T_1})(U_{eb_0} + U'_{eb_0})}{I_{T_1} i_1 + I_0 i_{T_1}},$$

$$R_{a_1} = \frac{r_1^2 (U'_0 i_{T_1} - \dot{U}_0 I_{T_1})}{(r_1^2 I_0 - r_2^2 I_{T_1})\, i_{T_1} + (r_1^2 i_1 + r_2^2 i_{T_1})\, I_{T_1}},$$

$$R_{10} = \frac{(r_2^2 I_{T_1} - r_1^2 I_0)\, \dot{U}_0 - (r_1^2 i_1 + r_2^2 i_{T_1})\, U'_0}{(r_1^2 I_0 - r_2^2 I_{T_1})\, i_{T_1} + (r_1^2 i_1 + r_2^2 i_{T_1})\, I_{T_1}}, \tag{11}$$

where

$$r_1^2 = R(R_{12} + R_{13}) + R_{12} R_{13},$$
$$r_2^2 = R(R_{12} + R_{13}),$$
$$U'_0 = I_0 R - E'_d - U'_{eb_0} - I_{T_1} \frac{R_{12} R_{13}}{r_1^2} R_a,$$
$$\dot{U}_0 = -i_1 R - \dot{e}'_d + \Delta U'_{eb_0} - i_{T_1} \frac{R_{12} R_{13}}{r_1^2} R_a;$$

U_{eb_0} , U'_{eb_0} , ΔU_{eb_0} and $\Delta U'_{eb_0}$ are the threshold voltages and their increments , defined for the corresponding triodes T_1 and T'_1 from Fig. 3, b.

As is obvious from (11), for certain special values of the parameters on the right, the magnitudes of resisters R_9, R_{a_1} and R_{10} may turn out to be zero.

Design of Relay Stages (Switching Circuits)

The design of relay stages from transistors T_2, T'_2, T_3 and T'_3 leads to the determination of resistances $R_2 = R'_2$, $R_4 = R'_4$, $R_5 = R'_5$, R_6, R_7, and $R_8 = R'_8$ for known load resistances $R_3 = R'_3$ and supply voltage E_3 . The six unknown resistances are found from the cutoff and saturation conditions of transistors T_2, T'_2, T_3 and T'_3 [2] and from two auxiliary relationships, the first of which expresses the condition that there be no shunting of the relay amplifier's input

$$R_4 \geqslant 10 R_{in} \tag{12}$$

(R_{in} can be set at 500 ohm for P13A), the second of which is the condition of insignificant losses in bias resistors R_6 and R_7:

$$10(R_6 + R_7) \leqslant R_3. \tag{13}$$

The cutoff condition for transistors T_2 and T'_2 is written in the form

$$I_{co_2} R_4 \leqslant \frac{E_s R_7}{R_3 + R_6 + R_7}, \tag{14}$$

where I_{co_2} is the temperature collector current of transistor T_2.

The cutoff condition for transistors T_3 and T'_3, neglecting the emitter current I_{e_2} of triode T_2 in resistors R_6 and R_7, is defined by

$$I_{co_3} R_8 \leqslant \frac{E_s R_6}{R_3 + R_6 + R_7}. \tag{15}$$

The saturation condition for triodes T_2 and T'_2, neglecting I_{co_3} and I_{e_2} in R_7, is written

$$\frac{r_a (r_c^3 - r_b^2 R_5) I_{co_2}}{R_5 E_s} \leqslant R_6 R_2 + R_8 (R_3 + R_6) - r_b^2 \left(\frac{R_7}{R_4} + \frac{R_3 + R_6}{\beta_2 R_2}\right), \tag{16}$$

where

$$r_a = R_3 + R_6 + R_7,$$
$$r_b^2 = R_2 R_5 + R_2 R_8 + R_5 R_8,$$
$$r_c^3 = R_2 R_5 R_8,$$

β_2 is the current transmission coefficient of the base of transistor T_2, and I_{c_2} is the saturation current of the collector of transistor T_2.

The saturation condition for transistors T_3 and T'_3 is defined by the inequality

$$\frac{E_s}{\beta_3 (R_3 + R_6 + R_7)} - I_{co_3} \leqslant I_{b_3}, \tag{17}$$

where I_{b_3} is the base current of transistor T_3. We give this condition in expanded form:

$$r_b^2 \left(\frac{E_s}{\beta_3} - I_{co_3} r_a\right) \leqslant E_s (R_3 R_5 + R_6 R_2) - I_{co_2} R_2 R_5 r_a. \tag{17'}$$

By taking , in (14)-(17), the value of I_{co} which corresponds to the heightened temperature, we can arrive at equalities. A huge increase in the right members of (14)-(17) leads to a lowering of the circuit's sensitivity (cf. the Appendix).

When the pickup is used in the autooscillatory mode, the half-period of the autooscillation, with the conditions

$$R'_{14} = R'_{14} = \infty, \quad R_7 = 0, \quad R_1 = R'_1 = \infty$$

may be found approximately from the formula

$$T = \frac{CE_s}{I_{co_1} + I_{co_2}} \left[\frac{R_2 R_6 + R_3 R_8 + R_6 R_8}{(R_2 + R_8)(R_3 + R_6)}\right], \tag{18}$$

where I_{co_1} is the collector current of transistor $T_1(T'_1)$ at equilibrium, the deviations from which are approximately proportional to the relatively small deviations of the regulated voltage E_{reg}.

Experimental Investigation

The voltage-deviation pickup, designed in accordance with the formulas given above for the case of E_{reg} = 24 v and E_s = 27 v, was subjected to experimental investigation. The pickup's basic parameters are given in the caption of Fig. 1. Testing of the pickup in the temperature range from +20 to +60 °C showed that it reacted reliably to deviations of ± 1 volt. The output current in loads R_9 and R'_9 in the cutoff state for a temperature of +60 °C did not exceed 1 ma. The circuit operated reliably on an inductive load (a differential electromagnetic mechanism). With output stages of transistors P4D, the circuit was capable of a switching power of 200 w. The results of an investigation of the pickup in the proportional mode for a self-excitation frequency of 50 cps are shown in Fig. 5.

Conclusions

The theoretical and experimental investigation provided gives a foundation for concluding that the voltage deviation pickup constructed of semiconducting elements was efficiently developed. The essential advantages of the pickup described —its small weight and dimensions, the increased resistance to shock and vibration, the long useful service life, inherent in semiconducting elements—permit the expanding of the domain of applicability of voltage deviation pickups.

The author wishes to express his gratitude to B. S. Sotskov for his valuable advice on the execution of the present work.

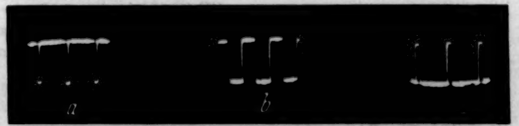

Fig. 5. Oscillograms of pickup output voltages with self-excitation. a is for E_{reg} = 24−0.15 v, b is for E_{reg} = 24 v, and c is for E_{reg} = = 24 + 0.15 v.

APPENDIX

Calculating the Sensitivity of a Relay Scheme

The sensitivity of a relay circuit is defined by the threshold values of controlling current for which the circuit transfers (operates).

In relay schemes constructed of transistors, the currents and voltages on the electrodes of these latter vary within such wide limits that there appear essential nonlinearities in the transistors' properties (cutoff region, saturation and nonlinear active region). However, for a broad class of transistor relay schemes, for definite threshold values of controlling current, it is not necessary to know in detail the nonlinear characteristics of the transistors. It suffices to know the characteristics in the neighborhoods of isolated points, corresponding to the moments of circuit transition points on the boundaries between the cutoff and saturation regions on the one hand, and the active region, on the other.

A nonlinear transistor can be presented as a linear "conditionally autonomous" three-pole (a four-pole with a short-circuited side) for the regions of cutoff and saturation, and also for two (or more) segments of the active region, for example, for the initial (close to the cutoff region) and for the final (close to the saturation region) segments.

Indeed, the behavior of a transistor for constant current in any form of connection (with common emitter, base, collector) is completely described by two nonlinear equations.

For the correspondingly chosen dependent and independent variables, there are six possible variants (systems) of equations. For example, for a circuit with a common emitter, the equations for the dependent base and collector currents have the form

$$I_b = Y_1(U_{eb}, U_{ec}), \quad I_c = Y_2(U_{eb}, U_{ec}),$$

where I_b is the base current, I_c is the collector current U_{eb} is the emitter-base voltage and U_{ec} is the emitter-collector voltage.

On any of the aforementioned segments (in the neighborhood of a point,), one can expand both functions in a Taylor series for two variables, and drop the terms for higher-order derivatives. For example , for the initial portion of the active domain,

$$I_b = \frac{\partial Y_1}{\partial U eb}(U_{eb} - U_{ebI}) + \frac{\partial Y_1}{\partial Y ec}(U_{ec} - U_{ecI}) +$$
$$+ Y_1(U_{ebI}, U_{ecI}), I_c = \frac{\partial Y_2}{\partial U_{eb}}(U_{eb} - U_{ebI}) +$$
$$+ \frac{\partial Y_2}{\partial U_{ec}}(U_{ec} - U_{ec\,I}) + Y_2(U_{ebI}, U_{ecI})$$

or

$$I_b = Y_{11I}U_{eb} + Y_{12I}U_{ec} + Y_{10I},$$
$$I_c = Y_{21I}U_{eb} + Y_{22I}U_{ec} + Y_{20I},$$

where Y_{11I} , Y_{12I}, Y_{21I} , and Y_{22I} are the nonautonomous transistor parameters for the transistor as a four-pole system of conductances for the initial active segment,

$$Y_{10I} = Y_1(U_{ebI}\ \ U_{ecI}) - (Y_{11I}U_{eb\,I} + Y_{12I}U_{ecI}),$$
$$Y_{20I} = Y_2(U_{eb\,I}\ \ U_{ecI}) - (Y_{21I}U_{eb\,I} + Y_{22I}U_{ec\,I})$$

are the "conditionally autonomous" parameters of the transistor as a four-pole for the initial active segment.

By using the well-known relationships for nonautonomous and autonomous parameters [3], one can rewrite the parameters obtained in any system of parameters and for any scheme for connecting the transistor. The parameters for the remaining segments are determined analogously.

A "conditionally autonomous" three-pole can be presented in the form of a nonautonomous three-pole (core) with external autonomous dipoles. Such a representation permits the use of the well-developed methods of analyzing schemes with nonautonomous multipoles [4].

By experimental measurements or by determining from static characteristics the aforementioned transistor parameters, one can replace the circuit of Fig. 1 by an equivalent linear replacement circuit including, together with dipoles, multipole elements and sources. The order of circuit design is as follows: For the first step, one determines the transmission coefficient of the portion of the circuit from E_{reg} to the output of the preamplifier R_1 and R'_1 may be grounded). The second step consists of the determination of the value of collector current of triode $T_1(T'_1)$ which is necessary to operate the relay output stages. For this, the transistors are replaced by "conditionally autonomous" three-poles. As a preliminary step, one determines the collectors' saturation currents, and removes outside the three-pole core the autonomous two-poles. Thereafter, the replacement circuit is constructed.

To determine one (negative) threshold value of the current applied to the input of triode T_2, it is sufficient to determine the magnitude of it for which the base current of cutoff triode T_2 becomes equal to the boundary base current at the beginning of the active portion; the value of this last current is determined from the triode's forward transmission characteristic.

To determine the second (positive) threshold value of current applied to the input of triode T_2, it is first necessary to find the value of base current of triode T_2 for which saturation of triode T'_2 occurs. For this, after disconnecting and grounding the left end of feedback resistor R_6 (Fig. 1), one sets up the matrix of conductances [Y] (or of impedances [Z]) by the method presented in [4]. By a well-known formula, one determines the current transmission factor from the base of T_2 to load R'_2:

$$K_I = \frac{\Delta_{12}}{\Delta_{22} + R'_2\Delta},$$

where Δ is the determinant of matrix [Y], and Δ_{12} and Δ_{22} are cofactors of the determinant [subscript 1 refers to the input (base of T_2) and subscript 2 refers to the output]. After this, one can determine the base current of triode T'_2 which corresponds to saturation of T'_2, and thereafter one finds the threshold value of the input current.

In our case, the problem is essentially simplified, since the circuit is symmetric and is controlled only by negative values of the input current, i.e., only one value of threshold current is determined.

We note that the method presented permits one to take into account the effect on relay sensitivity, not only of the transistors' nonlinearities, but also the temperature variations of their parameters. For this, it is necessary to know the transistor characteristics in the operating temperature range.

REGARDING THE THEORY OF THIRD-ORDER LINEAR SYSTEMS

Yu. G. Zarenin

(Kiev)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 3, pp. 417-419, March, 1960
Original article submitted September 28, 1959

The frequency properties of linear third-order systems are considered. The possible types of frequency characteristics are defined and the relationships which uniquely determine their form are found. The results of the investigation are illustrated by diagrams.

Many automatic control systems can be described by linear third-order differential equations with constant coefficients. In spite of this, the theory of third-order systems is still not completely worked out. In particular, there has not yet been obtained an exhaustive solution to the problem of investigating the frequency properties of these systems. The literature is lacking in statements concerning the possible types of amplitude-frequency characteristics for these systems, as well as any information as to how one might determine the exact number of extremal points of these characteristics (not to mention their coordinates), if the coefficients of the system's differential equation are known. Here, we attempt to fill this void.

The investigation of the amplitude-frequency characteristics of third-order systems is divided into three stages.

a) Determine the possible types of these characteristics. As the basis for classifying amplitude-frequency characteristics, it is convenient to take the number of their extremal points.

b) Elucidate the relationships by means of which one might analytically determine, from the form of the system's differential equation, the type of its frequency characteristic.

c) Define the abscissas of the extremal points of the system's amplitude-frequency characteristic in terms of the coefficients of its differential equation.

We write the differential equation of a third-order linear system in the form

$$(Ap^3 + Bp^2 + Cp + D)\varphi = \psi, \tag{1}$$

where p is the differentiation operator, φ is the instantaneous value of some physical quantity at the system's output which is of interest to us, ψ is the instantaneous value of the signal applied to the input and A, B, C, D are constant coefficients.

To obtain the simplest possible relationships in the sequel, it is convenient [1] to divide both sides of (1) by the coefficient of the highest-order derivative. Denoting the new coefficients thereby obtained by $\underline{a}$, $\underline{b}$, $\underline{c}$, and $\underline{d}$, we can write

$$(p^3 + ap^2 + bp + c)\varphi = d\psi. \tag{2}$$

With this, the equation of the amplitude-frequency characteristic has the form

$$K(\omega) = \left|\frac{d}{H(j\omega)}\right| = \frac{d}{\sqrt{(c - a\omega^2)^2 + (b\omega - \omega^3)^2}}. \tag{3}$$

The number of its extremal points equals the number of positive real roots of the first derivative with respect to ω of the radicand in the denominator of (3). After a single differentiation of this expression, we obtain a fifth-order polynomial which contains no free term; corresponding to this one may assert that the first extremum of a third-order system's frequency characteristic lies on the axis of ordinates. In addition to the root $\omega = 0$, the polynomial under consideration has four pairwise conjugate roots. By considering all these roots to be real, we arrive at the conclusion that the maximum possible number of extremal points of the system's amplitude-frequency characteristic equals three. The minimum number of extrema, realized in the case when all four of the aforementioned roots are imaginary, equals one.

Thus, for a third-order system only three types of frequency characteristics are possible (Fig. 1). The dashed lines show frequency characteristics which are, hypothetically, theoretically possible but which, in practice, are not realizable.

Let us consider in more detail the roots of the first derivative of the radicand expression. By differentiating this expression, and introducing the notation

$$b^2 - 2ac = N \text{ and } 2b - a^2 = R, \tag{4}$$

we obtain the polynomial

$$3\omega^5 - 2R\omega^3 + N\omega = 0, \tag{5}$$

the roots of which equal

$$\omega_1 = 0, \ \omega_{2,3,4,5} = \pm\frac{1}{\sqrt{3}}\sqrt{R \pm \sqrt{R^2 - 3N}}. \tag{6}$$

Discarding the roots less than zero, we obtain the abscissas of the extremal points of the system's amplitude-frequency characteristic:

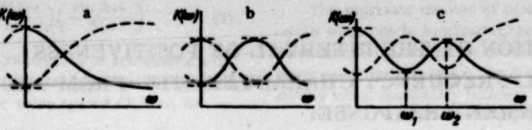

Fig. 1.

$$\omega_1 = 0, \quad \omega_2 = \frac{1}{\sqrt{3}}\sqrt{R+\sqrt{R^2-3N}} \text{ and } \omega_3 = \frac{1}{\sqrt{3}}\sqrt{R-\sqrt{R^2-3N}}. \tag{7}$$

The following conclusions derive from Expressions (7).

1. If N < 0 then, independently of the sign of R, frequency ω_3 is imaginary and ω_2 is real. The system's amplitude-frequency characteristic is a curve with two extrema—at the frequencies $\omega = \omega_1 = 0$ and $\omega = \omega_2$ (Fig. 1, b).

2. For N > 0 and R < 0, both frequencies ω_2 and ω_3 are imaginary. The amplitude-frequency characteristic has only one extremum —at the frequency $\omega = \omega_1 = 0$ (Fig. 1, a). The amplitude-frequency characteristic has the same form in the case when N > 0 and R > 0 but $R^2 < 3N$.

3. Frequencies ω_2 and ω_3 are both real only if the conditions N > 0, R > 0, and $R^2 > 3N$ all hold. With this, the amplitude-frequency characteristic has the form of a curve with extrema at the frequencies ω_1, ω_2, and ω_3 (Fig. 1, c).

The conclusions just drawn, together with (7), exhaust the problem of investigating the frequency properties of third-order systems.

For the practical use of these results, it is very convenient to employ a diagram with coordinates N and R (Fig. 2), on which the various hatchings indicate the regions corresponding to systems with various types of amplitude-frequency characteristics. Similar to those, like the well-known Vyshnegradskii diagram [1], which permit one, without solving equations, to judge of the stability and character of the transient response of a third-order system, the diagram of Fig. 2 gives a representation of its amplitude-frequency characteristic.

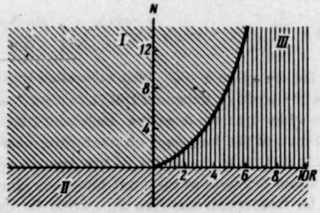

Fig. 2. I is the region of one extremum, II is the region of two extrema, and III is the region of three extrema.

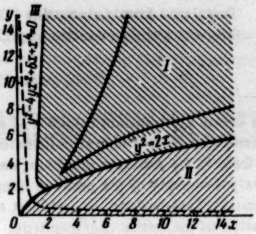

Fig. 3. I is the region of one extremum, II is the region of two extrema, and III is the region of three extrema.

It is interesting to note that the juxtaposition of the diagram proposed by us with the Vyshnegradskii diagram (Fig. 3) graphically illustrates the relationship between the character of a third-order system's transient response and the form of its amplitude-frequency characteristic.

This relationship is implicitly contained in the relationships obtained by Vyshnegradskii and in the relationships given in the present work and, if necessary, could easily be elucidated analytically.

DETERMINATION OF THE INTERVAL OF POSITIVENESS OF THE REAL FREQUENCY CHARACTERISTIC FROM THE GRAPH OF THE TRANSIENT RESPONSE

L. P. Shiniberov

(Leningrad)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 3, pp. 420-421, March, 1960
Original article submitted April 20, 1959

If one knows the transient response of a closed automatic control system to a unit step stimulus, then one may find from it, by a simple graphical construction, the boundary frequency of the positive interval of the real frequency characteristic ω_p without a detailed determination of the entire characteristic.

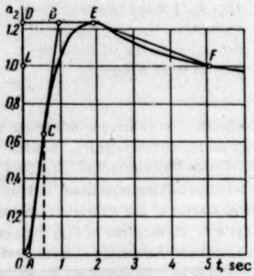

Fig. 1. Determination of ω_p from the graph of the transient response.

We assume that the curve of Fig. 1 is the transient response referred to for the output coordinate $\alpha_2 = f(t)$. On the figure we draw two auxiliary lines: line DE parallel to the axis of abscissas from the axis of ordinates to the maximum point of the transient response, and line AB, coinciding with the majority of points on the ascending (increasing) part of the transient response curve, from the axis of abscissas to line DE. We bisect line AB and find the value of time t_m which corresponds to the midpoint of this line (point C). Then, the boundary frequency of the positive interval can be determined from the formula

$$\omega_p = \frac{\pi}{2t_m}. \tag{1}$$

In the example given, $\omega_p = \pi/2(0.5) = 3.14\ \text{sec}^{-1}$, which is close to the true value of $\omega_p = 3.20\ \text{sec}^{-1}$.

We now prove the validity of the result obtained.

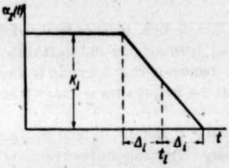

Fig. 2. Typical trapezoidal transient response.

We divide the curve of the transient response, given in Fig. 1, into three parts: 1) the unit step transient response $+1(t)$; 2) the positive trapezoid DEFL lying above the function $+1(t)$ with altitude $K_1 = DL$; 3) the negative trapezoid DBAO with altitude $K_2 = -OD$. From these trapezoidal characteristics it is possible to find the real frequency characteristic of the automatic control system. If we denote the elements of the trapezoidal characteristic as was done in Fig. 2, then in the given case the system's real frequency characteristic $R(\omega)$ will be expressed by the formula [1]

$$R(\omega) = \sum_{i=1}^{2} \left[K_i - \omega K_i t_i \left(\frac{\cos t_i \omega}{t_i \omega} \right) \left(\frac{\sin \Delta_i \omega}{\Delta_i \omega} \right) \right] + 1. \tag{2}$$

For the value $\omega = \omega_p$, this expression must vanish. Since the positive trapezoid DBEFL is always several times wider than the negative trapezoid DBAO, the maximum of the frequency characteristic constructed from it will lie in the region of low frequencies, and it will affect the form of the total frequency characteristic only for frequencies less than ω_p, while for frequencies close to ω_p or larger than ω_p, it will have a constant value, equal to K_1.

This means mathematically that, for frequencies $\omega > 5/t_1$, the term $\omega K_1 t_1 (\cos t_1 \omega / t_1 \omega)(\sin \Delta_1 \omega / \Delta_1 \omega)$ in (2) can be ignored, since it is significantly smaller than $0.1K_1$. Thus, in the neighborhood of frequency ω_p, the real frequency characteristic, when account is taken of the fact that $K_1 + K_2 + 1 = 0$, will be approximately expressed by the formula

$$R(\omega) = -\omega K_2 t_2 \left(\frac{\cos t_2\omega}{t_2\omega}\right)\left(\frac{\sin \Delta_2\omega}{\Delta_2\omega}\right). \qquad (3)$$

The curve for $R(\omega)$ constructed in accordance with (3) will pass through zero for the first time for $\cos t_2\omega / t_2\omega = 0$, which occurs for the value $t_2\omega = \pi/2$, i.e., for

$$\omega = \frac{\pi}{2t_m}, \quad \text{since} \quad t_2 = t_m$$

As is clear, the frequency $\omega = \pi/2t_m$ is the boundary frequency of the positive interval, i.e., (1) is valid.

The value of ω_p thus obtained may serve as an estimate of the cutoff frequency ω_c of the system's logarithmic amplitude characteristic since, as is well known, the logarithmic amplitude characteristic intersects the frequency axis for the values [2]

$$\omega_c = (0.55 - 0.7)\,\omega_p. \qquad (4)$$

The suggested method of determining ω_p gives good results when one is considering transient responses, either determined experimentally or stated as desirable, of power servo systems which are distinguished by comparatively small oscillatory indices; $M = 1.1$ to 1.4.

For other transfer functions, the error reaches 15 to 20 %, and this method can be used only for an approximate estimate of ω_p.

PROCESSING EXPERIMENTAL FREQUENCY CHARACTERISTICS

G. I. Monastyrshin

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 3, pp. 422-428, March, 1960
Original article submitted May 20, 1959

For recording forced oscillations, loop oscillographs are ordinarily used, recording both the stimulus and the reaction of the element. In those cases where the oscillations do not have a perfectly sinusoidal form, oscillogram processing is carried out by means of a harmonic analyzer which separates out the harmonic component of the reaction which has the same frequency as the stimulus; for brevity, we shall henceforth call it simply the reaction's harmonic component.

Figure 1 gives a set of oscillograms of a servo drive's oscillations, established under the action of sinusoidal stimuli of various frequencies and constant amplitudes. On these oscillograms, U is the stimulus and V is the servo drive's reaction. The oscillograms also bear the reaction's harmonic component. The cross on each oscillogram marks the maximum deviation of the servo drive's oscillation from the given harmonic component. We note that, in the example given, not only the sinusoidal character of the oscillation is disrupted, but, as is clear from Fig. 1, its periodicity is also disturbed to a certain extent, so that in the cases of Fig. 1, c and d the harmonic analysis is carried out over an interval of several (two) periods of the stimulus.

The results of the measurements are collected in the table, where ω_i is the angular frequency of the harmonic stimulus, A_i is the stimulus amplitude, B_i is the amplitude of the reaction's harmonic component, φ_i is the phase shift between the stimulus and the reaction's harmonic component and ΔB_i is the maximum deviation of the reaction from its harmonic component.

We remark that the table can be obtained without the intermediary of an oscillograph by means of direct measurements using the method cited in [1].

In what follows we shall not deal with any concrete form of the deviations of the forced oscillations from their harmonic components, but shall deal with the study abstractly, assuming that any character of these deviations is possible with limitations on the modulus of the ΔB_i. Corresponding to such a treatment, the forced oscillations are characterized, not by lines, but by the bands included between two sinusoids, equidistant from the harmonic component of the oscillation, and separated from it by the maximum deviation marked on the oscillograms.

By considering the reaction's harmonic component as the projection of the polar vector $\bar{B}_i$, we can interpret the deviations of actual oscillations from their harmonic components as the projections of an auxiliary vector $\Delta\bar{B}_i$, limited in modulus.

i	ω_i, sec.$^{-1}$	A_i, mm	B_i, mm	φ_i, degrees	ΔB_i, mm
1	3.123	31.0	20.95	— 47°20′	3
2	6.148	31.0	13.83	— 74°03′	4
3	12.45	31.0	7.36	—101°46′	3
4	25.13	31.0	3.61	—138°08′	5

If we abstract from the concrete definiteness of the rotation of this auxiliary vector we obtain, instead of the end of the vector $\bar{B}_i$, a circular smear with radius ΔB_i.

The vector interpretation allows one to note that when $\Delta B_i \ll B_i$ (for our purposes, it suffices in practice if $\Delta B_i < 0.5\,B_i$) the ratio $\Delta B_i : B_i$ is determined approximately both by the maximum relative variation of the harmonic component's amplitude and by the maximum variation of its phase (measured in radians) for which the harmonic oscillations will remain within the limits of the smear defined earlier or, what amounts to the same thing, within the limits of the forced oscillations' bands. In this sense, instead of the lines of the frequency, amplitude and phase characteristics, one can consider the bands of the amplitude and phase characteristics. Figure 2 shows such bands, constructed from the oscillograms of Fig. 1. In the neighborhood of the frequency 4 cps, the bands of the phase characteristic are not bounded, due to the fact that the condition on the smallness of ΔB_i does not hold.

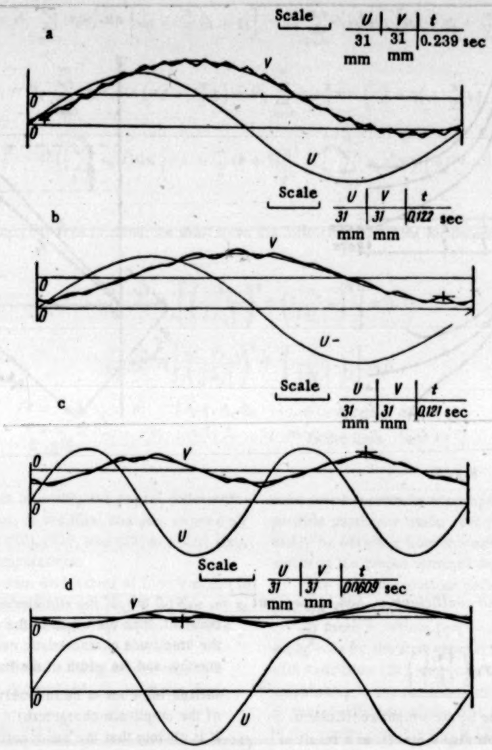

Fig. 1.

In using an element's experimental frequency characteristic, it may turn out to be advantageous to define the system by the differential equation corresponding to these characteristics [2-6]. For example, the problem arises in mathematical modelling of setting up the scheme which reproduces the frequency characteristics.

We assume that the linear differential equation defined by the experimental frequency characteristics has the form

$$\sum_{k=0}^{n} a_k U^{(k)} = \sum_{k=0}^{m} b_k V^{(k)}, \qquad (1)$$

where the $U^{(k)}$ are the stimulus and its derivatives, and the $V^{(k)}$ are the reaction and its derivatives.

As represented on the oscillograms, the stimulus U_1 and the reaction's harmonic component V_1 may be written in the form

$$U_1 = A_1 \sin \omega_1 t, \qquad (2)$$

$$V_1 = B_1 \sin (\omega_1 t + \varphi_1). \qquad (3)$$

To determine the numerical values of the coefficients a_k and b_k of (1), we use the approximate equation obtained by substituting (2) and (3) in (1):

$$\sum_{k=0}^{n} a_k A_1 \omega_1^k \sin\left(\omega_1 t + \frac{\pi}{2} k\right) \approx \sum_{k=0}^{m} b_k B_1 \omega_1^k \sin\left(\omega_1 t + \varphi_1 + \frac{\pi}{2} k\right). \qquad (4)$$

To provide a graphic representation, we denote the left and right members of (4) by polar vectors $\overline{R}_1$ and $\overline{S}_1$ (Fig. 3).

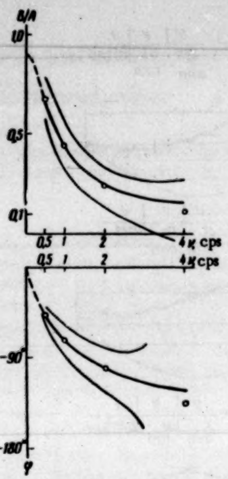

Fig. 2.

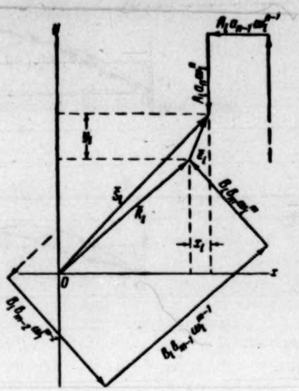

Fig. 3.

To find the unknown coefficients a_k and b_k, we start from the condition

$$\min \sum_i p_i \left(\frac{|\bar{\varepsilon}_i|}{|\bar{R}_i|} \right)^2, \tag{5}$$

where $\bar{\varepsilon}_i = \bar{S}_i - \bar{R}_i$ and the p_i are weight coefficients.

It is easily seen from Fig. 3 that if, as a result of seeking the values of the coefficients of (1), the vectors $\bar{\varepsilon}_i$ lie within the limits of certain circular smears whose radii are in the same ratios to the moduli of vectors $\bar{R}_i$ as the ΔB_i are to the B_i, then the forced oscillations defined by (1), with the values found for the coefficients, lie within the limits of the bands considered earlier.

In correspondence with this, by setting the requirements on the accuracy of the approximation of the frequency characteristics, and omitting the arbitrary coefficient of proportionality, we establish the weight coefficients:

$$p_i = \left(\frac{B_i}{\Delta B_i} \right)^2. \tag{6}$$

If in (6), instead of the quantities ΔB_i, which depend on the frequency of the forced oscillations, we use the quantity $\max \Delta B_i$ and omit the constant factor thereby entailed, then

$$p_i = B_i^2. \tag{7}$$

With this, if the stimulus amplitude is taken to be constant, then the width of the corresponding band of the amplitude characteristic ceases to depend on frequency, and the width of the band of the phase characteristic turns out to be inversely proportional to the value of the amplitude characteristic (for sufficiently small ΔB_i). It is obvious that the bands corresponding to (6) lie inside the bands defined by (7).

We note that (5) for $|\bar{\varepsilon}_i| \ll |\bar{R}_i|$, as may be observed from Fig. 3, is equivalent to the condition

$$\min \sum_i p_i (\Delta_i^2 + \delta_i^2), \tag{8}$$

where the Δ_i are the absolute deviations of the phase characteristic of (1) from the experimental one, measured in radians, and the δ_i are the relative deviations of the amplitude characteristic of (1) from the experimental.

For what follows, it is advantageous to give (5) in the form

$$\min \sum_i p_i \left[\left(\frac{x_i}{|\bar{R}_i|} \right)^2 + \left(\frac{y_i}{|\bar{R}_i|} \right)^2 \right]. \tag{9}$$

where x_i and y_i are the projections of vector $\bar{\varepsilon}_i$.

It is easily seen that

$$x_i = A_i \sum_{k=0}^{n} a_k \omega_i^k \sin\left[\omega_i t + \frac{\pi}{2}(k+1)\right] - B_i \sum_{k=0}^{m} b_k \omega_i^k \sin\left[\omega_i t + \varphi_i + \frac{\pi}{2}(k+1)\right], \tag{10}$$

$$y_i = A_i \sum_{k=0}^{n} a_k \omega_i^k \sin\left(\omega_i t + \frac{\pi}{2}k\right) - B_i \sum_{k=0}^{m} b_k \omega_i^k \sin\left(\omega_i t + \varphi_i + \frac{\pi}{2}k\right), \tag{11}$$

$$\bar{R}_i|^2 = A_i^2\left(\left\{\sum_{k=0}^{n} a_k \omega_i^k \sin\left[\omega_i t + \frac{\pi}{2}(k+1)\right]\right\}^2 + \left[\sum_{k=0}^{n} a_k \omega_i^k \sin\left(\omega_i t + \frac{\pi}{2}k\right)\right]^2\right). \tag{12}$$

With (10), (11), and (12) kept in mind, we shall have the following equations for determining the coefficients sought:

$$\begin{gathered}\frac{\partial}{\partial a_k}\sum_i p_i\left[\left(\frac{x_i}{|\bar{R}_i|}\right)^2 + \left(\frac{y_i}{|\bar{R}_i|}\right)^2\right] = 0, \\ \frac{\partial}{\partial b_l}\sum_i p_i\left[\left(\frac{x_i}{|\bar{R}_i|}\right)^2 + \left(\frac{y_i}{|\bar{R}_i|}\right)^2\right] = 0 \\ \begin{pmatrix} k = 1, 2, \ldots, n; & l = 0, 1, 2, \ldots, m \text{ in the case } a_0 = 1 \\ k = 0, 1, 2, \ldots, n; & l = 1, 2, \ldots, m \text{ in the case } b_0 = 1 \end{pmatrix}.\end{gathered} \tag{13}$$

Since the quantities following the partial differentiation signs in (13) do not, in the final analysis, depend on t, one can set t = 0 in (10), (11), and (12) as a first step, thus simplifying the computations.

If (1) does not contain derivatives of U or V then (13) will be linear since, in the first case, $|\bar{R}_i| = A_i$ (we set a_0 equal to unity) and, in the second, $|\bar{R}_i| \approx |\bar{S}_i| \doteq B_i$ (we set b_0 equal to unity).

Otherwise, the coefficients being sought can, to a first approximation, be determined, for example, from the condition

$$\min \sum_i |\bar{s}_i|^2. \tag{14}$$

To render more exact the solution thus obtained one might determine the quantities $|\bar{R}_i|$ graphically from the vector diagram or by (12) for t = 0 and the numerical values of the coefficients of the first approximation, where for the differentiation of the fractions in (13), one differentiates only the numerator (as in the case when the denominator does not depend on the parameter with respect to which the differentiation is being performed), which is possible if the numerator is sufficiently small with respect to the denominator.

Omitting the detailed computations, we give the final expressions determining the coefficients of the equation

$$\begin{aligned} U + a_1\dot{U} + a_2\ddot{U} + a_3U^{(3)} + a_4U^{(4)} + a_5U^{(5)} = \\ = b_0V + b_1\dot{V} + b_2\ddot{V} + b_3V^{(3)} + b_4V^{(4)} + b_5V^{(5)}. \end{aligned} \tag{15}$$

In terms of this example, we consider the structure of the formulation which permits one to obtain the analogous formulas for any more complicated case. The case considered apparently encompasses all practically possible particular cases. All these particular cases may easily be obtained from the one considered by simply omitting the proper terms of the expressions provided.

The normal equations defining the coefficients of (15) are given by (16).

In these equations, $p_i k_i^2 = 1$ (it is also possible to set $k_i^2 = 1$) for the first approximation in correspondence with condition (14), and may thereafter be determined graphically in the rendering more accurate of the solution by the coefficients of the first approximation by means of the vector diagram ($k_i^2 = |\bar{R}_i|^{-2}$) or by

$$\begin{aligned} k_i^2 = A_i^{-2}[(a_1\omega_i - a_3\omega_i^3 + a_5\omega_i^5)^2 \\ + (1 - a_2\omega_i^2 + a_4\omega_i^4)^2]^{-1}. \end{aligned} \tag{17}$$

For simpler cases it suffices, in (16), to delete the columns, and the rows symmetric with them about the principal diagonal in the matrix of the unknown coefficients, for the coefficients of the higher derivatives which are lacking in (15). The corresponding terms in (17) are also omitted. In the particular case when there are no derivatives in the left member of (15), there remain only the last six columns of the left side of (16) and, correspondingly, only the six last equations $k_i^2 = A_i^{-2}$, and the problem is significantly simplified. If there are no derivatives in the right member of (15), it is then advantageous to change the problem slightly, setting $b_0 = 1$ and taking a_0 as an unknown. In this case, the simplified normal equations obtained from (16) are analogous to the preceding ones if one first makes the following changes in (16): the b_k are replaced by the

$$
\begin{array}{rrrrrrrrrrrcl}
+a_1 \sum_i c_i\omega_i^2 & & -a_3 \sum_i c_i\omega_i^4 & & +a_5 \sum_i c_i\omega_i^6 & -b_0 \sum_i d_i\omega_i & -b_1 \sum_i e_i\omega_i^2 & +b_2 \sum_i d_i\omega_i^3 & +b_3 \sum_i e_i\omega_i^4 & -b_4 \sum_i d_i\omega_i^5 & -b_5 \sum_i e_i\omega_i^6 & = & 0 \\

-a_1 \sum_i e_i\omega_i^2 & -a_2 \sum_i d_i\omega_i^3 & +a_3 \sum_i e_i\omega_i^4 & +a_4 \sum_i d_i\omega_i^5 & -a_5 \sum_i e_i\omega_i^6 & & +b_1 \sum_i f_i\omega_i^2 & & -b_3 \sum_i f_i\omega_i^4 & & +b_5 \sum_i f_i\omega_i^6 & = & -\sum_i d_i\omega_i \\
a_1 \sum_i d_i\omega_i^3 & -a_2 \sum_i e_i\omega_i^4 & -a_3 \sum_i d_i\omega_i^5 & +a_4 \sum_i e_i\omega_i^6 & +a_5 \sum_i d_i\omega_i^7 & -b_0 \sum_i f_i\omega_i^2 & & +b_2 \sum_i f_i\omega_i^4 & & -b_4 \sum_i f_i\omega_i^6 & & = & -\sum_i e_i\omega_i^2 \\
a_1 \sum_i e_i\omega_i^4 & +a_2 \sum_i d_i\omega_i^5 & -a_3 \sum_i e_i\omega_i^6 & -a_4 \sum_i d_i\omega_i^7 & +a_5 \sum_i e_i\omega_i^8 & & -b_1 \sum_i f_i\omega_i^4 & & +b_3 \sum_i f_i\omega_i^6 & & -b_5 \sum_i f_i\omega_i^8 & = & \sum_i d_i\omega_i^3 \\
-a_1 \sum_i d_i\omega_i^5 & +a_2 \sum_i e_i\omega_i^6 & +a_3 \sum_i d_i\omega_i^7 & -a_4 \sum_i e_i\omega_i^8 & -a_5 \sum_i d_i\omega_i^9 & +b_0 \sum_i f_i\omega_i^4 & & -b_2 \sum_i f_i\omega_i^6 & & +b_4 \sum_i f_i\omega_i^8 & & = & \sum_i e_i\omega_i^4 \\
-a_1 \sum_i e_i\omega_i^6 & -a_2 \sum_i d_i\omega_i^7 & +a_3 \sum_i e_i\omega_i^8 & +a_4 \sum_i d_i\omega_i^9 & -a_5 \sum_i e_i\omega_i^{10} & & +b_1 \sum_i f_i\omega_i^6 & & -b_3 \sum_i f_i\omega_i^8 & & +b_5 \sum_i f_i\omega_i^{10} & = & -\sum_i d_i\omega_i^5
\end{array}
$$

where $c_i = p_i k_i^2 A_i^2$; $d_i = p_i k_i^2 A_i B_i \sin\varphi_i$; $e_i = p_i k_i^2 A_i B_i \cos\varphi_i$; $f_i = p_i k_i^2 B_i^2$. (16)

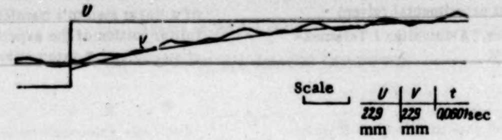

Fig. 4.

a_k and the a_k are replaced by the b_k and, in the expressions for the coefficients c_i, d_i, e_i, and f_i, A_i is replaced by B_i, B_i is replaced by A_i, φ_i is replaced by $-\varphi_i$ and the k_i^2 are defined as B_i^{-2}. One should then retain the six last equations and, correspondingly, the six last columns of the left members of these equations, determining the p_i by (6) or (7).

If, as a result of the computation of the coefficients of (15), the difference between its frequency characteristics and the experimental ones, defined by the harmonic components of the actual oscillations, turns out to be sufficiently small - for example, significantly less than the possible deviations inside the previously defined bands of the forced oscillations - we shall then consider that the problem of determining the linear equation which approximates the experimental frequency characteristics has been successfully solved.

In the concrete example considered, given by Figs. 1 and 2 and by the table, we are investigating an equation of the form

$$U + a_1\dot{U} = b_0 V + b_1\dot{V}, \tag{18}$$

for which we shall have the normal equations

$$\begin{gathered}
a_1 \sum_i p_i k_i^2 A_i^2 \omega_i^2 - \\
- b_0 \sum_i p_i k_i^2 A_i B_i \omega_i \sin\varphi_i - b_1 \sum_i p_i k_i^2 A_i B_i \omega_i^2 \cos\varphi_i = 0. \\
- a_1 \sum_i p_i k_i^2 A_i B_i \omega_i \sin\varphi_i + b_0 \sum_i p_i k_i^2 B_i^2 = \\
= \sum_i p_i k_i^2 A_i B_i \cos\varphi_i, \\
- a_1 \sum_i p_i k_i^2 A_i B_i \omega_i^2 \cos\varphi_i + \\
+ b_1 \sum_i p_i k_i^2 B_i^2 \omega_i^2 = - \sum_i p_i k_i^2 A_i B_i \omega_i \sin\varphi_i
\end{gathered} \tag{19}$$

Setting the p_i by (6) and taking, in correspondence with (17),

$$k_i^2 = A_i^{-2}(a_1^2\omega_i^2 + 1)^{-1} \tag{20}$$

we obtain, as the result of computing the first and second approximations and the corresponding rounding,

$$a_1 = -0.034, \quad b_0 = 1.11, \quad b_1 = 0.325.$$

The corresponding frequency characteristic is given in Fig. 2. The circles on the figure mark the experimental points, while the heavy lines show the results of the approximation.

It should not be overlooked that the frequency characteristics considered can not determine all the properties of the actual element. Due to this, the question as to the use of such a type of characteristics, and the equations approximating them, can form the subject of a concrete study.

For the example considered, Fig. 4 shows the reaction to a unit step function stimulus, obtained from (18) by computing the values of the coefficients, and the analogous reaction of the actual servo drive.

It may happen that, in practice, one does not succeed in obtaining a sufficiently small error of approximation of the experimental frequency characteristics. For example, these errors may remain beyond the limits of the experimentally defined bands of the forced oscillations. In this case, the question as to the possibility of using the results of the approximation can be decided by fixing the band of the forced oscillations in correspondence with the approximation errors obtained.

We note that a treatment analogous to that presented here is also possible in the case when the experimental results are free from nonlinear deviations, and only measurement errors distort them.

INFORMATION

THE ÉMU-8 ELECTRONIC ANALOG COMPUTER

As the result of the work on improving electronic analog computers and their elements which has been carried on at the Institute for Automation and Remote Control of the Academy of Science of the USSR in conjunction with a collective under the direction of G. N. Grigor'yan, there has been created a new electronic analog computer, type ÉMU-8, production of which has already begun.

Domain of Application of Type ÉMU-8 Electronic Analog Computer

The type ÉMU-8 electronic analog computer is designed for the investigation of linear and nonlinear dynamic systems. Structurally, it is a general-purpose computer capable of real-time operation (joined with elements of actual apparatus) with accelerated and retarded solution processes within the limits of its passband. The computer can be used to greatest effect in the solution of technological problems where the error in giving the original parameters is sufficiently large (from 5 to 10%).

Among these problems may be listed:

1) investigation of the dynamics of automatic control and regulation systems (automated systems, missile control, boiler aggregate regulation, steam turbine control, various automated electric drives, etc.);

2) certain problems of nuclear physics and technology;

3) investigation of combustion processes in internal-combustion engines;

4) investigation of transient responses in complicated electrical circuits;

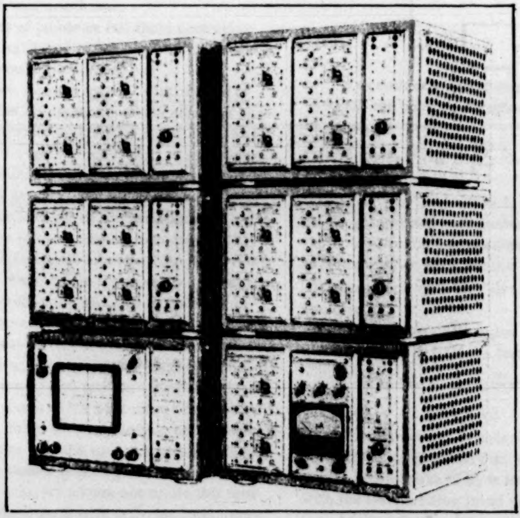
5) investigations in the area of nonlinear mechanics.

Brief Technical Characteristics of the ÉMU-8*

The ÉMU-8 computer consists of individual building blocks each of dimensions 450 x 460 x 320 mm. Each building block can provide the solution of linear and nonlinear differential equations up to second-order, inclusive.

---

* For more detailed technical characteristics of the computer plus its functional schematic, see Vestnik Akademii Nauk No. 7 (1958).



while the standard package of building blocks provides solutions of differential equations up to tenth-order, inclusive. Plug-in units permit the execution of the following mathematical operations: multiplication and division of two independent variables, multiplication by a constant factor, differentiation, integration, reproduction of various nonlinear functions and standard nonlinearities.

The character of the mathematical operations executed is determined by the type of plug-in units, which allows operational amplifiers to be used economically.

By choosing several building blocks with the necessary variants of plug-in units, one can solve problems of various complexity.

In the standard package, five building blocks are used.

Six block indicators are connected to each package to provide visual observation of problem solution.

Each building block is designed in the form of a completely independent instrument, and may be connected directly to a 220v line. The power requirement of each block is about 160w.

Line production of the computer was organized in 1960. The wholesale price of a package is 135,000 rubles.

ANALYTICAL CONTROLLER DESIGN. I

A. M. Letov

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 4, pp. 436-441, April, 1960
Original article submitted December 23, 1959

A solution is presented for the problem of analytical controller design in accordance with a given optimizing functional. The solution is given for the open region of definition of the system's differential equations. The cases of closed regions are worked out in Parts II and III of the present work, which are to be published in succeeding numbers of this journal.

1. Two Classes of Problems in Optimal System Theory

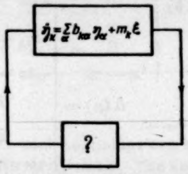
The construction of optimal systems leads to the solution of the allied mathematical problems, which are divided into two classes. The first of these is comprised of those problems which are related to the determination and calculation of the undisturbed modes of motion. Here, one has to do with those programs of automatic control for which the given undisturbed motion possesses the requisite extremal properties. We shall call such systems optimal with respect to control mode.

Systems for which the concept of optimality connotes the arrival at a given state in minimal time we shall find it convenient to call brachistochrone.

In the other class of problems fall those controllers which guarantee the existence of given properties of the disturbed motions (transient processes).

We shall call such systems optimal with respect to transient response. The set consisting of the object of control, the optimal programming element, and the optimal controller comprises an optimal automatic control system. In both cases the optimization problem can be treated as a two-point boundary problem, for the solution of which one may apply all the methods of the variational calculus and, in particular, the latest methods, developed in [1-7]. However, certain differences do exist between these two classes of problems. Thus, in the first case, the problem's solution is obtained in the form of a known function of time, which then becomes the basis for the design of the programming elements. In the second case, the analytical form of the control law appears as some function of the original coordinates of the control system, i.e., the problem consists of the construction of the controller's differential equation. Of course, the process of analytic controller construction is nothing else than the synthesis process. In particular, the synthesis process is here given the same meaning as in [1-5]. However, we choose not to use this term since many other authors use it with differing interpretations. On the other hand, the equivalent terminology "analytic construction" must suggest itself more strongly to engineers, since this terminology implies merely the search, by means of the tools of mathematical analysis, for the form of the controller's differential equation which will answer to the accepted criterion of optimality. In the present paper we consider the problem of the analytical construction (design) of optimal systems which are defined in open regions. In the succeeding papers we shall deal with the same problem as formulated for closed regions.

2. Initial Posing of the Analytical Design Problem



$\dot{\eta}_k = \sum_\alpha b_{k\alpha}\eta_\alpha + m_k\xi$
?

We consider a closed controlled system (cf. Fig. 1) in which the object's disturbed motion is given by the set of equations

$$g_k = \dot{\eta}_k - \Big(\sum_\alpha b_{k\alpha}\eta_\alpha + m_k\xi\Big) = 0 \qquad (2.1)$$

$$(k = 1, \ldots, n)$$

in the generalized coordinates η_k, while the equation of the controller for the coordinate ξ remains unknown. For definiteness, we shall assume that all the $b_{k\alpha}$ and m_k are given constants on which no restraints have as yet been imposed.

Let N be the open region in which (2.1) are given; any conditions in N of the form

$$\eta_1(0) = \eta_{10}, \ldots, \eta_n(0) = \eta_{n0}, \quad \xi(0) = \xi_0, \qquad (2.2)$$

$$\eta_1(\infty) = \ldots = \eta_n(\infty) = \xi(\infty) = 0$$

we shall call natural boundary conditions of the problem. They mean simply this, that whatever the transient response which arises in N, it must terminate, for t = ∞, with the system being found at the origin of coordinates.

As the criterion for system optimality, we choose the integral

$$I(\xi) = \int_0^\infty V\,dt \qquad (2.3)$$

of the positive definite quadratic form

$$V = \sum_k a_k \eta_k^2 + c\xi^2. \tag{2.4}$$

We shall seek such continuous functions $\xi, \eta_1 \ldots \eta_n$ (class C_1) with continuous first derivatives which give the integral in (2.3) a minimum value. The existence and uniqueness of the solution of this problem were proven in [7]. We now give ourselves the task of determining the form of this solution as well as the possibilities of using it for the purpose of an analytic design. The integral $I(\xi)$ is a functional defined on class C_1 of functions, and its value characterizes the integral of the squared error, weighted by the constants a_k and c, which the system will have in the course of the transient response lasting until t • = ∞. The problem consists in writing in analytic form

$$F(\dot{\xi}, \xi, \eta_1, \ldots, \eta_n) = 0 \tag{2.5}$$

the control law which, in conjunction with (2.1), will form a stable system and will guarantee the existence of a minimum for the integral in (2.3).

3. Solution of the Problem

We are dealing with the Lagrange variational problem, the procedures for the solution of which are very well known. Specifically, we first set up the function

$$H = V + \sum_k \lambda_k g_k, \tag{3.1}$$

where the λ_k are arbitrary multipliers.

Then,

$$\frac{\partial H}{\partial \dot{\eta}_k} = \lambda_k, \quad \frac{\partial H}{\partial \eta_k} = 2a_k\eta_k - \sum_\alpha \lambda_\alpha b_{\alpha k}; \quad \frac{\partial H}{\partial \dot{\xi}} = 0,$$
$$\frac{\partial H}{\partial \xi} = 2c\xi - \sum_\alpha m_\alpha \lambda_\alpha. \tag{3.2}$$

The equations of the variational problem have the form

$$\dot{\lambda}_k = -\sum_j b_{jk}\lambda_j + 2a_k\eta_k, \quad 0 = 2c\xi - \sum_j m_j\lambda_j. \tag{3.3}$$

To these, (2.1) should be adjoined.

The further steps in the procedure for analytic design (excluding singular cases) are as follows:

1. The equations of the variational problem must be solved jointly for the functions η_k and λ_k.

Let

$$\Delta(\mu) = \begin{vmatrix} b_{11} - \mu, \ldots, & b_{1n}, & \frac{m_1^2}{2c}, \ldots, & \frac{m_1 m_2}{2c} \\ \cdots & \cdots & \cdots & \cdots \\ b_{n1}, \ldots, & b_{nn} - \mu, & \frac{m_n m_1}{2c}, \ldots, & \frac{m_n^2}{2c} \\ 2a_1, \ldots, & 0, & -b_{11} - \mu, \ldots, & -b_{n1} \\ \cdots & \cdots & \cdots & \cdots \\ 0, \ldots, & 2a_n, & -b_{1n}, \ldots, & -b_{nn} - \mu \end{vmatrix} \tag{3.4}$$

be the system's characteristic determinant. It is easily proven that, if $\mu_1, \ldots, \mu_n$ are simple roots of the equation $\Delta(\mu) = 0$, then the numbers $-\mu_1, \ldots, -\mu_n$ are also simple roots. We assume that $\mu_1, \ldots, \mu_n$ are simple roots, $\mathrm{Re}\,\mu_k \neq 0$, and the roots are numbered in accordance with the inequalities

$$\mathrm{Re}\,\mu_k < 0 \quad (k = 1, \ldots, n). \tag{3.5}$$

This latter step is always possible by virtue of the aforementioned property of determinant (3.4). The general solution of the equations of the problem will consist of a linear combination of exponential functions of the form $c_k e^{\mu_k t}$ and $c_{n+k} e^{-\mu_k t}$ $(k = 1, \ldots, n)$, and will contain 2n arbitrary constants

$$c_1, \ldots, c_n, c_{n+1}, \ldots, c_{2n}.$$

2. By virtue of (2.2)• at infinity we set

$$c_{n+k} = 0 \ (k = 1, \ldots, n)$$

where the constants c_k can be chosen from the initial conditions. However, this operation is not necessary.

3. In the remaining 2n formulas which define the functions $\eta_1, \ldots, \eta_n, \lambda_1, \ldots, \lambda_n$, we eliminate the n functions of time $c_k e^{\mu_k t}$, as a result of which we find that

$$\lambda_j = \sum_\alpha \Delta_{j\alpha}\eta_\alpha \quad (j = 1, \ldots, n), \tag{3.6}$$

where the $\Delta_{j\alpha}$ are completely defined constants.

4. We substitute the values found for the λ_j in the last equation of (3.3), thus finding the controller's equation

$$\xi = p_1\eta_1 + p_2\eta_2 + \ldots + p_n\eta_n. \tag{3.7}$$

It remains to verify that (3.7), in conjunction with the initial equations (2.1), forms a stable† automatic control system. This verification is easily carried out. Indeed, the optimal system found has a general solution which is a linear combination of the exponential functions $c_k e^{\mu_k t}$ $(k = 1, \ldots, n)$. Consequently, the numbers μ_k $(k = 1, \ldots, n)$ are the roots of the characteristic equation of system (2.1), (3.7). We obtained ideal controller (3.7) with rigid feedback and with an infinitely fast servomotor [8]. Thus, we arrive at the conclusion that functionals like (2.3) lead to controllers which can not be realized.

4. Possible Generalizations of Functional (2.3)

We now consider an indefinite quadratic form such as

$$T = \sum_k \sum_j c_{kj}\eta_k\eta_j + \xi^2 \qquad (4.1)$$

and repeat the formulation of the Lagrange problem for the functional

$$I(\xi) = \int_0^\infty (T + V)\, dt.$$

The value of the functional $I(\xi)$ characterizes the integral of the squared position and velocity errors which the system will have in the course of the transient response lasting until $t^* = \infty$.

We remark that the solution of the problem may be simplified by eliminating the derivatives $\dot\eta_k$ in accordance with the original equations. It is reasonable, therefore, to consider first the simpler functional of the form

$$I(\xi) = \int_0^\infty (V + \dot\xi^2)\, dt. \qquad (4.2)$$

The computation will differ from the foregoing only in that now the expression $\partial H/\partial \dot\xi = 2\ddot\xi$ and does not equal zero. Therefore, instead of the last equation of (3.3), we get

$$2\ddot\xi = 2c\xi - \sum_j m_j\lambda_j. \qquad (4.3)$$

This equation, in conjunction with (2.1) and the first n equations of (3.3), solves the given problem. The solution procedure reduces to the implementation of the following operations:

1. The equations of the problem must be solved for the functions η_k, λ_k and ξ.

Let

$$\overline{\Delta}(\mu) = \begin{vmatrix} b_{11}-\mu, \ldots, & b_{1n}, & 0, \ldots, & 0, & m_1 \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ b_{n1}, \ldots, & b_{nn}-\mu, & 0, \ldots, & 0, & m_n \\ 2a_1, \ldots, & 0, & -b_{11}-\mu, \ldots, & -b_{n1}, & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ 0, \ldots, & 2a_n, & -b_{1n}, \ldots, & -b_{nn}-\mu, & 0 \\ 0, \ldots, & 0, & -m_1, \ldots, & -m_n, & 2c-\mu^2 \end{vmatrix} \qquad (4.4)$$

be the system's characteristic determinant. As in the case of (3.4), it possesses the property that $\overline{\Delta}(\mu) = \overline{\Delta}(-\mu)$. Therefore, the equation $\Delta(\mu) = 0$ will have the roots $\mu_1, \ldots, \mu_{n+1}$ (which we assume to be simple), with the property enunciated by (3.5), plus the roots $-\mu_1, \ldots, -\mu_{n+1}$. The system's general solution will consist of a linear combination of exponential functions of the form $c_k e^{\mu_k t}$ and $c_{n+1+k} e^{-\mu_k t}$ ($k = 1, \ldots, n+1$) and will contain $2n+2$ arbitrary constants.

2. By virtue of (2.2) at infinity we set $c_{n+1+k} = 0$ ($k = 1, \ldots, n+1$). The remaining constants can be determined from the initial conditions.

3. We now take the solution found for the function ξ. In the $n+2$ formulas found for the functions $\eta_1, \ldots, \eta_n$, ξ and $\dot\xi$, we eliminate the functions of time $c_1 e^{\mu_1 t}, \ldots, c_{n+1} e^{\mu_{n+1} t}$, as a result of which we find the controller's equation

$$\dot\xi = \sum_\alpha p_\alpha \eta_\alpha - r\xi. \qquad (4.5)$$

Here, the p_α and r are completely defined constants, determined in the course of implementing the enumerated operations. In conjunction with (2.1), (4.5) forms a stable optimal system. The stability, as in the previous case, is a consequence of the fact that the numbers $\mu_1, \ldots, \mu_{n+1}$ are roots of the optimal system's characteristic equation.

In contradistinction to the solution of Section 3, we obtained a linear controller with a limited variable servomotor speed. Such controllers can be realized if the region N is sufficiently small. The analytic design procedure in the case when the motion of the system is in a closed region N, when the optimal solution can be found on the region's boundary, will be considered in the subsequent papers.

5. Examples

For a first-order system, the equations of the variational problem will be

$$\dot\eta = b\eta + m\xi, \quad \dot\lambda = -b\lambda + 2a\eta, \quad 2\ddot\xi = 2c\xi - m\lambda. \qquad (5.1)$$

To these there correspond the characteristic equation

$$\mu^4 - (b^2 + c)\mu^2 + am^2 + cb^2 = 0 \qquad (5.2)$$

and the solution

$$\eta = c_1 e^{\mu_1 t} + c_2 e^{\mu_2 t},$$

$$\xi = \frac{\mu_1 - b}{m} c_1 e^{\mu_1 t} + \frac{\mu_2 - b}{m} c_2 e^{\mu_2 t}, \qquad (5.3)$$

$$\dot\xi = \frac{\mu_1(\mu_1 - b)}{m} c_1 e^{\mu_1 t} + \frac{\mu_2(\mu_2 - b)}{m} c_2 e^{\mu_2 t}.$$

The controller's equation has the form

$$\begin{vmatrix} 1 & 1 & \eta \\ \dfrac{\mu_1 - b}{m} & \dfrac{\mu_2 - b}{m} & \xi \\ \dfrac{\mu_1(\mu_1 - b)}{m} & \dfrac{\mu_2(\mu_2 - b)}{m} & \dot\xi \end{vmatrix} = 0$$

or, in expanded form,

$$\dot{\xi} = -\frac{(\mu_1 - b)(\mu_2 - b)}{m}\eta + (\mu_1 + \mu_2 - b)\xi. \quad (5.4)$$

For a second example, we consider the second-order system

$$\dot{\eta}_1 = b_{11}\eta_1 + b_{12}\eta_2 + m_1\xi, \quad \dot{\eta}_2 = b_{21}\eta_1 + b_{22}\eta_2 + m_2\xi. \quad (5.5)$$

To obtain the equations of the yariational problem, we must append

$$\begin{aligned} \dot{\lambda}_1 &= -b_{11}\lambda_1 - b_{21}\lambda_2 + 2a_1\eta_1, \\ \dot{\lambda}_2 &= -b_{12}\lambda_1 - b_{22}\lambda_2 + 2a_2\eta_2, \\ 2\ddot{\xi} &= 2c\xi - m_1\lambda_1 - m_2\lambda_2. \end{aligned} \quad (5.6)$$

The characteristic equation has the form

$$\bar{\Delta}(\mu) = \begin{vmatrix} b_{11} - \mu, & b_{12} & 0, & 0, & m_1 \\ b_{21}, & b_{22} - \mu, & 0, & 0, & m_2 \\ 2a_1 & 0, & -b_{11} - \mu, & -b_{21}, & 0 \\ 0, & 2a_2, & -b_{12}, & -b_{22} - \mu, & 0 \\ 0, & 0, & -m_1, & -m_2 & 2c - 2\mu^2 \end{vmatrix} = 0.$$

Let μ_1, μ_2, and μ_3 be the three roots for which $\mathrm{Re}\,\mu_s < 0$. We then have

$$\begin{aligned} \eta_1 &= \sum_{s=1}^{3} \Delta_1(\mu_s) e^{\mu_s t} c_s, \quad \eta_2 = \sum_{s=1}^{3} \Delta_2(\mu_s) e^{\mu_s t} c_s, \\ \xi &= \sum_{s=1}^{3} \Delta_5(\mu_s) e^{\mu_s t} c_s, \quad \dot{\xi} = \sum_{s=1}^{3} \mu_s \Delta_5(\mu_s) e^{\mu_s t} c_s. \end{aligned} \quad (5.8)$$

Here, Δ_1, Δ_2, and Δ_5 are the minors of the first, second, and fifth elements of the first row of the determinant in (5.7). It is obvious that the equation sought for the optimal controller will have the form

$$\begin{vmatrix} \Delta_1(\mu_1) & \Delta_1(\mu_2) & \Delta_1(\mu_3) & \eta_1 \\ \Delta_2(\mu_1) & \Delta_2(\mu_2) & \Delta_2(\mu_3) & \eta_2 \\ \Delta_5(\mu_1) & \Delta_5(\mu_2) & \Delta_5(\mu_3) & \xi \\ \mu_1\Delta_5(\mu_1) & \mu_2\Delta_5(\mu_2) & \mu_3\Delta_5(\mu_3) & \dot{\xi} \end{vmatrix} = 0. \quad (5.9)$$

The author sincerely thanks E. A. Barbashin and N. N. Krasovskii for their active participation in the discussions of the present problem, and for their helpful suggestions.

APPLICATION OF THE KRYLOV - BOGOLYUBOV METHOD OF CONSTRUCTING ASYMPTOTIC APPROXIMATIONS TO THE INVESTIGATION OF SYSTEMS WITH LAGS*

V. S. Kislyakov

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 4, pp. 442-455, April, 1960
Original article submitted July 4, 1959

The present paper treats of the application of the Krylov-Bogolyubov method of constructing asymptotic approximations to the investigation of linear and nonlinear systems with lags. The effectiveness of this application of the method is illustrated by the example of the investigation of the Minorsky equation.

Introduction

Today, as an effective instrument for the approximate investigation of nonlinear instruments, one may use the widely disseminated method developed by N. M. Krylov and N. N. Bogolyubov [1] for the construction of asymptotic approximations. This method, in a simplified variant (when only first approximations are considered), is called the harmonic balance method [2].

The nub of the asymptotic method of Krylov and Bogolyubov as applied, for example, to a nonlinear differential equation of the form

$$\ddot{x} + \omega^2 x = \varepsilon f(x, \dot{x}), \qquad (1)$$

where ϵ is a small positive parameter, reduces to the search for the general solution of this equation in the form of a formal series expansion in powers of the small parameter ϵ:

$$x = A\cos\psi + \varepsilon u_1(A, \psi) + \varepsilon^2 u_2(A, \psi) + \ldots, \qquad (2)$$

in which $u_1(A, \psi)$, $u_2(A, \psi)$,.... are periodic functions with period 2π. An additional condition is imposed on the functions u_1, u_2,..., which is expressed by the absence of the first harmonics in the Fourier expansions of these functions.

As a first approximation to the solution of (1), we take the expression

$$x = A\cos\psi, \qquad (3)$$

in which the amplitude A and the phase angle ψ are defined by the equations

$$\dot{A} = \varepsilon D_1(A), \quad \dot{\psi} = \omega + \varepsilon B_1(A). \qquad (4)$$

The coefficients $D_1(A)$ and $B_1(A)$ in (4) are defined as the first (fundamental) harmonics of the expansion of the nonlinear function in a Fourier series:

$$D_1(A) = -\frac{1}{2\pi\omega}\int_0^{2\pi} f(A\cos\psi, -A\omega\sin\psi)\sin\psi\, d\psi, \qquad (5)$$

$$B_1(A) = -\frac{1}{2\pi\omega A}\int_0^{2\pi} f(A\cos\psi, -A\omega\sin\psi)\cos\psi\, d\psi. \qquad (6)$$

As a second approximation to the solution of (1), we take the expression

$$x = A\cos\psi + \varepsilon u_1(A, \psi), \qquad (7)$$

in which A and ψ are defined by the equations

$$\begin{aligned} \dot{A} &= \varepsilon D_1(A) + \varepsilon^2 D_2(A), \\ \dot{\psi} &= \omega + \varepsilon B_1(A) + \varepsilon^2 B_2(A), \end{aligned} \qquad (8)$$

and u_1 is defined by the formula

$$u_1 = -\frac{1}{\omega^2}\sum_{n=2}^{\infty}\frac{g_n(A)\cos n\psi + h_n(A)\sin n\psi}{n^2 - 1}, \qquad (9)$$

where $g_n(A)$ and $h_n(A)$ are coefficients of the Fourier series:

$$\begin{aligned} g_n(A) &= \frac{1}{2\pi}\int_0^{2\pi} f(A\cos\psi, -A\omega\sin\psi)\cos n\psi\, d\psi, \\ h_n(A) &= \frac{1}{2\pi}\int_0^{2\pi} f(A\cos\psi, -A\omega\sin\psi)\sin n\psi\, d\psi, \end{aligned} \qquad (10)$$

and the coefficients $D_2(A)$ and $B_2(A)$ in (8) are defined by the corresponding formulas (cf. [2]).

As a third approximation to the solution of (1) we take the expression

$$x = A\cos\psi + \varepsilon u_1(A, \psi) + \varepsilon^2 u_2(A, \psi) \text{ etc.} \qquad (11)$$

In automatic control systems (ACS) one is frequently most interested in the so-called stationary (steady-state) oscillations. This is related to the fact that all nonstationary oscillations, after a quite rapid transient response, approximate to steady-state oscillations and, almost immediately after the initiation of an oscillatory process, this process can be considered as being stationary. A stationary mode, as is well known, is characterized by a constant amplitude, i.e., such that the derivative of the amplitude with respect to time is zero. For the system described by (1), the steady state is defined by the condition

---

*Some results of this paper were briefly presented at the Sixth Scientific-Engineering Conference of Junior Scientists on Automatic Control of the IAT AN SSSR (Jan. 19-21, 1959) and, synoptically, at a seminar on differential-difference equations at Moscow State University (May 28, 1959).

$$\dot{A} = \varepsilon D_1(A) + \varepsilon^2 D_2(A) + \ldots = 0. \tag{12}$$

The method under consideration, i.e., the Krylov-Bogolyubov method of constructing asymptotic approximations, can be successfully employed, as will be shown below, for differential equations with lagging arguments. With this, the Krylov-Bogolyubov method, when combined with the Routh-Hurwitz criterion, turns out to be a simple and effective means both for finding the steady-state periodic mode and for determining the boundary of the region of stability of the controlled system with lags described by linear and quasi-linear differential equations with lagging arguments. The present paper is based on [3], in which there is contained the foundation for the method of approximate computations of periodic solutions of differential equations with lagging arguments, as well as on the results of simulation studies. The foundation for the possibility of using the asymptotic methods of Krylov and Boglyubov for the investigation of systems with lags will be given in the second part of the present paper.

1. Equivalent Linearization of Nonlinear Oscillatory ACS with Lags by the Krylov-Bogolyubov Method

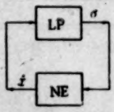

Fig. 1. Block schematic of an ACS with lags. LP is the linear portion and NE is the nonlinear element with lags.

We consider an ACS consisting, in the general case, of a linear portion and a nonlinear element with lags (Fig. 1). The equation of the linear portion may, in general, be arbitrary† while the equation of the nonlinear element has the form

$$\dot{x}(t) = f[\sigma(t-\tau)]. \tag{1.1}$$

An equation of the form of (1.1), in which the lag enters into the argument of the nonlinear function, may be treated, in particular cases, as the equation describing the executive organ of an ACS. In this case, the function $f[\sigma(t-\tau)]$ represents the acting generalized lagged force engendered by the executive organ in accordance with the value of the argument $\sigma(t-\tau)$, where τ is a positive constant which characterizes the temporal delay. In each controlled system, the argument σ expresses the total (sum) pulse (signal) formed in accordance with the control law adopted for the problem. It is assumed that the function $f[\sigma(t-\tau)]$ lies in a subclass A' of class A of functions [4], i.e., satisfies conditions of the form

$$f[\sigma(t-\tau)] = 0 \quad \text{for} \quad \sigma(t-\tau) = 0;$$

$$\left[\frac{df[\sigma(t-\tau)]}{d\sigma(t-\tau)}\right]_{\sigma(t-\tau)=0} \geqslant k > 0,$$

$$\sigma(t-\tau)\varphi[\sigma(t-\tau)] > 0$$

$$\text{for} \quad \sigma(t-\tau) \neq 0,$$

where $\varphi[\sigma(t-\tau)] = f[\sigma(t-\tau)] - k\sigma(t-\tau)$, and $\underline{k}$ is a given constant. This function also satisfies the Dirichlet conditions in the control range $2|\bar{\sigma}|$, and can be presented in the form of a linear portion and a small nonlinear correction:

$$f[\sigma(t-\tau)] = k\sigma(t-\tau) + \varepsilon\varphi[\sigma(t-\tau)], \tag{1.2}$$

where $\varepsilon(\varepsilon \ll 1)$, introduced by means of the substitution $\bar{x}(t) = \varepsilon x(t)$, is a small parameter.

We now find a linear element which is equivalent, in a first approximation, to the nonlinear element of (1.1). We write the differential equation of the linear element in the form

$$\dot{x}(t) = a_1(A)\sigma(t) + a_2(A)\dot{\sigma}(t), \tag{1.3}$$

where $a_1(A)$ and $a_2(A)$ are the amplitude-dependent coefficients of the linear element.

It is required to determine the values of the coefficients $a_1(A)$ and $a_2(A)$ and to resolve the question of the physical interpretation of equivalent formula (1.3). For this we can use the standard electrical engineering concepts of active and reactive power. The active power developed by the executive organ during one period of oscillation corresponding, in the given case, to average power, will equal the work of the force $f[\sigma(t-\tau)]$ during a period T of oscillation, divided by the magnitude of T, i.e.,

$$\frac{1}{T}\int_0^T f[\sigma(t-\tau)]\,\dot{\sigma}(t)\,dt. \tag{1.4}$$

The reactive power will equal

$$\frac{1}{T}\int_0^T f[\sigma(t-\tau)]\,\dot{\sigma}\left(t-\frac{T}{4}\right)dt. \tag{1.5}$$

We now show that the value of the coefficient $a_1(A)$ can be obtained by equating the reactive powers of the nonlinear and the linear elements, and that the value of the coefficient $a_2(A)$ can be obtained by a corresponding equating of the active powers. Thus, in accordance with (1.5) and presenting $f[\sigma(t-\tau)]$ in the form of (1.2), we obtain

---

† The Krylov-Bogolyubov method permits the linearization of a system's nonlinear element independently of the other system parameters.

$$\frac{1}{T}\int_0^T f[\sigma(t-\tau)]\,\dot{\sigma}\left(t-\frac{T}{4}\right)dt =$$

$$= \frac{k}{T}\int_0^T \sigma(t-\tau)\,\dot{\sigma}\left(t-\frac{T}{4}\right)dt +$$

$$+ \frac{\varepsilon}{T}\int_0^T \varphi[\sigma(t-\tau)]\,\dot{\sigma}\left(t-\frac{T}{4}\right)dt. \qquad (1.6)$$

We assume, in a first approximation, that the quantity $\sigma(t)$, during the time interval $T = 2\pi/\omega$, varies harmonically:

$$\sigma(t) = A\cos\omega t, \quad \dot{\sigma}(t) = -A\omega\sin\omega t. \qquad (1.7)$$

By substituting the quantity in (1.7) into (1.6) for the reactive power, and introducing the new independent variable $\psi = \omega t$, we get

$$\frac{1}{T}\int_0^T f[\sigma(t-\tau)]\,\dot{\sigma}\left(t-\frac{T}{4}\right)dt = \frac{A^2 k\omega}{2}\cos\omega\tau +$$

$$+ \frac{\varepsilon A\omega}{2\pi}\int_0^{2\pi} \varphi[A\cos\omega(t-\tau)]\cos\psi\,d\psi. \qquad (1.8)$$

By substituting the quantity defined by (1.3) into (1.5) for the reactive power, and by taking (1.7) into account, we have

$$\frac{1}{T}\int_0^T a_1(A)\,\sigma(t)\,\dot{\sigma}\left(t-\frac{T}{4}\right)dt -$$

$$- \frac{1}{T}\int_0^T a_2(A)\,\dot{\sigma}(t)\,\dot{\sigma}\left(t-\frac{T}{4}\right)dt = \frac{a_1(A)\,A^2\omega}{2}. \qquad (1.9)$$

From a comparison of (1.8) and (1.9) we obtain the value of coefficient $a_1(A)$:

$$a_1(A) = k\cos\omega\tau -$$

$$- \frac{\varepsilon}{\pi A}\int_0^{2\pi} \varphi[A\cos\omega(t-\tau)]\cos\psi\,d\psi. \qquad (1.10)$$

In exactly the same fashion, by substituting $f[\sigma(t-\tau)]$, in the form of (1.2), in (1.4) for the active power, we get

$$\frac{1}{T}\int_0^T f[\sigma(t-\tau)]\,\dot{\sigma}(t)\,dt = \qquad (1.11)$$

$$= \frac{k}{T}\int_0^T \sigma(t-\tau)\,\dot{\sigma}(t)\,dt + \frac{\varepsilon}{T}\int_0^T \varphi[\sigma(t-\tau)]\,\dot{\sigma}(t)\,dt.$$

By substituting the quantity (1.7) in (1.11), we obtain

$$\frac{1}{T}\int_0^T f[\sigma(t-\tau)]\,\dot{\sigma}(t)\,dt = -\frac{kA^2\omega\sin\omega\tau}{2} -$$

$$- \frac{\varepsilon A\omega}{2\pi}\int_0^{2\pi} \varphi[A\cos\omega(t-\tau)]\sin\psi\,d\psi. \qquad (1.12)$$

By substituting in (1.4) for the active power, the quantity defined by (1.3), and by taking (1.7) into account, we have

$$\frac{1}{T}\int_0^T a_1(A)\,\sigma(t)\,\dot{\sigma}(t)\,dt + \frac{1}{T}\int_0^T a_2(A)\,\dot{\sigma}^2(t)\,dt =$$

$$= \frac{A^2\omega^2 a_2(A)}{2}. \qquad (1.13)$$

From a comparison of (1.12) and (1.13) we obtain the value of coefficient $a_2(A)$:

$$a_2(A) = -\frac{k\sin\omega\tau}{\omega} - \frac{\varepsilon}{\pi A\omega}\int_0^{2\pi} \varphi[A\cos\omega(t-\tau)]\sin\psi\,d\psi. \qquad (1.14)$$

The method of determining the equivalent coefficients $a_1(A)$ and $a_2(A)$ by (1.10) and (1.14) can be called the power principle, or the energetic balance principle for a nonlinear element with lags. It is easily shown (cf. the Appendix) that, when the harmonic balance principle is applied in the case when n = 1, one can obtain the values themselves of the coefficients. In accordance with (A.8) and (A.9), (1.10) and (1.14) can be given in the form

$$a_1(A) = \left(k + \frac{\varepsilon g_1(A)}{A}\right)\cos\omega\tau - \frac{\varepsilon h_1(A)}{A}\sin\omega\tau, \qquad (1.15)$$

$$a_2(A) = -\left(k + \frac{\varepsilon g_1(A)}{A}\right)\frac{\sin\omega\tau}{\omega} - \frac{\varepsilon h_1(A)}{A\omega}\cos\omega\tau, \qquad (1.16)$$

where $g_1(A)$ and $h_1(A)$ are the coefficients of the nonlinear function's Fourier series expansion for the case n = 1.

2. Determination of the Steady-State Periodic Mode Parameters in Systems with Time Lags

As the first example of the use of the Krylov-Bogolyubov method of asymptotic approximations, we consider a system described by an ordinary first-order linear differential equation with constant coefficients and lagging argument:

$$x + kx(t-\tau) = 0. \qquad (2.1)$$

Equation (2.1) was investigated by Schmidt [5] by means of a rigorous method for extracting the roots of the so-called transcendental function ‡. Schmidt showed that (2.1) possesses a periodic solution of the form

$$x = c_1\cos\omega t + c_2\sin\omega t, \qquad (2.2)$$

where c_1 and c_2 are arbitrary constants, with the condition that ω is defined by means of the equation

$$\omega = k = \frac{1}{\tau}\left(\frac{\pi}{2} \pm 2\pi n\right) \quad (n = 0, 1, 2, \ldots) \qquad (2.3)$$

---

‡ E. Schmidt considered the transcendental function

$$l(\omega) = i\omega - k\exp(-i\omega\tau) = -k\cos\omega\tau + i(\omega + k\sin\omega\tau). \qquad (2.1a)$$

In his notation, instead of k, τ, ω in (2.1) and (2.1a), there stand λ, h, ν.

By the Krylov-Bogolyubov method, the coefficients a_1 and a_2 of the equivalent system, defined by (1.15) and (1.16), will equal for the example under consideration, ($\epsilon = 0$):

$$ {}_1 = k\cos\omega\tau, \quad a_2 = \frac{-k\sin\omega\tau}{\omega}, \tag{2.4}$$

and the system's equivalent equation has the form

$$\left(1 - \frac{k\sin\omega\tau}{\omega}\right)\dot{x} + k\cos\omega\tau\, x = 0. \tag{2.5}$$

A periodic solution of (2.5) occurs with the conditions that

$$1 - \frac{k\sin\omega\tau}{\omega} = 0, \qquad k\cos\omega\tau = 0. \tag{2.6}$$

As is easily seen, (2.3) follows from this. Thus, the first approximation gives a result which coincides quantitatively with the exact solution of the ordinary linear differential equation with lagged argument which is being considered.

As a second example of the use of the Krylov-Bogolyubov method, we consider the questions connected with the search for the steady-state periodic mode (autooscillation) which occurs under certain conditions in nonlinear oscillatory systems with artifically introduced damping. The system is described by the so-called Minorsky** differential equation

$$\ddot{y}(t) + 2r\dot{y}(t) + \omega_0^2 y(t) + 2q\dot{y}(t-\tau) = \rho\dot{y}^3(t-\tau). \tag{2.7}$$

where r, ω_0 and q are positive constants and ρ is a small positive constant. By considering ρ to be sufficiently small, we set

$$\rho = \varepsilon\nu$$

and present (2.7) in the form of a system of two equations:

$$\dot{y} = z. \quad \dot{z} = -2rz - 2qz(t-\tau) - \omega_0^2 y + \varepsilon\nu z^3(t-\tau). \tag{2.8}$$

On the basis of the theorem on existence and uniqueness proven by Krasovskii†† [3], one can assert that, if the quasi-linear system (2.8) has a periodic solution for $\epsilon=0$ (the so-called generating solution) $y(t,0)$ then, if the condition $|\epsilon| < \epsilon_0$ holds, where ϵ_0 is some positive constant, there exists a unique periodic solution $y(t,\epsilon)$.

We start initially with the periodic solution for $\epsilon = 0$ (the generating solution), defined by the system of equations

$$\dot{y} = z. \quad z = -2rz - 2qz(t-\tau) - \omega_0^2 y. \tag{2.9}$$

By defining the coefficients a_1 and a_2 of the equivalent system by (1.15) and (1.16) (for the case $\epsilon = 0$), we obtain the following equality:

$$2qz(t-\tau) = a_1 z(t) + a_2\dot{z}(t) = 2q\cos\omega\tau\, z(t) - \frac{2q\sin\omega\tau}{\omega}z(t). \tag{2.10}$$

By substituting the value of $2qz(t-\tau)$ in (2.9), we get

$$\dot{y} = z. \quad \dot{z} = -b_1 z - b_2 y. \tag{2.11}$$

where

$$b_1 = \frac{2r + 2q\cos\omega\tau}{1 - \frac{2q\sin\omega\tau}{\omega}}. \quad b_2 = \frac{\omega_0^2}{1 - \frac{2q\sin\omega\tau}{\omega}}.$$

The characteristic equation of (2.11) has the form

$$D(\lambda) = \begin{vmatrix} -\lambda & +1 \\ -b_2 & -b_1 - \lambda \end{vmatrix} = 0 \tag{2.12}$$

or

$$\lambda^2 + b_1\lambda + b_2 = 0. \tag{2.13}$$

Equation (2.13) is an ordinary algebraic equation, and one may apply to it the familiar classical formulas of the theory of linear oscillations, in particular, the Routh-Hurwitz stability criterion. By this criterion, the system described by characteristic (2.13) will lie on the boundary of stability and will manifest undamped periodic oscillations in case

$$R = \Delta_{n-1} = b_1 = 0, \tag{2.14}$$

where Δ_{n-1} is the (n-1)th Hurwitz determinant.

Condition (2.14) occurs when

$$R = 2r + 2q\cos\omega\tau = 0. \tag{2.15}$$

The frequency of the periodic oscillations is defined by the formula

$$\omega^2 = \frac{\omega_0^2}{1 - \frac{2q\sin\omega\tau}{\omega}}. \tag{2.16}$$

By eliminating q from (2.15) and (2.16), we find that

$$\operatorname{tg}\omega\tau = -\frac{\omega^2 - \omega_0^2}{2r\omega}. \tag{2.17}$$

It is easily seen that the periodic solution of (2.13) occurs under the following conditions:

$$\operatorname{tg}\omega\tau < 0. \quad \cos\omega\tau < 0 \tag{2.18}$$

or

$$\frac{\pi}{2} + 2\pi n \leqslant \omega\tau < \pi + 2\pi n \quad (n = 0, 1, 2, \ldots) \tag{2.19}$$

In case of equality, $\omega\tau = \pi + 2\pi n$, the frequency ω of the periodic oscillations either coincides with, or is a multiple of, the natural frequency ω_0 of the system, and the phenomenon of resonance supervenes.

The frequency of the periodic oscillations is determined by a graphic solution of transcendental (2.17), and must satisfy (2.19). The amplitude A is an arbitrary constant, as is ordinarily the case when linear systems are being considered. It should be mentioned that, in the example under consideration, an arbitrarily small delay $\tau > 0$ may give rise to periodic oscillations in a system described by (2.9). In the case when $\tau = 0$, no periodic oscillations exist in the system described by (2.9) for any combination of the coefficients since, by our assumptions, the coeffi-

---

**An equation of the form of (2.7) was investigated by Minorsky [6,7], and then by Pinney [9], as related to the search for periodic oscillations.

†† Independently of Krasovskii, an analogous theorem was proven by Khalanai [10].

cients ω_0, $\underline{r}$, $\underline{q}$ are positive nonzero numbers.

We now determine the periodic solution of (2.8) for $\epsilon \neq 0$. As a first approximation, we give the periodic solution in the form

$$y = A\cos\omega t, \tag{2.20}$$

where the amplitude A and the frequency ω are determined from the solution of the equation obtained from (2.8) by use of the Krylov-Bogolyubov method of equivalent linearization. Determining the coefficients of the equivalent system from (1.15) and (1.16), we have the following equations:

$$\rho z^3(t-\tau) = a_3 z(t) + a_4 \dot{z}(t) = \frac{3}{4}\rho A^2 \cos\omega\tau z(t) - \frac{3}{4}\rho A^2 \frac{\sin\omega\tau}{\omega}\dot{z}(t). \tag{2.21}$$

By substituting the values of $2qz(t-\tau)$ and $\rho z^3(t-\tau)$ in (2.8), we get

$$\dot{y} = z.\quad \dot{z} = -b_3 z - b_4 y. \tag{2.22}$$

where

$$b_3 = \frac{2r + \cos\omega\tau\left(2q - \frac{3}{4}\rho A^2\right)}{1 - \frac{\sin\omega\tau}{\omega}\left(2q - \frac{3}{4}\rho A^2\right)}.$$

$$b_4 = \frac{\omega_0^2}{1 - \frac{\sin\omega\tau}{\omega}\left(2q - \frac{3}{4}\rho A^2\right)}.$$

In this case, the system's characteristic equation will be

$$D(\lambda) = \begin{vmatrix} -\lambda & +1 \\ -b_4 & -b_3 - \lambda \end{vmatrix} = 0 \tag{2.23}$$

or

$$\lambda^2 + b_3\lambda + b_4 = 0. \tag{2.24}$$

For fixed values of the amplitude A, characteristic equation (2.24) is an ordinary algebraic equation, to which we apply the Routh-Hurwitz stability criterion. By this criterion, the system described by (2.24) will lie on the boundary of stability, and periodic oscillations will occur in it if

$$R(A) = \Delta_{n-1} = b_3 = 0. \tag{2.25}$$

which occurs for

$$R(A) = 2r + \cos\omega\tau\left(2q - \frac{3}{4}\rho A^2\right) = 0. \tag{2.26}$$

With this, the frequency of the periodic oscillations is determined by the formula

$$\omega^2 = \frac{\omega_0^2}{1 - \frac{\sin\omega\tau}{\omega}\left(2q - \frac{3}{4}\rho A^2\right)}. \tag{2.27}$$

By eliminating $2q - 3\rho A^2/4$ from (2.26) and (2.27), we find

$$\operatorname{tg}\omega\tau = -\frac{\omega^2 - \omega_0^2}{2r\omega}. \tag{2.28}$$

The expression for the amplitude is determined from (2.26):

$$A = \left[\frac{8(r + q\cos\omega\tau)}{3\rho\cos\omega\tau}\right]^{1/2}. \tag{2.29}$$

Equations (2.28) and (2.29) must satisfy (2.19) and, moreover, the condition

$$q\,|\cos\omega\tau| > r \qquad \left(\text{for}\ \ q > \frac{3}{8}\rho A^2\right). \tag{2.30}$$

which, if satisfied, makes (2.29) physically meaningful (A is real).

The joint solution of (2.28) and (2.29) is most easily begun with a determination of the frequency ω of the steady-state periodic oscillations, specifically, with a graphic solution of transcendental equation (2.28). For this, we present (2.28) in the form of two terms:

$$\operatorname{tg}\omega\tau = \frac{\omega_0^2}{2r\omega} - \frac{1}{2r}\omega. \tag{2.31}$$

the first term of which is the equilateral hyperbola $\xi_1 = \omega_0^2/2r\omega$ with the ξ and ω axes for asymptotes, and the second term is the straight line $\xi_2 = \omega/2r$, with slope $-1/2r$. Using algebraic addition of the ordinates of these two curves for fixed values of ω_0 and $\underline{r}$, we obtain the sum curve (Fig. 2), whose intersections with the tangent curve in the second, sixth, etc. quadrants define the frequencies of the steady-state oscillations of which, if the graph is to be believed, there is an infinite set. However, it is easily shown that not all, but only a strictly finite number $\underline{n}$, of the frequencies obtained from the graphic solution of (2.28) satisfy (2.30) and, consequently, (2.29). Indeed, it is clear from Fig. 2 that, as the ω_i tend to infinity ($i = 2,3,\ldots,n,\ldots$), where we understand by ω_i the frequencies obtained from the intersections of the tangent curves with the curve in the sixth, tenth, etc. quadrants, $\tan\omega_i\tau \to \infty$. With this, $\cos\omega_i\tau \to 0$ and, for any frequency ω_{n+1}, there can occur a violation of (2.30), i.e., the condition of physical realizability of (2.29) no longer holds. Thus, as a first approximation to the solution of (2.7), we obtain the expression‡‡

$$y(t) = \sum_{s=1}^{n} A_s \cos\omega_s t. \tag{2.32}$$

in which the amplitudes A_s ($s = 1,2,\ldots,n$) are determined from (2.29) and the frequencies corresponding to them, which satisfy (2.28) and (2.29), are determined from the graphic solution of (2.28).

As a second approximation to the solution of (2.7), neglecting quantities of the order of smallness of ρ^2, we get the expression

$$y(t) = \sum_{s=1}^{n} A_s \cos\omega_s t + \rho\sum_{s=1}^{n} u_1(A_s, \psi_s). \tag{2.33}$$

where u_1 is defined by a formula analogous to (9):

$$u_1 = -\frac{1}{\omega^2}\sum_{n=2}^{\infty} \frac{\bar{g}_n(A)\cos n\psi + \bar{h}_n(A)\sin n\psi}{n^2 - 1}. \tag{2.34}$$

---

‡‡The proof that every solution y(t) can be given in the form of a sum of partial solutions is carried out in the second part of this paper.

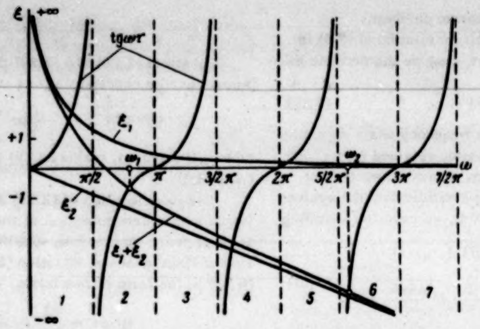

Fig. 2. Graphic solution of transcendental equation (2.28).

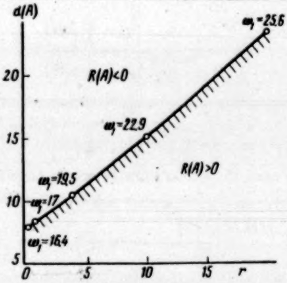

Fig. 3. Boundary of the stability region of system of equations (2.22) in the r, d(A) plane.

and $\bar{g}_n(A)$ and $\bar{h}_n(A)$ are defined by (A.8) and (A.9). In our case,

$$u_1 = \frac{1}{32} A^3 \frac{\cos 3\omega (t - \tau)}{\omega^2}. \tag{2.35}$$

Then, the second approximation has the form

$$y(t) = \sum_{s=1}^{n} A_s \cos \omega_s t + \frac{\rho}{32} \sum_{s=1}^{n} \frac{A_s^3 \cos 3\omega_s (t - \tau)}{\omega_s^2}$$

etc. (2.36)

3. Construction of the Boundaries of the Stability Region for the System of Equations (2.22) and the Investigation of Stability of the Steady-State Periodic Mode (Auto-Oscillation)***

In our example, the boundary of the stability region, as was already stated, is defined by the condition

$$R(A) = 2r + \cos \omega\tau \left(2q - \frac{3}{4} \rho A^2\right) = 0 \quad (\cos \omega\tau < 0). \tag{3.1}$$

By introducing the notation $d(A) = q - 3\rho A^2/8$ and $k(\omega) = 1/|\cos \omega\tau|$, we construct the boundary of the stability region in the r, d(A) plane. This boundary is some curve whose equation may be written in the form

$$d(A) = k(\omega) r. \tag{3.2}$$

For the fixed values $\omega_0^2 = 20$, $\tau = 0.1$ sec, the boundary of the stability region is shown in Fig. 3. It divides the r, d (A) plane into the region of stability, where $R(A) > 0$, and the region of instability, where $R(A) < 0$. Since d(A) is a function of amplitude, each fixed value of A has its own representative point. Therefore, the oscillations corresponding to boundary points of the system's parameter values, defined by (3.1), may be stable for certain values of A and unstable for other amplitude values. The oscillations on the boundary of the region will be stable if

$$\left(\frac{dR(A)}{dA}\right)_{R(A)=0} > 0, \tag{3.3}$$

and unstable if this expression is negative.

In analogy with the criterion for determining safe and dangerous boundaries due to Bautin [11], we may assume that the boundary is dangerous "in the small" if the following inequality holds in its neighborhood:

$$\left(\frac{dR(A)}{dA}\right)_{A\to 0} < 0. \tag{3.4}$$

If this expression is positive, then the boundary is safe "in the small". Dangerous and safe portions of the boundary

***In investigating the stability of the steady-state oscillatory mode, we take the amplitude $A_1 = A$ of the fundamental harmonic into account, but ignore the amplitudes A_i $(i = 2,3,\ldots)$ as being small high-frequency quantities.

are separated from each other by bifurcation points which are characterized by the condition

$$\left(\frac{dR(A)}{dA}\right)_{R(A)=0} = 0. \tag{3.5}$$

Bautin's idea may easily be generalized to the case of stability "in the large", i.e., for A→ ∞. Mathematically, this may be determined as follows. The boundary of stability of the system is safe "in the large" if the following inequality holds:

$$\left(\frac{dR(A)}{dA}\right)_{A\to\infty} > 0. \tag{3.6}$$

If the inverse inequality holds, then the boundary is dangerous "in the large".

Since, for nonlinear systems with lags R(A) depends not only on amplitude but also on the frequency of oscillation, then (3.3) can be rewritten in the form

$$\left(\frac{dR(A)}{dA}\right)_{R(A)=0} = \left(\frac{\partial R(A)}{\partial A}\right)_{R(A)=0} + \left(\frac{\partial R(A)}{\partial \omega}\right)_{R(A)=0} \frac{d\omega}{dA} > 0. \tag{3.7}$$

For the example under consideration, we have

$$\left(\frac{dR(A)}{dA}\right)_{R(A)=0} = -\frac{3}{2}A\rho\cos\omega\tau - \tau\sin\omega\tau\left(2q - \frac{3}{4}\rho A^2\right)\frac{d\omega}{dA},$$

$$\frac{d\omega}{dA} = \frac{3\omega\rho A\sin\omega\tau}{2\left[\left(2q - \frac{3}{4}\rho A^2\right)(\sin\omega\tau + \omega\tau\cos\omega\tau) - 2\omega\right]}, \tag{3.8}$$

where

$$\sin\omega\tau = \frac{\omega^2 - \omega_0^2}{\omega\left(2q - \frac{3}{4}\rho A^2\right)}, \tag{3.9}$$

$$\cos\omega\tau = -\frac{2r}{2q - \frac{3}{4}\rho A^2}. \tag{3.10}$$

By substituting the values of (3.9) and (3.10) in (3.8), we get

$$\left(\frac{dR(A)}{dA}\right)_{R(A)=0} = \frac{3\rho A\left[\omega^2(4r^2\tau + 2r) + 2r\omega_0^2 + \tau(\omega^2 - \omega_0^2)^2\right]}{2\left(2q - \frac{3}{4}\rho A^2\right)\left[\omega^2(2r\tau + 1) + \omega_0^2\right]}. \tag{3.11}$$

The point A = 0 is a bifurcation point, since

$$\left(\frac{dR(A)}{dA}\right)_{A\to 0} = 0. \tag{3.12}$$

The oscillation is stable in the small, since the quantity dR(A)/dA remains positive as A→ 0. According to Bautin [11], the boundary is "safe" in the small. The point A→ ∞ is also a bifurcation point since

$$\left(\frac{dR(A)}{dA}\right)_{A\to\infty} = -0. \tag{3.13}$$

Thus the question of the stability or instability of the oscillations for A → ∞ remains an open one, and requires a more detailed consideration, i.e., investigation of higher approximations and taking into account of oscillations of the form $A_i \cos\omega_i t$ (i = 2,3,...,n). This investigation does not lie within the scope of the present paper.

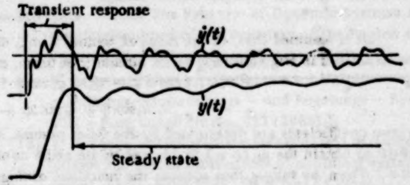

Fig. 4. Oscillogram of the steady-state periodic process in a nonlinear system with lags.

In conclusion, we compare our results with those obtained by Minorsky [6-8]. This latter author considered the appearance of self-excited oscillations in dynamic systems which were described both by linear and by nonlinear differential equations with lagged arguments of the form of (2.7), i.e., essentially linear and nonlinear problems. In considering linear problems, the author arrived at the conclusion that there exist an infinite number of frequencies of self-excited oscillations. In practice, however, in his words, only the basic frequency of the self-excited oscillations is ordinarily observed, which he also considers in his investigation of nonlinear problems. It was shown in the present work that in an autonomous dynamic system described by (2.7) there may exist, not only the fundamental self-excitation frequency, but higher frequencies as well, although their number is strictly finite. The periodic solutions are obtained in the form of sums of series of small parameters, and an estimate of the degree of approximation can always be obtained from the remainder term. Use of the Krylov-Bogolyubov method, in conjunction with the Routh-Hurwitz criterion, allows one to consider, moreover, the boundary of the region of stability of (2.7) and to determine its "dangerous" and "safe" segments. It should be mentioned that the theoretical results obtained from the investigation of the Minorsky equation by means of the Krylov-Bogolyubov asymptotic method were confirmed by simulating the system under consideration on an electronic analog computer. Figure 4 shows the oscillogram of the steady-state periodic process (autooscillation) arising on the boundary of stability of the system considered.

The author wishes to express his deep gratitude to A. M. Letov and Ya. Z. Tsypkin for a number of valuable remarks which have been incorporated in the present work.

APPENDIX

Equivalent Linearization of a Nonlinear Element with Lags by the Harmonic Balance Method

Let the function of the nonlinear element to be linearized have the form

$$F = \varphi\,[\sigma\,(t-\tau)]. \tag{A.1}$$

while its argument σ varies harmonically:

$$\sigma\,(t) = A\cos\omega t = A\cos\psi. \tag{A.2}$$

It is assumed that, in the range of control $2|\,\bar{\sigma}\,|$, the function F satisfies the Dirichlet conditions and may be expanded in trigonometric series without free term, of the form

$$\begin{aligned} F = \varphi\,[A\cos\omega\,(t-\tau)] &= \bar{g}_1\cos\psi + \bar{g}_2\cos 2\psi + \cdots + \bar{g}_n\cos n\psi + \cdots \\ \ldots &+ \bar{h}_1\sin\psi + \bar{h}_2\sin 2\psi + \cdots + \bar{h}_n\sin n\psi + \cdots, \end{aligned} \tag{A.3}$$

whose coefficients are determined by the Euler process, in which both members of (A.3) are multiplied by $\cos n\psi d\psi$ to obtain the $\bar{g}_n$ ($n = 1, 2, \ldots$), and by $\sin n\psi d\psi$ to obtain the $\bar{h}_n$ ($n = 1, 2, \ldots$), and then integrated from 0 to $+2\pi$. Then, by taking into account the functions' orthogonality properties, we get

$$\bar{g}_n = \frac{1}{\pi}\int\limits_0^{2\pi}\varphi\,[A\cos\omega\,(t-\tau)]\cos n\psi\,d\psi. \tag{A.4}$$

$$\bar{h}_n = \frac{1}{\pi}\int\limits_0^{2\pi}\varphi\,[A\cos\omega\,(t-\tau)]\sin n\psi\,d\psi. \tag{A.5}$$

We give $\sin n\psi$ and $\cos n\psi$ in the form

By substituting the expressions thus obtained in (A.4) and (A.5), we get

$$\bar{g}_n = \frac{\cos n\omega\tau}{\pi}\int\limits_0^{2\pi}\varphi\,[A\cos\psi]\cos n\,d\psi - \frac{\sin n\omega\tau}{\pi}\int\limits_0^{2\pi}\varphi\,[A\cos\psi]\sin n\psi\,d\psi, \tag{A.6}$$

$$\bar{h}_n = \frac{\cos n\omega\tau}{\pi}\int\limits_0^{2\pi}\varphi\,[A\cos\psi]\sin n\psi\,d\psi + \frac{\sin n\omega\tau}{\pi}\int\limits_0^{2\pi}\varphi\,[A\cos\psi]\cos n\psi\,d\psi \tag{A.7}$$

or

$$\bar{g}_n = g_n\cos n\omega\tau - h_n\sin n\omega\tau. \tag{A.8}$$

$$\bar{h}_n = h_n\cos n\omega\tau + g_n\sin n\omega\tau. \tag{A.9}$$

where g_n and h_n are the ordinary coefficients of the Fourier series for the nonlinear function without lags. We now substitute (A.8) and (A.9) in (A.3) and group terms with identical Fourier series coefficients. By using the theorem concerning sines and cosines of a doubled angle, we obtain

$$\begin{aligned} F = \varphi\,[A\cos\omega\,(t-\tau)] = g_1\cos\omega\,(t-\tau) + g_2\cos 2\omega\,(t-\tau) + \cdots + h_1\sin\omega\,(t-\tau) + \\ + h_2\sin 2\omega\,(t-\tau) + \cdots \end{aligned} \tag{A.10}$$

In the sequel we shall use either the form in (A.3) or the form in (A.10). Let the nonlinear element be given in the form of (1.2) and the equation of the equivalent linear element be written in the form of (1.3). We use the harmonic balance principle to determine $a_1(A)$ and $a_2(A)$. By substituting (A.2) in (1.2) and taking into account only the fundamental (first) harmonic of the oscillation, we get

$$\begin{aligned} f\,[A\cos\omega\,(t-\tau)] &= kA\cos\omega\,(t-\tau) + \varepsilon\bar{g}_1\cos\psi + \varepsilon\bar{h}_1\sin\psi = \\ &= Ak\,(\cos\psi\sin\omega\tau + \sin\psi\sin\omega\tau) + \varepsilon\bar{g}_1\cos\psi + \varepsilon\bar{h}_1\sin\psi, \end{aligned} \tag{A.11}$$

where g_1 and h_1 are the coefficients of the trigonometric series defined for the case n = 1 by (A.8) and (A.9). We now compare the oscillation of (A.11) with the oscillations obtained by substituting (A.2) in (1.3). From a comparison of the coefficients of the sines and cosines we obtain two equations for determining the unknown coefficients a_1 and a_2:

$$a_1\,(A)\,A = Ak\cos\omega\tau + \varepsilon\bar{g}_1, \quad -a_2\,(A)\,A\omega = Ak\sin\omega\tau + \varepsilon\bar{h}_1. \tag{A.12}$$

From whence

$$a_1\,(A) = \left(k + \frac{\varepsilon\bar{g}_1}{A}\right)\cos\omega\tau - \frac{\varepsilon h_1}{A} - \sin\omega\tau, \tag{A.13}$$

$$a_2\,(A) = -\left(k + \frac{\varepsilon h_1}{A}\right)\frac{\sin\omega\tau}{\omega} - \frac{\varepsilon h_1}{A}\cos\omega\tau. \tag{A.14}$$

ON STEADY-STATE MODES IN AUTOMATIC CONTROL SYSTEMS*

B. V. Shirokorad

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 4, pp. 456-464, April, 1960
Original article submitted December 12, 1959

The present paper discusses certain basic concepts and methods of automatic control system (ACS) theory which are related to the existence of steady-state modes of autonomous systems with the coexistence of several independent frequencies.

We limit ourselves to the consideration of the broadest class of autonomous ACS, the properties of which are described by a system of ordinary differential equations, given in the Cauchy form:

$$x = f_k(x_1, x_2, \ldots, x_n) \qquad (k = 1, 2, \ldots, n), \quad (1)$$

where the right member lies in some previously given class of functions, defined in a fixed region G, and does not explicitly contain the time parameter t.

Such systems were called dynamic by Birkhoff [1].

Lyapunov [2] called each (undisturbed) solution of (1) (following Routh's example) a steady-state solution with respect to the initiation of disturbance†. Subsequently, however, it turned out that such a general term was inconvenient, and it fell into desuetude. It developed that it was more convenient to apply the term "steady-state modes" to the more specialized motions of (1) which correspond to stable equilibrium positions (or points of rest). In the investigation of an ACS a basic role is played by the problem of determining the steady-state modes (for example, resting points, periodic, almost periodic, and the most general recurring [1] motions) which are stable with respect to other, transient, motions which approximate to these steady-state motions (control quality). All other motions (for example, generation or autooscillation of missile steering, generation of incorrect alignment of the autonomous contour of a power drive or steering mechanism) turn out to be undesirable, and they are considered from the point of view of the necessity for finding the limitation to be imposed on the ACS which will prevent their appearance in the operating modes (from whence the interest in the tuning of the controller's transfer ratio, the determination of the possible external noise conditions, etc.).

The introduction of the concept of the steady-state mode was an obvious step for linear or for two-dimensional nonlinear ACS with continuous right members of (1), but this was definitely not so for two-dimensional ACS with discontinuous right members, and even less so for multidimensional nonlinear ACS. For these, other fundamental concepts also seemed unclear, concepts such as establishment (of the steady-state mode), roughness (of adjustment), physical realizability, and others.

It was known even in A. Poincaré's time that the two-dimensional system (1) with continuous right members could have, in the phase plane (in the given case, in the velocity plane of A. Liénard), only two forms of steady-state modes: an equilibrium position with one state, or a periodic mode with many states.

If the right members of the two-dimensional system are discontinuous, then oscillatory motions of a new type, not converging to those mentioned above, might appear (for example, such motions appear in the systems treated in [3,4]).

In multidimensional systems described by (1), even with continuous right members, guaranteeing the existence (for t from - ∞ to + ∞) of a unique and continuous dependence of the solution on the initial conditions, there might appear very complicated oscillatory modes, with the coexistence of several, and even infinitely many, incommensurable frequencies.

No mention was made of the existence of such modes even in such fundamental textbooks as [5-7]. Moreover, Teodorchik [8] asserted‡ that, in many cases, one of the frequencies must, in the course of time, dominate over the others, such that after the lapse of some time the (established) mode will be nonetheless periodic (i.e., in actual systems, almost periodic modes do not exist).

Such circumstances led to an incorrect estimate of the value of studying the aforementioned modes in designing ACS. In particular, the problem of uncovering the very simplest of them – the almost periodic ones – in an ACS in the case n ≥ 3 was completely undeveloped, although the properties of such modes in differential equations were described by such authors as Poincaré, d'Anjou, Hayashi, Nemytskii [9], and others.

The etiology of the longstanding incorrect opinion as to the nonexistence of actual steady-state modes with many states of a more complicated nature than periodic ones is related to a very essential factor having to do with experimental observations, as well as to the widespread use of the harmonic balance method without account being taken of its domain of permissible applicability. The fact of the matter is that, in making our observations, we cannot distinguish between, for example, periodic and almost periodic steady-state modes, since the accuracy of the instruments and the intervals of observation time are quite limited. These individually noncharacterizeable steady-state modes present themselves to us phenomenologically as recurrent motions, i.e., those which were introduced into consideration as the most general motions by Birkhoff [1] in 1928. They are characterized by the property that, for each $\epsilon > 0$, there exists its own interval of observation T such that any trajectory of duration T of the recurrent steady-state mode will contain in its ϵ-envelope all the trajectories (as time varies from $-\infty$ to $+\infty$). Thus, an operator taking an observation during a time interval greatly exceeding T will always touch upon a "diffuse cycle" (a periodic mode with noise).

*Presented at the All-Moscow Seminar on Nonlinear ACS Methods of March 18, 1959, and at the First All-Union Session of Mechanics of January 29, 1960.

†Lyapunov assumed that the f_k were analytic functions.

‡However, his proofs suffered from mathematical incorrectness.

However, from the heuristic point of view, it is not at all a matter of indifference whether we have to do with a periodic steady-state mode, distorted by random noise or, for example, with an almost periodic mode. In the first case, an analytic investigation of the ACS is possible; in the second case, such an investigation is frequently impossible for the reasons previously cited.

Not only Birkhoff but, in the 1930's, Andronov **, spoke of the importance of investigating almost periodic steady-state modes. Finally, Aizerman [10] came out convincingly in defense of the physical reality of these steady-state modes and the necessity of studying them analytically for designing ACS.

1. Definition and Internal Properties of Dynamic Systems

We preface the more graphical explication and illustrations by a somewhat abstract definition of the dynamic system given by (1) and by a description of certain of its properties, borrowed from topological dynamics [11]. This digression allows an exact mathematic formulation to be given, but does not impair the understanding of the following simpler material.

Let X be a topological space of certain elements $x \in X$, which we shall call a phase space, and let the x be phases (points). Further, let T be a topological group of elements $t \in T$ (such that every pair $t_1, t_2 \in T$ is put into correspondence with a third element $t_3 \in T$). We call T the time group, with moments t. In X we define a transformation F which puts each point $x \in X$ into correspondence with another point of X which we denote by $xF \in X$. The topological product XT is mirrored by the transformation F in X, i.e., each pair (x,t), where $x \in X$ and $t \in T$, corresponds to a point (x,t)F. Descriptively (axiomatically), we define the topological transformation group, denoted briefly by the triplet (X,T,F), which satisfies the following axioms:

1. Identity axiom. In the group T there exists an initial moment of time $0 \in T$ (0 need not be a number) such that the pair t and 0 corresponds to t, and the pair (x,0) is put into correspondence, by transformation F, with the point (x,0)F = x.

2. Homomorphism axiom. If the pair t_1, $t_2 \in T$ corresponds to $t_3 \in T$, then $[(x, T_1)F, t_2]F = (x, t_3)F$.

3. Continuity axiom. The transformation F is one-to-one and continuous (i.e., topological).

If X is a metric space with metric ρ, and the moments of time $t \in T$ are real numbers then, in accordance with the continuity axiom, (x,t)F is a continuous function of the collection (x,t), i.e., for each $t \in T$ and a given pair of numbers $\epsilon > 0$ and $x \in X$ there exists another pair of numbers $\delta = \delta(x,t) > 0$ and $\tau = \tau(x,t)$ such that, for any $y \in X$ and $t_1 \in T$ such that $\rho(x,y) < \delta$ and $|t - t_1| < \tau$, the following inequality holds: $\rho[(x,t)F, (y,t_1)F] < \epsilon$.

By a trajectory (motion) we mean the geometric locus of the images of the fixed point $x \in X$ under the transformation F, corresponding to all the $t \in T$.

If, for all $t \in T$ the transformation F takes the set $I \subset X$ into itself, then I is called an invariant. For example, a singular point (a rest or equilibrium state), each trajectory, the set of all trajectories passing through all the limit points of a fixed almost periodic trajectory (in the case of a metric space X, cf. below), are invariant sets.

It is easily seen that the triplet (I,T,F) satisfies the three axioms given above and, consequently, is itself a topological transformation group (with the induced topology of X).

A nonempty closed invariant set I is called minimal (I_{min}) if it does not contain an invariant set as a proper subset. In the example given above, the invariant set of almost periodic trajectories is minimal.

If, on I_{min}, the invariant J is defined with respect to the points $t \in T$ then we say that I_{min} possesses J-internal stability.

Each trajectory (or resting point) possesses a natural (trivial) invariant: the transformation F takes it into itself for all $t \in T$.

Turning now to the other side, we consider metric invariants. For this we assume that X is a metric space with the metric ρ, and the moments of time $t \in T$ are real numbers. The set I_{min} has S-internal stability (in the sense of Franklin [12]) if, for any pair $\epsilon > 0$ and $x \in I_{min}$ there exists $\delta = \delta(\epsilon, x) > 0$ such that, for each $y \in I_{min}$ lying in the δ-neighborhood of x [i.e., for $\rho(x,y) < \delta$], there will hold, for all moments of time $t \in T$ (i.e., for $-\infty < t < +\infty$

$$\rho[(\dot{x}, t)F, (y, t)F] \leqslant \varepsilon. \tag{2}$$

If, moreover, I_{min} is bounded, i.e., there exists a phase $y \in X$ such that, for each $x \in I_{min}$, $\rho(x, y) < \text{const} < +\infty$, then, by means of the Vitali covering theorem, it is easily proven that in this case δ will depend only on ϵ, and $I_{\min}$ will represent a recurrent motion (in the sense of G. D. Birkhoff [1]), i.e., for each pair $\varepsilon > 0$ and $x \in I_{\min}$ there will exist a $\tau_* = \tau_*(\varepsilon, x) > 0$ such that, for any other pair $t_0, t \in T$ one finds a number $\tau = \tau(t) \in (t_0 - \tau_*, t_0 + \tau_*)$, for which

---

**This latter was communicated to the author by El'shin who consulted with Andronov during those years.

$$\rho[(x, t)F, (x, \tau)F] < \varepsilon. \quad (3)$$

Then, a fortiori, $I_{\min}$ will consist of L-internal stable trajectories (in the sense of Lagrange), i.e., there will exist a $y \in X$ such that, for each fixed $x \in I_{\min}$ and all $t \in T$

$$\rho[(x, t)F, y] < \text{const} < +\infty. \quad (4)$$

Each recurrent trajectory is P-internally stable, meaning that it possesses the local recurrence property (repeatability) in contradistinction to the integral property of (3) (in the sense of Poisson [1]). i.e., for any pair $\varepsilon, \tau > 0$ and any $x \in I_{\min}$ there exist two moments of time, $t_1 < -\tau$ and $t_2 > \tau$ for which

$$\rho[(x, t)F, x] < \varepsilon. \quad (5)$$

The converse is not true. It does not follow from the P-internal stability given by (5) that the trajectory is recurrent, as given by (3).

Since a continuous function on a closed set is uniformly continuous, it follows from the continuity axiom and Vitali's covering theorem, that a closed trajectory (cycle) has S-internal stability and, consequently, presents a recurrent motion.

Markov [13] showed that each bounded S-internally stable $I_{\min}$ consists of almost periodic trajectories, i.e., trajectories such that each of their components is a Bohr almost periodic function, i.e., is expanded in a trigonometric series

$$\sum_{i=1}^{\infty} (a_i \sin \omega_i t + b_i \cos \omega_i t), \quad (6)$$

where the a_i and b_i are constants, and the numbers ω_i need not be integers (in contradistinction to Fourier series).

The following property holds for an almost periodic trajectory $(x,t)F$. For any $\epsilon > 0$ there exists a $\tau_* = \tau_*(\epsilon) > 0$ such that, for each $t_0 \in T$ in the semi-interval $[t_0, t_0 + \tau_*]$ there exists at least one number τ (the so-called almost-period with respect to ϵ) for which

$$\rho[(x, t+\tau)F, (x, t)F] \leqslant \varepsilon \quad (7)$$

for all $t \in T$.

In particular, if (7) holds for $\epsilon = 0$, then the trajectory is called periodic (a cycle) with period τ. In this case, all the ω_i $(i = 1,2,\ldots)$ in (6) will be integers.

We note that dynamic ACS (1) may not satisfy the three enumerated axioms. For example, let X be the ordinary n-dimensional Euclidean space, T the set of real numbers, and $\varphi(x)$ a continuous decreasing function such that $\varphi(x_0) < 0$ for some $x_0 > 0$. Then, the trajectory defined by the equation $\dot{x} = \varphi(x)$ does not exist (i.e., can not be continued) for $t < \int_{x_0}^{+\infty} dx / \varphi(x) < 0$, if this latter integral exists.

It is known that each L-internally stable trajectory (1) can be continued.

A trajectory of the type in (1) that can be continued and is uniformly continuous in t is S-internally stable since, in this case, for each $\epsilon > 0$ there exists a $\delta = \delta(\epsilon) > 0$ such that (7) holds for $0 < \tau < \delta$ and any t.

Local continuity in t is a necessary but not a sufficient condition for S-internal stability. For example, the trajectory $y = 1/(1-x)$ of the system $\dot{x} = 1$, $\dot{y} = -1/(1-x)^2$ which passes through the point (0,1) for $t = 0$ does not possess S-internal stability.

We mention still one more important circumstance. A trajectory of type (1) which can not be continued is necessarily unbounded. The converse is not true. There exist trajectories which are simultaneously S-internally stable and L-internally unstable. Tricomi [14] first encountered such motions in a rotor (armature) of a synchronous motor which lagged the stator's rotating magnetic field by the angle θ, the motion being described by the equation

$$\ddot{\theta} + A\dot{\theta} + B\sin\theta = C. \quad (8)$$

where $A > 0$, $B > C > 0$. The law of this motion is defined by the continuous periodic function $\vartheta = \vartheta(t)$ with period τ:

$$0 = \vartheta + \frac{2\pi}{\tau}t. \quad (9)$$

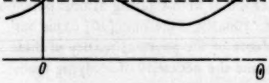

Fig. 1

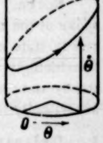

Fig. 2

Fig. 1. Slipping mode of an asynchronous motor's rotor.

Fig. 2. Cylindrical phase plot of an asynchronous motor's rotor slippage.

On the phase (velocity) Liénard $\{\theta, \dot{\theta}\}$ plane, this law takes the form of the unbounded curve shown in Fig. 1.

This law of motion also has another geometric interpretation. On a phase cylinder (Fig. 2), it is given by a closed curve (a cycle) with elliptical form, and is bounded.

The dual interpretation just given has a curious meaning. According to Nemytskii's classification [9], each bounded S-internally stable and (simultaneously) asymptotically stable (external, in the sense of A. M. Lyapunov) trajectory represents a steady-state mode. Consequently, in the sense of Nemytskii, the mode given by (9)[††], depending on the choice of the coordinate system, is simultaneously both steady-state and not steady-state.

[††] It is known that the mode of (9) is asymptotically stable in the sense of Lyapunov.

2. Definition of the Steady-State Mode

We assume *a priori* that, in topological space X, a limiting operation is defined, and that the group T is a well-ordered set of elements ‡‡.

Let I_{min} be embedded in the open region U. The set of points $\underline{x}$ which lie in U but do not lie in I_{min} is called the open envelope of I_{min}, and is denoted by $U(I_{min})$.

If there exists a $U(I_{min})$ such that, for each of its points, there is an increasing sequence $t_i \in T$ $(i = 1, 2, \ldots)$

$$t_1 < t_2 < \ldots < t_n < \ldots \tag{10}$$

such that

$$(x.\, t_n)F \to I_{min} \quad \text{for} \quad n \to +\infty. \tag{11}$$

then I_{min} is called orbitally asymptotically stable (in the sense of Poincaré) in the positive direction. In this case, $U(I_{min})$ is called the domain of attraction of I_{min}.

Correspondingly, one speaks of a negative direction, if the sequence in (10) is a decreasing one.

If there exist simultaneously two sequences, one increasing and the other decreasing, one says that I_{min} is simply orbitally asymptotically stable.

If, moreover, there exists a point $y \in I_{min}$ such that, in addition to (11), there holds the relationship

$$(x.\, t_n)F \to (y.\, t_n)F \quad \text{for} \quad n \to +\infty. \tag{12}$$

then one says that I_{min} is asymptotically stable in the sense of A. M. Lyapunov [in, respectively, the positive, negative, and in both directions where, in the latter case, one says that I_{min} is unconditionally asymptotically stable (in the sense of G. Dirichlet)].

If the space X is a metric one, then the definitions just given assume their ordinary meanings***.

Each mode of motion which is an internally and orbitally asymptotically stable (externally) I_{min} is called a steady-state mode. The corresponding process of establishing the steady state is defined by the limiting process of (11) in the sense of the topology of X.

Each I_{min} of steady-state modes has a domain of attraction. For example, such domains do not exist for any invariant set of motions defined by the equation $\ddot{x} + x = 0$.

Nemytskii [9] showed that the presence of a domain of attraction in an almost periodic mode essentially simplifies its structure. Thus, for example, each asymptotically stable (in the sense of Lyapunov) steady-state mode of a three-dimensional system is either an equilibrium position (with one state) or a periodic mode or an almost periodic mode (with many states) having not more than two independent frequencies. The images of these motions in phase space are, respectively, a point, a closed curve, and an irrational toroidal winding. Whether the analogous suppositions hold for n-dimension systems, for n>3, is not yet known, but is probable.

The domain of attraction of an almost periodic steady-state mode can not keep its trajectories isolated. An infinite set of trajectories passing through the limit points of these almost periodic trajectories will also be embedded in the domain of attraction. All these trajectories will also be almost periodic, with the same frequencies as the first one. The trajectory of a periodic steady-state mode can be unique in its domain of attraction.

We note in conclusion that Nemytskii [9], following Franklin [12], insists that each steady-state mode must be S-internally stable. He starts from the condition that "if at some moment of time two states were neighboring, it must follow that in the future these states must remain neighboring, since otherwise the mode under investigation either would have in the past, or will have in the future, some tendency to development consisting of a separation of these two states from each other, which would render it impossible to speak of a steady-state mode". These words seem essentially unconvincing and unclear, so that the development in time must be understood only from the point of view of the limitation given in (2).

Since every motion in time is a development, then each temporal invariant may, with equal justification, be taken as an indication of nondevelopment (in the meaning defined by him), stationary nature, or establishment in time. The choice of some temporal invariant or another must be determined, not by subjective conceptions, but by the objective problem which supervenes in the concrete investigation of an ACS. On this score, one could give many convincing examples from practice.

3. On Certain Methods of Investigating Almost Periodic Steady-State Modes in an ACS

The simplest method of investigation is a modification of Minorsky's approximate "stroboscopic" method [16], well-known in nonlinear mechanics, this method being a further development of the principle introduced into science in 1883 by A. Gulden and Linstedt [17]†††. The limits of applicability of the "stroboscopic" method were determined by Urabe [18].

For greater clarity we demonstrate this method by the example of a four-dimensional ACS without, however, lessening the generality.

We turn to the example of a "blind" winged missile, circling (without lateral banking) at a constant altitude under the action of residual voltage U (of a hysteresis magnetic or "zero drift" vacuum tube amplifier).

---

‡‡The topological transformation group (X,T,F) is a semi-ordered set if T is well-ordered [11].

***We note that, in the monograph of Zubov [15], orbital stability, as given by (11), is called stability in the sense of Lyapunov, which can lead to misunderstandings. For example, for an isolated orbit of a heavenly body (a Sputnik moving in accordance with Kepler's law in a conservative central force field $\ddot{\eta} = -\mu r/|r|r^2$ (where $\underline{r}$ is the vector of the body and μ is the gravitational constant), the orbit is unstable in the sense of Lyapunov and orbitally stable.

†††Their work also served as the starting point for the development of the results of Krylov and Bogolyubov.

In the particular case, the missile equations can be put in the form

$$\ddot{\beta} + c_1\dot{\beta} + c_2\beta + c_3\delta = 0. \qquad (13)$$
$$\dot{\psi} = \dot{\beta} + c_4\beta$$

(where c_1, c_2, c_3, and c_4 are positive numbers, and β, ψ and δ are the angles of lateral slipping, course, and rudder deviation from the neutral position), while the autopilot equations are

$$\dot{\delta} = f(\sigma), \quad \sigma = i(\dot{\beta} + \nu\beta - U) - \delta. \qquad (14)$$

where $f(\sigma)$ is the piecewise-smooth velocity characteristic of the steering mechanism [$\sigma f(\sigma) > 0$ for $\sigma \neq 0$, $f(0) = 0$], $i > 0$ is the autopilot's rigid feedback coefficient and $\nu > 0$ is the transfer ratio of the accelerometer for lateral linear acceleration.

We assume a priori that oscillations are observed in the system, and that the conditions for applying the "stroboscopic" method are satisfied ‡‡‡. We may then set

$$\beta = \beta_0 + x(t)\sin nt + y(t)\cos nt, \quad \sigma = z(t)\sin nt, \qquad (15)$$

where $\beta_0 = c_3 U/(c_3\nu + c_2/i)$. n is angular frequency, and x(t), y(t), and z(t) are slowly varying functions of time (in relation to the period $2\pi/n$).

On the basis of the previously given theorem of V. V. Nemytskii [9], the state equilibrium positions and the periodic modes of the $\{x,y,z\}$ phase space of the stroboscopic projections of the hyperplanes of the $\{\beta, \dot{\beta}, \delta\}$ phase space of (13)-(14) completely define all the bounded steady-state modes (possessing S-internal stability) of (13)-(14) [owing to the degeneration of (13), since the second equation does not depend on the first]. A study of the three-dimensional (induced) system of equations in the $\{x,y,z\}$ phase space can be carried out by the methods presented in [19-25] and others. However, there are as yet no effective methods for determining the domains of attraction (except for what was presented in [23]).

It so happens that, under certain conditions, the $\{x,y,z\}$ phase space contains a unique stable cycle. It is then easily seen that the cylindrical $\{\beta, \dot{\beta}, \delta, \psi\}$ phase space of (13)-(14) will contain a unique (bounded) steady-state almost periodic mode with two coexisting independent frequencies n and $c_4\beta_0$, so long as the latter are incommensurable.[1]

This same result is attained by the (exact) method of the topological product, the essence of which is as follows.

By well-known topological methods [23] one proves the existence of a stable oscillatory mode in $\{\beta, \dot{\beta}, \delta\}$ phase space.

The cylindrical $\{\beta, \dot{\beta}, \delta, \psi\}$ phase space is considered as the topological product of the $\{\beta, \dot{\beta}, \delta\}$ hyperplane and the $\{\psi\}$ circle. By this we arrive at the result given above

It should be mentioned that the topological product method has thus far been applied only to those ACS whose equations are either degenerate, or reduce in some fashion to those groups of which one, at least, is amenable to the application of one of the methods of investigation given in [19-25].

The author wishes to express his gratitude to V. V. Nemytskii and M. I. Fl'shin for their comments, reflected in the present work.

DETERMINING PULSE SYSTEM OPTIMUM WEIGHTING FUNCTION WHICH ENSURES THE EXTREME OF A FUNCTIONAL

N. I. Andreev

(Kharkov)

Translated from Avtomatika i Telemekhanika, Vol 21, No. 4 pp. 465-473, April, 1960
Original article submitted October 17, 1959

A method is described for finding the optimum pulse system which ensures an extreme of a sufficiently general criterion in the form of a functional I = Φ($I_1,\ldots,I_{n+1}$), where Φ is a known function, and I_i are quadratic functionals of the weighting function of the system.

The methods for the determination of the optimum linear pulse systems minimizing the mean-square-error at its output are given in [1,2]. The least mean-square-error criterion seems a suitable choice in many cases when selecting a dynamic system. In practice, however, when evaluating and comparing various pulse systems one often encounters cases where the most suitable criterion is a more complex probability characteristic of the accuracy of the system operation. A characteristic of this type may be, for example, the probability P of the system error not exceeding by numerical value a certain given quantity c. In a specific case the probability P may usually be expressed in terms of mathematical expectation and variance of the separate components of the error, the components having different distributions. (When the components of the system error also depend on one another the moments due to their correlation should also be considered. For example, if the error of the system is composed of the sum of mathematical expectation a and a random component normally distributed with variance σ^2, then

$$P = \frac{1}{\sqrt{2\pi}\sigma}\int_{-c}^{c}\exp\left[-\frac{(a+x)^2}{2\sigma^2}\right]dx = I(a^2, \sigma^2). \qquad (1)$$

In the case when the mathematical expectation of the error is a, and the first random component Z_1 of the error is distributed normally with variance σ^2, and the second random component Z_2 has a rectangular distribution within the interval from -b to +b, and Z_1 and Z_2 are independent, then

$$P = \frac{1}{\sqrt{2\pi}2b\sigma}\int_{-c}^{c}\left\{\int_{-b}^{b}\exp\left[-\frac{(a+y+x)^2}{2\sigma^2}\right]dx\right\}dy = I(a^2, \sigma^2, b^2). \qquad (2)$$

In the often encountered case when the quantity c is small, (1) and (2) assume a simpler form:

$$P \approx \frac{\sqrt{2}c}{\sqrt{\pi}\sigma}\exp\left[-\frac{a^2}{2\sigma^2}\right], \qquad (1a)$$

$$P \approx \frac{c}{\sqrt{2\pi}\sigma b}\int_{-b}^{b}\exp\left[-\frac{(a+y)^2}{2\sigma^2}\right]dy. \qquad (2a)$$

The quantities a^2, σ^2, b^2 are quadratic [3,4,6] functionals of the system weighting function. In a more general case a^2, σ^2, b^2 also depend parametrically on time. Consequently, even the optimum system which at any given moment of time is extreme depends on time and is thus nonstationary.

We shall assume henceforth that the criterion I for selecting the optimum system is a given function Φ of n + 1 quadratic functionals I_i (i = 1,..., n + 1) which in turn depend on the weighting function of the pulse system. The problem of determining the optimum linear pulse system according to the I criterion is formulated in the same way as in [3,5] when determining the optimum linear system of a continuous type.

We assume that there is a method of finding an optimum weighting function $k_0[n,m,\epsilon]$* of a pulse system with given time of the transient process and such that the function will ensure the extreme of the quadratic functional

$$I_{\text{II}} = \theta_1 I_1(k[n,\ m,\ \varepsilon]) + \ldots + \theta_n I_n(k[n,\ m,\ \varepsilon]) + I_{n+1}(k[n,\ m,\ \varepsilon]) \qquad (3)$$

for arbitrary values of the parameters θ_i. A method is sought to determine the optimum weighting function $k^*[n,m,\epsilon]$ with the same transient process time interval, and such that it will ensure the extreme of the functional

$$I = I(k[n,\ m,\ \varepsilon]) = \Phi(I_1, \ldots, I_{n+1}). \qquad (4)$$

The time is here expressed in integral units [1,2]. The time in conventional units is obtained from the integral units as follows: t = nT + mT + εT at any moment of time, t = mT at the discrete values of time. The quantity T is the pulse sampling period, otherwise the control time interval of the pulse system, and ε varies from 0 to 1.

---

*The weighting function $k[n,m,\epsilon]$ of a pulse system with variable parameters of the equivalent (reducible) continuous part expresses its response at the moment t = n + m + ε to a unit impulse applied to the input at the moment t = n – 0.

The problem is solved at an arbitrary moment of time regarded as a parameter.

The difference between the formulations of this problem and of [3,5] lies in the latter continuous case being the optimum system in the class of all the possible linear systems with the same given duration of the transient process; and in our problem the optimum system is selected from the class of pulse linear systems with given pulse sampling period as well as duration of transient process. All the pulse system weighting functions with a given pulse sampling period form a linear manifold (which also holds good for weighting functions of continuous linear systems)[†]. Therefore, all the derivations and proofs obtained in [3,5] for linear systems of continuous type could be repeated by replacing everywhere "linear system" (of continuous type) with "pulse system" (with given pulse sampling period). We just state the fundamental result without reproducing the derivations.

The necessary conditions which must be fulfilled by the weighting function $k^\circ[n,m,\epsilon]$ ensuring the extreme of the functional I are:

a) The function k° should ensure the extreme of the functional I_{II}, i.e., it is required that:

$$k^\circ = k_0[n, m, \varepsilon, \theta_1, \dots, \theta_n]\,|_{\theta_i=\theta_{i0}}; \tag{5}$$

b) The following should be valid:

$$\left.\frac{\partial I\,(k_0\,[n, m, \varepsilon, \theta_1, \dots \theta_n]}{\partial\theta_i}\right|_{\theta_j=\theta_{j0}} \tag{6}$$

$$(i, j = 1, \dots, n).$$

or (a special case) the condition below must be fulfilled:

$$\frac{\partial\Phi\,[I_1(k^\circ), \dots I_{n+1}(k^\circ)]}{\partial I_l} = 0 \qquad (l = 1, \dots n+1).$$

which illustrates the fact that the function Φ reaches its extreme within the domain of variability of the I_i functionals. This special case is usually of no practical importance.

The condition a) enables one to reduce the complex task of determining the function k° at which the extreme of I occurs to a less complex one of finding k_0 at which the extreme of I_{II} occurs. Determining the function $k_0 = k_0[n,m,\epsilon,\theta_1, \dots, \theta_n]$ is the principal stage in the solution of our problem. Once the function $k_0[n,m,\epsilon, \theta_1, \dots, \theta_n]$ has been obtained explicitly for arbitrary values of the parameters θ_i, it is easy to determine the values of the parameters $\theta_i = \theta_{i0}$ satisfying the condition b)[‡]. Where only approximations to the function are obtained, the values of the parameters $\theta_i = \theta_{i0}$ are also evaluated approximately, for example, graphically. As long as the number n of the parameters θ_i remains small, the determination of the values θ_{i0} is fairly straightforward and easy. This is why the determination of the weighting function $k_0[n,m,\epsilon,\theta_1, \dots, \theta_n]$ ensuring the extreme of I_{II} should have primary attention. Methods of determining k_0 with data given in other forms have been sufficiently developed [6, 7 and others]. The functionals I, I_i, I_{II} obtained when investigating the pulse systems differ from the corresponding functionals I, I_i, I_{II} obtained when examining the continuous linear systems (the integrals in the latter case correspond to sums in the former one).

In the case of a pulse system, the determination of k_0 can be reduced to the solution of linear algebraic equations [1,2]. As is known, in the continuous case k_0 is determined as a solution of a certain linear integral equation. The actual form of the equations depends in both cases on the way in which the data are given.

We shall consider one method of determining the optimum weighting function of a pulse system from the criteria (1a). Let on the input of the pulse system be impressed a useful signal $X[n, \epsilon]$ which can be represented as a sum of a known nonrandom continuous function $x[n,\epsilon]$ and a random function $X^\circ[n,\epsilon]$ distributed normally with xero mean and correlation function $R_x[n-m, n-l]$. The interference $Z[n,\epsilon]$ also occurs at the input; it is a random function normally distributed with zero mean and correlation function $R_z[n-m, n-l]$. In order to simplify the subsequent exposition, it is assumed that interference and signal are not correlated, that is, $M[XZ] = 0$. The pulse system at the output is given by the function $HX[n,\epsilon]$, where H is a linear operator. The time of the system transient process is equal to N.

In this case the error is equal to

$$E[n, \varepsilon] = \left\{\sum_{m=0}^{N} x[n-m]\,k[n-m, m, \varepsilon] - Hx[n, \varepsilon]\right\} + \tag{7}$$

$$+\left\{\sum_{m=0}^{N} X^\circ[n-m]\,k[n-m, m, \varepsilon] - HX^\circ[n, \varepsilon]\right\} + \sum_{m=0}^{N} Z[n-m]\,k[n-m, m, \varepsilon]$$

(the effect of initial conditions being neglected).

In the expression (7) the first term represents the mathematical expectation a of the error, the second and the third term being random components of the error.

[†] A set of M is called linear manifold when its elements satisfy the following rules: when k_1 and k_2 belong to M, then $a_1k_1 + a_2k_2$ also belongs to M, whatever the arbitrary numbers a_1, a_2.

[‡] It was shown in [3, 5] that in order to determine $\theta_i = \theta_{i0}$ one can utilize another condition:

$$\frac{\partial I}{\partial I_j} \Big/ \frac{\partial I}{\partial I_{n+1}} = \theta_j \quad (j = 1, \dots, n).$$

instead of condition b).

We denote by I_1 the variance of the error:

$$I_1 = \sigma^2 = M[(E-a)^2] = \sum_{l=0}^{N}\sum_{m=0}^{N} R_z[n-m, n-l]\,k[n-m, m, \varepsilon]\,k[n-l, l, \varepsilon] + \\ + \sum_{l=0}^{N}\sum_{m=0}^{N} R_x[n-m, n-l]\,k[n-m, m, \varepsilon]\,k[n-l, l, \varepsilon] - \\ - 2\sum_{l=0}^{N} HR_x[n-l, n+\varepsilon]\,k[n-l, l, \varepsilon] + HHR_x[n+\varepsilon, n+\varepsilon]. \tag{8}$$

In the last but one term, the operator H on the correlation function R_x operated with respect to its second argument.

We denote by I_2 the square of the mathematical expectation of the error E:

$$I_2 = a^2 = (M[E])^2 = \left\{\sum_{m=0}^{N} x[n-m]\,k[n-m, m, \varepsilon] - Hx[n, \varepsilon]\right\}^2. \tag{9}$$

The functional I_{II} in this case takes the form

$$I_{II} = \theta_1 I_1 + I_2. \tag{10}$$

Bearing in mind what was stated previously, one has to find a weighting function $k_0[n, m, \epsilon, \theta_1]$ which will ensure the extreme of the functional (10). The necessary condition satisfied by such a function k_0 is [6,8] the vanishing of the first variation of the functional I_{II}

$$\left.\frac{dI_{II}\{k[n, m, \varepsilon, \theta_1] + \Delta\varkappa[n, m, \varepsilon]\}}{d\Delta}\right|_{\Delta=0} = 0 \tag{11}$$

for any weighting function κ of a pulse system with pulse sampling period T and time N of the transient process.

We rewrite the expression for the quadratic functional $I_{II}[k + \Delta\kappa]$ in the expanded form

$$I_{II}[k + \Delta\varkappa] = I_{II}[k] + 2\Delta D_1 + \Delta^2 D_2. \tag{12}$$

where

$$D_1 = \sum_{l=0}^{N} \varkappa[n-l, l, \varepsilon]\left\{\sum_{m=0}^{N} k[n-m, m, \varepsilon, \theta_1](\theta_1 R_z[n-m, m-l] + \right. \\ + \theta_1 R_x[n-m, n-l] + x[n-l]\,x[n-m]) - x[n-l]\,Hx[n, \varepsilon] - \\ \left. - \theta_1 HR_x[n-l, n+\varepsilon]\right\},$$

$$D_2 = \sum_{l=0}^{N}\sum_{m=0}^{N} \varkappa[n-l, l, \varepsilon]\,\varkappa[n-m, m, \varepsilon](\theta_1 R_2[n-m, n-l] + \\ + \theta_1 R_x[n-l, n-m] + x[n-m]\,x[n-l]).$$

It follows from (11) and (12) that

$$\sum_{l=0}^{N} \varkappa[n-l, l, \varepsilon]\left\{\sum_{m=0}^{N} k[n-m, m, \varepsilon, \theta_1](\theta_1 R_z[n-m, n-l] + \right. \\ + \theta_1 R_x[n-m, n-l] + x[n-l]\,x[n-m]) - \theta_1 HR_x[n-l, n+\varepsilon] - \\ \left. - x[n-l]\,Hx[n, \varepsilon]\right\} = 0. \tag{13}$$

In order that (13) be valid for an arbitrary function κ from the admissible class, it is necessary that the relation given below be valid:

$$\sum_{m=0}^{N} k[n-m, m, \varepsilon, \theta_1](\theta_1 R_z[n-m, n-l] + \theta_1 R_x[n-m, n-l] + \\ + x[n-l]\,x[n-m]) - \theta_1 HR_x[n-l, n+\varepsilon] - x[n-l]\,Hx[n, \varepsilon] = 0 \\ (l = 0, 1, \ldots, N). \tag{14}$$

To prove it, let us assume that the relation (14) is not valid for certain $l = l_1$, $0 \leq l_1 \leq N$; the parameters n, ϵ, θ_1 are assumed constant. When $l = l_1$ the left-hand side of (14) is equal to some $S \neq 0$. Knowing that κ is an arbitrary function, we choose κ in the following way:

$$\varkappa[n-l_1, l_1, \varepsilon] = 1, \ \varkappa[n-l, l, \varepsilon] = 0 \qquad (l \neq l_1).$$

But if κ is chosen in this way, (13) is not true. Consequently, our assumption has been proved to be wrong.

The relation (14) is also a sufficient condition for the function $\underline{k}$ to minimize I_{II} when $\theta_1 \geq 0$. It follows, namely, from (12) that, when $\underline{k} = \underline{k}_0$ satisfies (14), then $I_{II}[k_0+\varkappa] = I_{II}[k_0] + D_2$, where $D_2 \geq 0$.

It follows that $I_{II}[k_0+\varkappa] \geqslant I_{II}[k_0]$ for an arbitrary κ, which is what we had to prove.

The values $\theta_1 < 0$ are, as a rule, of no practical importance.

The solution $k_0[n,m,\epsilon,\theta_1]$ of the simultaneous linear algebraic equations (14) must be substituted in (8) and (9) to obtain the relations $a^2 = a^2(\theta_1)$, $\sigma^2 = \sigma^2(\theta_1)$; subsequently, by using (1a), it is easy to obtain P as a function of θ_1. Then the value $\theta_1 = \theta_{10}$ corresponding to the maximum of P is found from $dP(\theta_1)/d\theta_1 = 0$. The optimum weighting function of a pulse system is in our case: $k^* = k_0[n,m,\epsilon,\theta_{10}]$; the greatest value of probability – which points to the optimum system – is $P_0 = P(\theta_{10})$.

The conditions which ensure the extreme of the functional I actually occurring at k^* are not considered in the present paper. For pulse systems these conditions can be formulated analogously to those in [5] for continuous systems.

When dealing with a complex problem the main difficulty lies in solving the simultaneous equations (14) or similar equations. In a number of special cases of a similar character, the simultaneous equations can be solved exactly [1]. In the general case, the solving of such or similar equations can be accomplished by means of various approximate methods. The method of the steepest descent [4,6] appears to be particularly appropriate. We shall also apply it directly to determine the extreme of the quadratic functional I_{II}. (A description is given of the main features of this method when it is utilized to find the minimum of the functional I_{II}.

Let the selection of the first approximation of $k[n-m, m, \epsilon] = k_1[n-m, m, \epsilon]$, based on arbitrary considerations. We find next the direction of the gradient in the normed space of functions $k[n-m, m, \epsilon]$, that is, the direction along which the functional I_{II} decreases most steeply. The norm of a function $\underline{k}$ is defined by

$$\|k[n-m, m, \varepsilon]\| = \sum_{m=0}^{N} k^2[n-m, m, \varepsilon]. \qquad (15)$$

The function $\kappa_1[n-m, m, \epsilon]$, which corresponds to the direction of the gradient, should ensure the extreme of the quantity

$$\left.\frac{dI_{II}(k_1[n-m, m, \varepsilon] + \Delta\varkappa_1[n-m, m, \varepsilon])}{d\Delta}\right|_{\Delta=0} \qquad (16)$$

under the condition

$$\sum_{m=0}^{N} \varkappa_1^2[n-m, m, \varepsilon] = 1. \qquad (17)$$

It follows that this function should also ensure the unconditional extreme of the expression

$$\left.\frac{dI_{II}(k_1[n-m, m, \varepsilon] + \Delta\varkappa_1[n-m, m, \varepsilon])}{d\Delta}\right|_{\Delta=0} + \qquad (18)$$
$$+ \mu \sum_{m=0}^{N} \varkappa_1^2[n-m, m, \varepsilon],$$

with μ being the Lagrange multiplier whose value can be found from the constraint (17) (in our problem the multiplier does not appear to be real and therefore is not found from the condition (17)). Bearing in mind that I_{II} is a quadratic functional one is able to write down

$$I_{II}(k_1[n-m, m, \varepsilon] + \Delta\varkappa_1[n-m, m, \varepsilon]) = \qquad (19)$$
$$= I_{II}[k_1] + 2\Delta A_1 + \Delta^2 A_2,$$

where A_1, A_2 depend only on κ_1 and κ_2 but do not depend on Δ, A_1 being of the form

$$A_1 = \sum_{m=0}^{N} B_1[n-m, m, \varepsilon]\, L\varkappa_1[n-m, m, \varepsilon].$$

The expression $B_1[n-m, m, \epsilon]$ here depends only on k_1, but not on κ_1; L is a linear transformation (on κ_1) operator. It is easy to see that in the case often encountered in practice, when $L\kappa_1 = \kappa_1$, the necessary condition for the extreme of the functional (18) is, with an accuracy of up to multiplier μ, of the form

$$\varkappa_1[n-m, m, \varepsilon] = B_1[n-m, m, \varepsilon]. \qquad (20)$$

As the second approximation of the function $\underline{k}$ one takes

$$k_2 = k_1 + \Delta_1\varkappa_1,$$

where κ_1 is given by (20) and Δ_1 is obtained from the condition that when $\Delta = \Delta_1$ then the function $\phi(\Delta) = I_{II}(k_1 + \Delta\varkappa_1)$ reaches its minimum (its extreme). Then $\kappa_1 = B_1$. It follows from (9) that $\Delta_1 = -(A_1 / A_2)$.

The third and subsequent approximations are determined by applying analogous considerations. The evaluation of successive approximations can easily be programmed for a digital computer.

The described method can also be applied to evaluate the extreme of the I functional. Now the determination of $\kappa_l[n-m, m, \epsilon]$ is somewhat more involved (in the expression $\left.\frac{dI}{d\Delta}\right|_{\Delta=0} = \sum_{i=0}^{n+1} \frac{\partial I}{\partial I_i} \left.\frac{dI_i}{d\Delta}\right|_{\Delta=0}$ one has to evaluate also the derivatives $\frac{\partial \Phi}{\partial I_i}$ when $k = k_l$) and the procedure of finding the consecutive values $\Delta_1, \Delta_2, \ldots,$ becomes appreciably more difficult because of the difficulty of determining the extreme of the generally complex function $\xi(\Delta) = I(k_l + \Delta \kappa_l)$. However, in this case it is not indispensable to determine the values of the parameters $\theta_i = \theta_{i0}$ which were introduced only as an artifice. In each individual case one has to decide whether one should try to find directly the extreme of I or whether to find first the weighting function which will ensure the extreme of I_{II} at various values of the parameters θ_i and subsequently determine the values $\theta_i = \theta_{i0}$.

In the specific case when the functional I_{II} is given by (8), (9) and (10), A_1 and A_2 are expressed by means of k_1 and κ_1 as follows:

$$A_1 = \sum_{l=0}^{N} \Big\{ \sum_{m=0}^{N} k_1 [n-m, m, \varepsilon] (\theta_1 R_z [n-m, n-l] + \theta_1 R_x [n-m, n-l] + $$

$$+ x[n+l]\, x[n-m]) - \theta_1 H R_x [n-l, n+\varepsilon] - x[n-l]\, Hx[n, \varepsilon] \Big\} \varkappa_1 [n-l, l, \varepsilon],$$

$$A_2 = \sum_{l=0}^{N} \sum_{m=0}^{N} (\theta_1 R_z [n-m, n-l] + \theta_1 R_x [n-m, n-l] + x[n-m]\, x[n-l]) \times$$

$$\times \varkappa_1 [n-l, l, \varepsilon]\, \varkappa_1 [n-m, m, \varepsilon],$$

$$\varkappa_1 = B_1 = \sum_{m=0}^{N} k_1 [n-m, m, \varepsilon] (\theta_1, R_z [n-m, m, \varepsilon] + \theta_1 R_x [n-m, m, \varepsilon] +$$

$$+ x[n-l]\, x[n-m]) - \theta_1 H R_x [n-l, n, \varepsilon] - x[n-l]\, Hx[n, \varepsilon],$$

$$\Delta_1 = -\frac{A_1}{A_2} = -\frac{\sum_{l=0}^{N} \varkappa_1^2 [n-l, l, \varepsilon]}{A_2} = -\frac{\sum_{l=0}^{N} B_1^2 [n-l, l, \varepsilon]}{A_2}.$$

As a rule, the method of steepest descent implies a rapid convergence. In each case the speed of convergence depends on the starting element k_1 as well as on the form of the functional taken as the norm of the function k. The starting element k_1 should be taken such that its norm be finite.

Example. Let useful signal X and interference Z be impressed on the input of a linear pulse system. The useful signal may be represented in the form $X = vt + X^{\circ}$, where X° is a random variable with a large variance, v a given quantity, and t the time.

The interference behaves as a stationary random process of normal distribution with the following characteristics: its mathematical expectation $M[Z] = 0$, its correlation function $R_z(\tau) = e^{-\alpha|\tau|}$. The variables X and Z are independent.

It is required to determine the weighting function of the pulse system with duration N = 1 of the transient process (the pulse sampling period is T) which would ensure maximum probability that the extrapolation error

$$E = X[n + \varepsilon + \varepsilon_e] - (X[n] + Z[n])\, \kappa [n, 0, \varepsilon] - \\ - (X[n-1] + Z[n-1])\, k[n-1, 1, \varepsilon] \tag{21}$$

shall not exceed by numerical value a small quantity c. The probability of $|E| \leq c$, with c small, is found from the formula (1a).

The weighting function k selected is subjected to the restriction

$$k[n, 0, \varepsilon] + k[n-1, 1, \varepsilon] = 1, \tag{22}$$

which is feasible, since variable X° must have a large variance. It is known that the condition (22) produces nonstability of the xero order. Taking into account the initial data in our example and (22), we shall pick k in the class of stationary weighting functions. Consequently, $k = k[m, \epsilon]$ and (22) becomes

$$k[0, \varepsilon] + k[1, \varepsilon] = 1. \tag{22a}$$

Expression (21) can be rewritten in this case as

$$E = X^{\circ} + vT(n + \varepsilon + \varepsilon_e) - X^{\circ} - vTnk[0, \varepsilon] - \\ - vT(n-1)\, k[1, \varepsilon] - Z[n]\, k[0, \varepsilon] - \\ - Z[n-1]\, k[1, \varepsilon] = vT(\varepsilon + \varepsilon_e) + vTk[1, \varepsilon] - \\ - Z[n]\, k[0, \varepsilon] - Z[n-1]\, k[1, \varepsilon],$$

where $\epsilon_e T$ is the extrapolation time.

We determine a^2, σ^2, and I_{II}:

$$a^2 = (M[E])^2 = v^2 T^2 (\varepsilon + \varepsilon_e + k[1, \varepsilon])^2, \tag{23}$$

$$\sigma^2 = M[(E-a)^2] = k^2[0, \varepsilon] + \\ + 2e^{-\frac{\alpha}{T}} k[0, \varepsilon]\, k[1, \varepsilon] + k^2[1, \varepsilon], \tag{24}$$

$$I_{II} = \theta_1 \sigma^2 + a^2 = \theta_1 (k^2[0, \varepsilon] + \\ + 2e^{-\frac{\alpha}{T}} k[0, \varepsilon]\, k[1, \varepsilon] + k^2[1, \varepsilon]) + \\ + v^2 T^2 (\varepsilon + \varepsilon_e + k[1, \varepsilon])^2. \tag{25}$$

It is necessary to find function k_0 minimizing I_{II} under the condition (22a). This function should ensure the unconditional minimum of the functional

$$'' = I_{II} + 2\gamma_0 (k[0, \varepsilon] + k[1, \varepsilon]), \tag{26}$$

where γ_0 is a Lagrange multiplier which can be determined from (22a). To determine k_0 we utilize (14) which in our case can be written as

$$\theta_1 k[0,\varepsilon] + \theta_1 e^{-\frac{\alpha}{T}} k[1,\varepsilon] = -\gamma_0,$$

$$\theta_1 e^{-\frac{\alpha}{T}} k[0,\varepsilon] + (\theta_1 + v^2T^2)\, k[1,\varepsilon] = -\gamma_0 - v^2T^2(\varepsilon + \varepsilon_e). \tag{27}$$

Solving the simultaneous equations (27) and (22a) we obtain

$$k_0[0,\varepsilon] = \frac{\theta_1 e^{-\frac{\alpha}{T}}[\gamma_0 + v^2T^2(\varepsilon + \varepsilon_e)] - \gamma_0(\theta_1 + v^2T^2)}{\theta_1\left(\theta_1 - \theta_1 e^{-2\frac{\alpha}{T}} + v^2T^2\right)},$$

$$k_0[1,\varepsilon] = \frac{\gamma_0\theta_1\left(e^{-\frac{\alpha}{T}} - 1\right) - v^2T^2(\varepsilon - \varepsilon_e)}{\theta_1\left(\theta_1 - \theta_1 e^{-2\frac{\alpha}{T}} + v^2T^2\right)}, \tag{28}$$

$$\gamma_0 = \frac{\theta_1\left[\theta_1\left(1 - e^{-2\frac{\alpha}{T}}\right) + v^2T^2\right] + v^2T^2(\varepsilon + \varepsilon_e)\left(1 - \theta_1 e^{-\frac{\alpha}{T}}\right)}{2\theta_1\left(e^{-\frac{\alpha}{T}} - 1\right) - v^2T^2}.$$

Formulas (28) enable one to determine the function k_0 when the values of ε and θ_1 are given. By keeping constant the value of the standardized time ε, one should find k_0 for several values of $\theta_1 \geq 0$ and determine subsequently the function $P = P(\theta_1)$; it is easy then to evaluate the value $\theta = \theta_{10}$ which corresponds to the maximum of P.

CONCLUSION

The presented method of finding the optimum pulse system ensuring the extreme of I seems to be more laborious when compared with the method of finding the pulse system ensuring the minimum of the mean-square error of the system, but basically, both methods are equally complex. The criterion I is sufficiently general; it can be utilized when selecting automatic control systems designed for various purposes. This method can also be used in the selection of optimum nonlinear systems [9].

THE EFFECT OF STATIONARY RANDOM PROCESSES ON AUTOMATIC CONTROL SYSTEMS CONTAINING ESSENTIALLY NONLINEAR ELEMENTS

G. I. Pyatnitskii

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 4, pp. 474-480, April, 1960
Original article submitted June 22, 1959

A method of calculating nonlinear automatic control systems under the action of stationary random processes is proposed. The method presented is a generalization of the method of statistical linearization and allows one to take into account the distortion of the spectrum of a random process by nonlinear elements.

At the present time the statistical calculation of automatic control systems containing essentially nonlinear elements is accomplished by the method of statistical linearization [1]. In essence this method consists in replacing a nonlinear element by an amplifier equivalent to it in some sense. The method is fairly simple and therefore is widely applicable in practice.

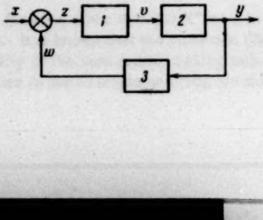
However, this method may never be considered completely justified, since the replacement of a nonlinear element by a linear amplifier does not take into consideration the distortion of the signal spectrum by the nonlinear element, and this distortion may in some cases prove to have a significant influence on the action of the system.

In this paper a more systematic approach to the problem of the statistical calculation of nonlinear systems is presented, in which the method of statistical linearization appears as the first approximation to the solution of the problem. As a consequence, one may estimate the applicability of the method of statistical linearization to a definite class of automatic control systems. The method presented may thus be considered a generalization and development of the ordinary method of statistical linearization.

1. Formulation of the Problem

We consider a system with feedback shown schematically in the figure. It contains one nonlinear element 1 with so-called standard characteristics [2]. All the remaining links are assumed to be linear with constant parameters. Any system containing one nonlinear element may be brought into such a form.

Suppose link 2 has weight function $g(t)$ and frequency characteristic $G(\omega)$, and the link consisting of 2 and 3 in series has weight function $k(t)$ and frequency characteristic $K(\omega)$.



We suppose the input to the system to be a Gaussian stationary random process $x(t)$; let m_x be the mathematical expectation, and σ_x^2 and $R_x(\tau)$ the variance and correlation function of the input process.

The problem consists in calculating the variance σ_y^2 and mathematical expectation m_y of the system's output process $y(t)$.

The process $z(t)$ represents the difference between the input process $x(t)$ and the process $w(t)$, which appears as a result of $z(t)$ acting through the nonlinear element and the succeeding linear elements. The presence of the nonlinear element leads to the fact that the distribution law for the random process at its output will necessarily not be Gaussian. However, the process is "normalized" by passing through the linear elements, so that the distribution law for the process $w(t)$ will be nearer to normal than the distribution law for the process at the output of the nonlinear element. Considering that the process $z(t)$ consists of the normal process $x(t)$ and the "normalized" process $w(t)$, one may assume that the distribution law $z(t)$ will be near normal. Proceeding from this, we make the assumption that the process $z(t)$ possesses a normal two-dimensional distribution law.

This assumption provides the possibility of solving the problem posed comparatively simply, since it is well known how normal fluctuations are transformed by a nonlinear element [2]. A similar assumption is made also in the method of statistical linearization.

2. Formation of the Basic Equation

Let $R_z(\tau)$ and $R_w(\tau)$ be correlation functions for processes $z(t)$ and $w(t)$, respectively, and $R_{zw}(\tau)$ and $R_{wz}(\tau)$, the mutual correlation functions for these processes.

We have the following equation:

$$R_x(\tau) = R_z(\tau) + R_w(\tau) + R_{zw}(\tau) + R_{wz}(\tau). \quad (1)$$

We shall find expressions for $R_w(\tau)$, $R_{zw}(\tau)$ and $R_{wz}(\tau)$ in terms of $R_z(\tau)$.

The normal two-dimensional distribution law for the process z(t) at $m_z = 0$ may be put into the form of a series [3,4]

$$f(z, z_\tau) = \frac{1}{\sigma_z^2} \sum_{n=0}^{\infty} \frac{\rho_z^n(\tau)}{n!} \Phi^{(n+1)}\left(\frac{z}{\sigma_z}\right) \Phi^{(n-1)}\left(\frac{z_\tau}{\sigma_z}\right), \tag{2}$$

where $\rho_z(\tau) = R_z(\tau)/\sigma_z^2$, $\Phi(x)$ is the probability integral defined by

$$\Phi(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{x} e^{-\frac{t^2}{2}} dt, \tag{2'}$$

and $\Phi^{(n)}(x)$ is the nth derivative of this probability integral with respect to x.

Let the characteristic of the nonlinear element, that is, the connection between the output v(t) and input z(t) of the nonlinear element be given by the relation

$$v = F(z). \tag{3}$$

Characteristics for a different type of nonlinear element are introduced in [1].

Using (2) and (3), one may calculate the mathematical expectation and correlation function of the process v(t) at the output of the nonlinear element [2]:

$$m_v = \int_{-\infty}^{\infty} F(z + m_z)\, d\Phi\left(\frac{z}{\sigma_z}\right), \tag{4}$$

$$R_v(\tau) = \sum_{n=1}^{\infty} \eta_n^2 \frac{\rho_z^n(\tau)}{n!}, \tag{5}$$

where

$$\eta_n = \int_{-\infty}^{\infty} F(z + m_z)\, d\Phi^{(n)}\left(\frac{z}{\sigma_z}\right). \tag{6}$$

The correlation function $R_w(\tau)$ may be written in the form

$$R_w(\tau) = \int_0^\infty \int_0^\infty k(\alpha) k(\beta) R_v(\tau - \alpha + \beta)\, d\alpha\, d\beta$$

or, considering (5),

$$R_w(\tau) = \sum_{n=1}^{\infty} \frac{\eta_n^2}{n!} \int_0^\infty \int_0^\infty k(\alpha) k(\beta) \rho_z^n(\tau - \alpha + \beta)\, d\alpha\, d\beta. \tag{7}$$

Analogously, for $R_{zw}(\tau)$ and $R_{wz}(\tau)$ we have the expressions

$$R_{zw}(\tau) = -\sigma_z \eta_1 \int_0^\infty k(\alpha) \rho_z(\tau + \alpha)\, d\alpha \tag{8}$$

and

$$R_{wz}(\tau) = -\sigma_z \eta_1 \int_0^\infty k(\alpha) \rho_z(\tau - \alpha)\, d\alpha. \tag{9}$$

Substituting (7), (8), and (9) into (1), we obtain an integral equation for $\rho_z(\tau)$:

$$\begin{aligned} &\sigma_z^2 \rho_z(\tau) - \eta_1 \sigma_z \int_0^\infty k(\alpha) [\rho_z(\tau + \alpha) + \rho_z(\tau - \alpha)]\, d\alpha + \\ &+ \eta_1^2 \int_0^\infty \int_0^\infty k(\alpha) k(\beta) \rho_z(\tau - \alpha + \beta)\, d\alpha\, d\beta + \\ &+ \sum_{n=2}^{\infty} \frac{\eta_n^2}{n!} \int_0^\infty \int_0^\infty k(\alpha) k(\beta) \rho_z^n(\tau - \alpha + \beta)\, d\alpha\, d\beta = \sigma_x^2 \rho_x(\tau). \end{aligned} \tag{10}$$

The equation obtained is nonlinear, since it contains a power of the function $\rho_z(\tau)$ higher than first. However, the nonlinear terms contain the factor $\eta_n^2/n!$ which, as an immediate calculation shows, is small in comparison to unity and is less that η_1^2. This circumstance allows us to apply the known method of expansion in powers of small parameters to the solution of (10). Such parameters in this case are $\eta_n^2/n!$. But it is not convenient to expand in powers of these parameters, since the number of them is infinite. Hence, it is more suitable by far to proceed in the following manner. We introduce the factor μ^n in front of the terms of the sums in the left portion of (10) and expand in powers of μ. From here on the solution proceeds according to the usual rules. Finally, one sets μ equal to one in the resulting expression. This may be done, because it is not necessary to consider μ to be a small quantity (in comparison with unity), since $\eta_n^2/n!$ are the small parameters.

3. Solution of the Integral Equation

Taking the above into consideration, we rewrite (10) in a somewhat modified form. We transfer the sum with the nonlinear terms to the right side and adjoin the factor μ^n before the terms of this sum:

$$\begin{aligned} &\sigma_z^2 \rho_z(\tau) - \sigma_z \eta_1 \int_0^\infty k(\alpha) [\rho_z(\tau + \alpha) + \rho_z(\tau - \alpha)]\, d\alpha + \\ &+ \eta_1^2 \int_0^\infty \int_0^\infty k(\alpha) k(\beta) \rho_z(\tau - \alpha + \beta)\, d\alpha\, d\beta = \\ &= \sigma_x^2 \rho_x(\tau) - \sum_{n=2}^{\infty} \mu^n \frac{\eta_n^2}{n!} \int_0^\infty \int_0^\infty k(\alpha) k(\beta) \rho^n(\tau - \alpha + \beta)\, d\alpha\, d\beta. \end{aligned} \tag{11}$$

We represent the solution to (11) in the form of a series:

$$\rho_z(\tau) = \sum_{m=0}^{\infty} \mu^m \rho_m(\tau). \tag{12}$$

Substituting (12) into (11), we obtain

$$\sum_{m=0}^{\infty}\mu^m \Big\{\sigma_z^2\rho_m(\tau) - \eta_1\sigma_z\int_0^{\infty} k(\alpha)\,[\rho_m(\tau+\alpha) + \rho_m(\tau-\alpha)]\,d\alpha + \\ + \eta_1^2\int_0^{\infty}\!\!\int_0^{\infty} k(\alpha)\,k(\beta)\,\rho_m(\tau-\alpha+\beta)\,d\alpha\,d\beta\Big\} = \sigma_x^2\rho_x(\tau) - \\ - \sum_{n=2}^{\infty}\;\sum_{m_1,\,\dots,\,m_n=0}^{\infty} \mu^{n+m_1+m_2+\,\dots\,+m_n}\frac{\eta_n^2}{n!}\int_0^{\infty}\!\!\int_0^{\infty} \rho_{m_1}\rho_{m_2}\rho_{m_3}\cdots\rho_{m_n}\,k(\alpha)\,k(\beta)\,d\alpha\,d\beta. \tag{13}$$

Now it is necessary to equate terms with equal powers of μ on the right and left sides. As a result we obtain a system of equations allowing us to determine successively the functions $\rho_m(\tau)$, expressing each in terms of the preceding. For concise notation we shall consider the left side of (11) as some linear integral operator L acting on the function $\rho_z(\tau)$:

$$L\rho_z(\tau) = \sigma_z^2\rho_z(\tau) - \sigma_z\eta_1\int_0^{\infty} k(\alpha)\,[\rho_z(\tau+\alpha) + \rho_z(\tau-\alpha)]\,d\alpha + \\ + \eta_1^2\int_0^{\infty}\!\!\int_0^{\infty} k(\alpha)\,k(\beta)\,\rho_z^n(\tau-\alpha+\beta)\,d\alpha\,d\beta. \tag{14}$$

Considering this, we obtain the following system of equations:

$$L\rho_0(\tau) = \sigma_x^2\rho_x(\tau), \tag{15}$$

$$L\rho_1(\tau) = 0, \tag{16}$$

$$L\rho_2(\tau) = -\frac{\eta_2^2}{2!}\int_0^{\infty}\!\!\int_0^{\infty} k(\alpha)\,k(\beta)\,\rho_0^2(\tau-\alpha+\beta)\,d\alpha\,d\beta, \tag{17}$$

$$L\rho_3(\tau) = -\frac{\eta_3^2}{3!}\int_0^{\infty}\!\!\int_0^{\infty} k(\alpha)\,k(\beta)\,\rho_0^3(\tau-\alpha+\beta)\,d\alpha\,d_\beta, \tag{18}$$

$$L\rho_4(\tau) = -\frac{\eta_4^2}{4!}\int_0^{\infty}\!\!\int_0^{\infty} k(\alpha)\,k(\beta)\,\rho_0^4(\tau-\alpha+\beta)\,d\alpha\,d\beta - \frac{\eta_2^2}{2!}\int_0^{\infty}\!\!\int_0^{\infty} 2\rho_2\rho_0 k(\alpha)\;k(\beta)\,d\alpha\,d\beta, \tag{19}$$

$$L\rho_5(\tau) = -\frac{\eta_5^2}{5!}\int_0^{\infty}\!\!\int_0^{\infty} k(\alpha)\,k(\beta)\,\rho_0^5\,d\alpha\,d\beta - \\ - \frac{\eta_3^2}{3!}\int_0^{\infty}\!\!\int_0^{\infty} k(\alpha)\,k(\beta)\,3\rho_0^2\rho_2\,d\alpha\,d\beta - \frac{\eta_2^2}{2!}\int_0^{\infty}\!\!\int_0^{\infty} k(\alpha)\;k(\beta)\,2\rho_0\,\rho_3\,d\alpha\,d\beta. \tag{20}$$

This system of equations may be easily solved by Fourier analysis. If we introduce the notation

$$S_m(\omega) = \int_{-\infty}^{\infty} \rho_m(\tau)\,e^{-i\omega\tau}d\tau, \tag{21}$$

then, taking the Fourier transform of (15)-(20), and performing simple transformations, we obtain the following expressions for $S_m(\omega)$:

$$S_0(\omega) = \frac{1}{|\sigma_z - \eta_1 K(i\omega)|^2} \sigma_x^2 S_x(\omega), \tag{22}$$

$$S_1(\omega) \equiv 0, \tag{23}$$

$$S_2(\omega) = -\frac{|K(i\omega)|^2}{|\sigma_z - \eta_1 K(i\omega)|^2} \frac{\eta_2^2}{2} \frac{1}{2\pi} \int\limits_{-\infty}^{\infty} S_0(\nu) S_0(\omega - \nu)\, d\nu, \tag{24}$$

$$S_3(\omega) = -\frac{|K(i\omega)|^2}{|\sigma_z - \eta_1 K(i\omega)|^2} \frac{\eta_3^2}{3!} \frac{1}{(2\pi)^2} \int\limits_{-\infty}^{\infty} S_0(\nu_1) S_0(\nu_2) S_0(\omega - \nu_1 - \nu_2)\, d\nu_1 d\nu_2, \tag{25}$$

$$S_4(\omega) = -\frac{|K(i\omega)|^2}{|\sigma_z - \eta_1 K(i\omega)|^2} \Bigg[\frac{\eta_2^2}{2!} \frac{1}{2\pi} \int\limits_{-\infty}^{\infty} 2 S_2(\nu) S_0(\omega - \nu)\, d\nu + \tag{26}$$

$$+ \frac{\eta_4^2}{4!} \frac{1}{(2\pi)^3} \int\limits_{-\infty}^{\infty} S_0(\nu_1) S_0(\nu_2) S_0(\nu_3) S_0(\omega - \nu_1 - \nu_2 - \nu_3)\, d\nu_1 d\nu_2 d\nu_3 \Bigg],$$

$$S_5(\omega) = -\frac{|K(i\omega)|^2}{|\sigma_z - \eta_1 K(i\omega)|^2} \Bigg[\frac{\eta_2^2}{2!} \frac{1}{2\pi} \int\limits_{-\infty}^{\infty} 2 S_0(\nu) S_3(\omega - \nu)\, d\nu +$$

$$+ \frac{\eta_3^2}{3!} \frac{1}{(2\pi)^2} \int\limits_{-\infty}^{\infty} 3 S_0(\nu_1) S_0(\nu_2) S_2(\omega - \nu_1 - \nu_2)\, d\nu_1 d\nu_2 + \tag{27}$$

$$+ \frac{\eta_5^2}{5!} \frac{1}{(2\pi)^4} \int\limits_{-\infty}^{\infty} S_0(\nu_1) S_0(\nu_2) S_0(\nu_3) S_0(\nu_4) S_0(\omega - \nu_1 - \nu_2 - \nu_3)\, d\nu_1 d\nu_2 d\nu_3 d\nu_4 \Bigg].$$

. . . .

Here $K(i\omega)$ is the frequency characteristic of the serially joined links 2 and 3 (see the figure), corresponding to the weight function $k(t)$.

Considering that

$$\rho_m(\tau) = \frac{1}{2\pi} \int\limits_{-\infty}^{\infty} S_m(\omega) e^{i\omega\tau} d\omega. \tag{28}$$

and also bearing (12) in mind, we obtain for $\rho_z(\tau)$ the expression

$$\rho_z(\tau) = \frac{1}{2\pi} \int\limits_{-\infty}^{\infty} \sum_{m=0}^{\infty} S_m(\omega) e^{i\omega\tau} d\omega. \tag{29}$$

The functions $S_m(\omega)$ entering into (29) depend on the values m_z and σ_z, which are unknown beforehand. It is necessary to calculate them. We obtain the first equation for the determination of m_z and σ_z from (29):

$$\sigma_z^2 = \frac{1}{2\pi} \int\limits_{-\infty}^{\infty} \sigma_z^2 \sum_{m=0}^{\infty} S_m(\omega)\, d\omega. \tag{30}$$

Since the mathematical expectation m_x of the input process is constant, one may write the following equation for the mathematical expectation of the process $z(t)$:

$$m_z = \frac{m_x}{1 + k_0 \chi(m_z, \sigma_z)}\,. \tag{31}$$

where k_0 is the amplification coefficient of the system, and $\chi = m_y / m_z$ is determined by (4). Equation (31) is a second equation for determining m_z and σ_z. Similar equations are also obtained by the method of statistical linearization. For systems whose linear parts are described by differential equations of higher order, the following method of solution of (30) and (31) is usually employed.

For the initial values of m_z and σ_z one may take any quantities, let us say m_x and σ_x. Setting them into the right sides of (30) and (31), we obtain m_{z1} and σ_{z1}, in general different from m_{z0} and σ_{z0}. Then the values m_{z1} and σ_{z1} obtained should again be substituted into the right sides of (30) and (31), after which the new m_{z2} and σ_{z2} are obtained. This process is to be continued until upon a substitution, results are obtained which coincide with zero-order accuracy with the results of the preceding substitution. We note that the procedure of substitution consists in calculating the functions $S_m(\omega)$ from (22) - (27) for given values of m_z and σ_z, thereafter calculating (30), as well as (31). Practical calculation by the method of statistical linearization shows that a similar procedure of solving the equation allows a sufficiently rapid calculation of m_z and σ_z.

After m_z and σ_z are calculated, and also $\eta_1(m_z, \sigma_z)$, $\eta_2(m_z, \sigma_z)$ and so on, the variance of the process y(t) at the output is easily calculated, by using (7) for $\tau = 0$, and substituting the weight function $g(\sigma)$ of link 2 in the straight circuit, for $k(\sigma)$. Taking the Fourier transform, we obtain the following relation:

$$\sigma_y^2 = \frac{1}{2\pi} \int_{-\infty}^{\infty} |G(i\omega)|^2 \Big\{ \eta_1^2 S_z(\omega) + \frac{\eta_2^2}{2!} \frac{1}{2\pi} \int_{-\infty}^{\infty} S_z(\nu) S_2(\omega - \nu)\, d\nu + \\ + \frac{\eta_3^2}{6} \frac{1}{(2\pi)^2} \int_{-\infty}^{\infty} S_z(\nu_1) S_z(\nu_2) S_z(\omega - \nu_1 - \nu_2)\, d\nu_1\, d\nu_2 + \ldots \Big\}. \tag{32}$$

where $S_z = \sum_{m=0}^{\infty} S_m(\omega)$ for the calculated values m_z and σ_z.

We return to (22). It represents an equation for the calculation of the spectral density of the process at the input to the nonlinear element by the method of statistical linearization. Hence, the method of statistical linearization is obtained as the first approximation to a more complete solution to the problem. The functions $S_m(\omega)$ for $m > 0$ are further approximations. Since they contain the parameters $\eta^2/2!$, $\eta^3/3!$, etc., which under definite conditions are negligible, the further approximations under these conditions carry but small contributions in forming the spectral density, and the method of statistical linearization gives the correct solution. However, there may occur conditions under which one may not neglect the further approximations, and then the method of statistical linearization yields an invalid solution. This may occur, for example, when the spectrum of the signal x(t) is essentially concentrated in a neighborhood of the frequency ω_0, and the linear link has a resonance at the frequency $2\omega_0$ or $3\omega_0$, and so on. In order to clarify these conditions, it is necessary to carry out numerical calculations for different specific cases. Such a calculation may be accomplished simply with contemporary computing machines.

CONCLUSION

In this paper it is shown that under the assumption on normal distribution of a random process at the input to a nonlinear element, the problem of calculating the dispersion at the output of a system with feedback containing a nonlinear element may be solved more accurately than may be done using only the method of statistical linearization.

The method of statistical linearization is obtained as the first approximation in the approach to the solution of the problem presented, and consequently, the possibility arises of being able to test its applicability in different cases.

The calculations by the formulas given may be carried out with the aid of contemporary computational techniques.

In conclusion, I take this opportunity to thank R. L. Stratonovich deeply for valuable counsel and direction given by him in connection with this paper.

AN INTERPOLATION METHOD FOR ANALYZING AUTOMATIC CONTROL SYSTEM ACCURACY UNDER RANDOM STIMULI

V. I. Chernetskii

(Leningrad)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 4, pp. 481-488, April, 1960
Original article submitted December 23, 1959

An approximate method is suggested for constructing the solution of a system of ordinary differential equations containing random functions and random variables, and formulas are derived for the computation of the moments. The method is a development of certain ideas of Chebyshev [1].

INTRODUCTION

In designing or, when necessary, in improving an automatic control system, the problem arises of analyzing the accuracy of control when one takes into account random disturbances acting on the system.

The systems of differential equations which describe the operation of an automatic control system with random stimuli are, in the general case, nonlinear:

$$\frac{dY_i}{dt} = F_i(t, Y_1, Y_2, \ldots, Y_n, X_1(t), X_2(t), \ldots, X_l(t), \lambda_1, \lambda_2, \ldots, \lambda_s). \qquad (1)$$
$$t = 0, \quad Y_i(0) = y_{i0} \quad (i = 1, 2, \ldots, n).$$

where the Y_i are parameters characterizing the control process, $X_1(t), X_2(t), \ldots, X_l(t)$ are random functions of time whose probability characteristics are assumed to be given, and $\lambda_1, \lambda_2, \ldots, \lambda_s$ are random variables whose probability characteristics are also assumed to be given.

The initial conditions ($t = 0$, $Y_i(0) = y_{i0}$) are also random variables with known probability characteristics. The functions F_i ($i = 1, 2, \ldots, n$) are such that there exists a unique solution of system (1) for each choice of random initial conditions, random variables $\lambda_1, \ldots, \lambda_s$ and random functions $X_1(t), X_2(t), \ldots, X_l(t)$.

Ordinarily, to analyze accuracy of a control system, the nonlinear differential equations are replaced, with certain assumptions, by linear ones, and then one uses the quite well developed methods for analyzing the accuracy of linear systems with random stimuli present [2,3]. Of all the existing linearization methods, the most practical in the given case is Kazakov's statistical linearization method [4,5].

In [6,7], for the analysis of accuracy of nonlinear systems with random stimuli, there were presented quite general theoretical methods which could serve as starting points for the construction of engineering methods and, in the simplest cases, for engineering calculations as well. Thus, in [7], Dostupov put forward an engineering method for analyzing the accuracy of nonlinear control systems with random stimuli, this method being a development of Pugachev's method which assumes the use of the latest computing technology.

In the present work we present a new approximate method for analyzing the accuracy of an automatic control system with random stimuli, wherein the use of electronic computers is also assumed, but where the method is based on other principles than those of [6,7] and does not require that one solve an auxiliary system of algebraic equations, as is the case in [7].

1. Posing of the Problem

If we use the canonical expansions of the random functions $X_1(t), X_2(t), \ldots, X_l(t)$ and limit ourselves to a finite number of terms in these expansions, we may approximately replace system (1) of differential equations by a system of the form

$$\frac{dY_i}{dt} = F_i(t, Y_1, Y_2, \ldots, Y_n, \lambda_1, \lambda_2, \ldots, \lambda_m). \qquad (2)$$
$$t = 0, \quad Y_i(0) = y_{i0} \quad (i = 1, 2, \ldots, n).$$

which contains only random variables in the right members, thus significantly simplifying the investigation.

All the assumptions made relative to (1) remain in force for this new system. Moreover, without reducing the generality, one may assume that the initial conditions are not random, since otherwise one could attain such a position by a linear change of variables, which would only entail an increase in the number of random variables entering the right members of (2).

The random variables $\lambda_1, \lambda_2, \ldots \lambda_m$ will be assumed to be independent, which is also not a very rigid requirement, since in many practical cases one may attain this state by means of a linear transformation of these quantities. As the probability characteristics of the random variables, there are given the distribution densities $P_1(\lambda_1), P_2(\lambda_2), \ldots, P_m(\lambda_m)$, for which there exist moments of every order, i.e., $\int \lambda_j^k P_j(\lambda_j)\, d\lambda_j = m_j^{(k)}$, where the $m_j^{(k)}$ are certain constants for any k and j ($k = 0, 1, 2, \ldots$; $j = 1, 2, \ldots, m$).

Since, by assumption, there exists a unique solution of (2) for each choice of the random variables $\lambda_1, \lambda_2, \ldots, \lambda_m$, which are independent parameters of this system, then the solution of system (2) can be given in the form of certain functions of time and the random variables $\lambda_1, \lambda_2, \ldots, \lambda_m$:

$$Y_i = Y_i(t, \lambda_1, \lambda_2, \ldots, \lambda_m) \qquad (i = 1, 2, \ldots, n). \quad (3)$$

For the set of functions in (3), which are solutions of (2) for any values of the random variables $\lambda_1, \ldots, \lambda_m$, we shall assume the existence of the second moments, i.e.,

$$M[Y_i^2] = \int_{\Delta} \ldots \int Y_i^2(t, \lambda_1, \lambda_2, \ldots, \lambda_m) \prod_{j=1}^{m} P_j(\lambda_j)\, d\lambda_j = K_i \qquad (i = 1, 2, \ldots, n). \quad (4)$$

where the K_i are constants and Δ is the range of values of the random variables $\lambda_1, \ldots, \lambda_m$, and is an m-dimensional finite or infinite parallelopiped.

We choose some set of numbers $\{\mu_{1k_1}, \mu_{2k_2}, \ldots, \mu_{mk_m}\}$ ($k_1 = 0, 1, 2, \ldots, q$; $k_2 = 0, 1, 2, \ldots, q$; $k_m = 0, 1, 2, \ldots, q$) which represents $(q+1)^m$ points in region Δ.

Let a known solution of (1) be computed at each of the aforementioned points:

$$y_i(t, \mu_{1k_1}, \mu_{2k_2}, \ldots, \mu_{mk_m}) \qquad (i = 1, 2, \ldots, n) \quad (5)$$

$$(k_1 = 0, 1, 2, \ldots, q;\ k_2 = 0, 1, 2, \ldots, q;\ \ldots;\ k_m = 0, 1, 2, \ldots, q).$$

It is required, from the given set (5) of solutions of (2), to construct the functions

$$Y_{iq}(t, \lambda_1, \lambda_2, \ldots, \lambda_m) \qquad (i = 1, 2, \ldots, n), \quad (6)$$

which are sufficiently accurate approximations to the solution and, from the functions in (6), to construct the simplest possible formulas for computing the solution's probability characteristics.

1. Probability Principle for Constructing Approximate Solutions

One of the most general principles for construction of the functions in (6) is the principle of minimum probability for each fixed q.

In the case under consideration, this principle may be formulated as follows: from among the set of all the functions $\widetilde{Y}_{iq}(t, \lambda_1, \lambda_2, \ldots, \lambda_m)$, constructed on the basis of the functions $y_i(t, \mu_{1k_1}, \mu_{2k_2}, \ldots, \mu_{mk_m})$, we choose a function such that

$$P[|\widetilde{Y}_{iq} - Y_i(t, \lambda_1, \lambda_2, \ldots, \lambda_m)| > \varepsilon] = \min \qquad (i = 1, 2, \ldots, n) \quad (7)$$

for each fixed q, where $\epsilon > 0$ is any arbitrarily small given number; the symbol P[...] denotes the probability that the inequality within the square brackets actually holds.

If the probability in (7) tends to zero as q increases, one has convergence in probability, which is ordinarily written in the form of a limiting equality,

$$\lim_{q\to\infty} P[|\widetilde{Y}_{iq}(t, \lambda_1, \lambda_2, \ldots, \lambda_m) - Y_i(t, \lambda_1, \lambda_2, \ldots, \lambda_m)| > \varepsilon] = 0 \quad (i = 1, 2, \ldots, n). \quad (8)$$

Instead of the minimum probability principle, one may use the computationally simpler principle of the minimum of the second moment of the difference between the exact and the approximate solutions:

$$M[(\widetilde{Y}_{iq} - Y_i)^2] = \int_{\Delta} \ldots \int (\widetilde{Y}_{iq} - Y_i)^2 \prod_{j=1}^{m} P_j(\lambda_j)\, d\lambda_j = \min \qquad (i = 1, \ldots, n). \quad (9)$$

Indeed, according to Chebyshev's inequality,

$$P[|\widetilde{Y}_{iq} - Y_i| > \varepsilon] < \frac{M[(\widetilde{Y}_{iq} - Y_i)^2]}{\varepsilon^2}. \quad (10)$$

It follows from Chebyshev's inequality that, if

$$\lim_{q\to\infty} M[(\widetilde{Y}_{iq} - Y_i)^2] = 0, \quad (11)$$

then there will be convergence in probability.

If the function $\widetilde{Y}_{iq}$ is chosen from the class of all possible m-dimensional polynomials of degree q, then the problem of minimizing the second moment is, in theory, easily solved.

Indeed, by virtue of the assumptions as to the weight functions, for each function $P_j(\lambda_j)$ ($j = 1, 2, \ldots, m$) there exists [9] a system, unique to within a common factor, of orthogonal polynomials $H_{j0}, H_{j1}, H_{j2}, \ldots$, i.e., such that

$$\int_{a_j}^{b_j} H_{ji}(\lambda_j)\, H_{jk}(\lambda_j)\, P_j(\lambda_j)\, d\lambda_j = \begin{cases} 0 & \text{for} \quad i \neq k, \\ C_{ij}^2 & \text{for} \quad i = k, \end{cases}$$

where the numbers a_j and b_j can be infinite.

Let

$$Y_i^{(F)} = \sum_{n_1 n_2 \ldots n_m} a_{in_1 n_2 \ldots n_m}(t) \prod_{j=1}^{m} H_{jn_j}(\lambda_j). \quad (12)$$

where

$$a_{in_1 n_2 \ldots n_m}(t) = \frac{\int_{\Delta} \ldots \int Y_i \prod_{j=1}^{m} H_{jn_j}(\lambda_j)\, P_j(\lambda_i)\, d\lambda_j}{\int_{\Delta} \ldots \int \prod_{j=1}^{m} H_{jn_j}^2(\lambda_j)\, P_j(\lambda_j)\, d\lambda_j} \quad (13)$$

$$(n_1, n_2, \ldots, n_m = 0, 1, 2, \ldots).$$

From the theory of Fourier series we know that the minimum of the integral in (9) in the class of all possible m-dimensional polynomials of degree q is furnished by segments of the Fourier series for the functions Y_i ($i = 1, 2, \ldots, n$), i.e., the polynomials

$$Y_{iq}^{(F)} = \sum_{n_1 n_2 \ldots n_m} a_{in_1 n_2 \ldots n_m}(t)$$

$$\prod_{j=1}^{m} H_{jn_j}(\lambda_j) \quad \begin{pmatrix} n_1 = 0, 1, 2, \ldots, q \\ n_2 = 0, 1, 2, \ldots, q \\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot \\ n_m = 0, 1, 2, \ldots, q \end{pmatrix}. \tag{14}$$

However, the problem we have posed can be considered solved only theoretically since, for the computation of the m-fold integrals entering into (14), there are only $(q + 1)^m$ points at which the values of the integrands may be assumed to be known.

If the solution of (2) can be presented exactly in the form of m-dimensional polynomials in the random variables $\lambda_1, \lambda_2, \ldots, \lambda_m$ of degrees not exceeding the number $\underline{q}$, then the problem as posed can be solved exactly by means of Lagrange interpolating polynomials.

In fact, in this case, from the given $(q + 1)^m$ interpolation nodes, one can construct, using the Lagrange interpolation formula for the m-dimensional case [8], an m-dimensional polynomial of degree not exceeding $\underline{q}$:

$$Y_{iq} = \sum_{k_1 k_2 \ldots k_m} y_i(t, \mu_{1k_1}, \mu_{2k_2}, \ldots, \mu_{mk_m}) \tag{15}$$

$$\prod_{j=1}^{m} \frac{\omega_{j,q+1}(\lambda_j)}{\omega'_{j,q+1}(\mu_{jk_j})(\lambda_j - \mu_{jk_j})}$$

$$(i = 1, 2, \ldots, n)\,(k_1 = 0, 1, 2, \ldots, q;$$

$$k_2 = 0, 1, 2, \ldots, q; \ldots; k_m = 0, 1, 2, \ldots, q).$$

coinciding identically with the solution of (2), where

$$\omega_{j,q+1}(\lambda_j) =$$

$$= (\lambda_j - \mu_{1k_j})(\lambda_j - \mu_{2k_j}) \ldots (\lambda_j - \mu_{mq_j}); \quad \omega'_{j,q+1}(\mu_{jk_j})$$

is the derivative, computed for $\lambda_j = \mu_{jk_j}$.

However, the case more frequently arises in the applications when the solution can be given in the form of m-dimensional polynomials of degree $\underline{q}$ only approximately, and the interpolation polynomials of (15), therefore, will in general be only approximations whose closeness, in some sense or other, to the solution of (2) depends on the choice of the interpolation nodes.

Since the interpolation nodes can be chosen arbitrarily, it is then necessary to so manage this choice that the second moments of the difference between the solution and the approximation to it in the form of interpolation polynomials be, for each fixed q, as close as possible to their minimum values attainable in the class of all possible m-dimensional polynomials of degree $\underline{q}$, and so that the approximation, in the form of interpolation polynomials, converge in probability to the exact solution of (2).

If one chooses as the $(q + 1)^m$ interpolation nodes all possible combinations of roots of the orthogonal polynomials $H_{j,\, q+1}(\lambda_j)(j = 1, 2, \ldots, n)$ of degree q + 1, which may always be done since the roots of these polynomials are real, different, and lie in the intervals of orthogonality, then these requirements can, to a known degree, be satisfied [9].

In this case, the interpolation polynomials which are the approximate solution may be written in the form

$$\widetilde{Y}_{iq} = \sum_{k_1 k_2 \ldots k_m} y_i(t, \mu_{1k_1}, \mu_{2k_2}, \ldots, \mu_{mk_m})$$

$$\prod_{j=1}^{m} \frac{H_{j,q+1}(\lambda_j)}{H'_{j,q+1}(\mu_{jk_j})(\lambda_j - \mu_{jk_j})} \tag{16}$$

$$(i = 1, 2, \ldots, n) \quad (k_1 = 0, 1, 2, \ldots, q;$$

$$k_2 = 0, 1, 2, \ldots, q; \ldots; k_m = 0, 1, 2, \ldots, q);$$

$$H_{j,q+1}(\lambda_j) = (\lambda_j - \mu_{1kj})(\lambda_j - \mu_{2kj}) \ldots (\lambda_j - \mu_{mk_j});$$

$H_{j,q+1}(\mu_{jk_j})$ is the derivative, computed for $\lambda_j = \mu_{jk_j}$; the numbers μ_{jk_j} satisfy the algebraic equations

$$H_{j,q+1}(\mu_{jk_j}) = 0 \qquad (j = 1, 2, \ldots, m).$$

It can be shown that the construction of the interpolation polynomial by (16) with the thus chosen interpolation nodes, which we shall for brevity henceforth call Chebyshev type nodes, is equivalent to the construction of the segment of the Fourier series from the $(q + 1)^m$ first terms if, in computing the coefficients of the expansion, one uses a Gauss type formula for mechanical quadrature corresponding to weights equal to the given probability density functions. Since Gauss type mechanical quadrature formulas are the quadrature formulas with the highest degree of algebraic accuracy then, in general, it is impossible to give a set of $(q + 1)^m$ interpolation nodes from which one could construct an m-dimensional polynomial of degree $\underline{q}$ lying closer to the segment of Fourier series (14), from the point of view of minimizing the integral in (9), than the polynomial constructed from the Chebyshev type nodes.

As was established earlier [cf. (11)], to prove convergence in probability it suffices to establish a limiting equality to zero of the second moment of the difference between the exact and the approximate solutions.

In the given case,

$$\lim_{q \to \infty} \int \underset{\Delta}{\cdots} \int (Y_i - \overline{Y}_{iq})^2 \prod_{j=1}^{m} P_j(\lambda_j)\, d\lambda_j =$$

$$= \int \underset{\Delta}{\cdots} \int Y_j^2 \prod_{j=1}^{m} P_i(\lambda_j)\, d\lambda_j -$$

$$- 2 \lim_{q \to \infty} \int \underset{\Delta}{\cdots} \int \widetilde{Y}_i Y_{iq}$$

$$\prod_{j=1}^{m} P_j(\lambda_j)\, d\lambda_j + \lim_{q \to \infty} \int \underset{\Delta}{\cdots} \int \widetilde{Y}_{iq}^2 \prod_{j=1}^{m} P_j(\lambda_j)\, d\lambda_j = 0, \tag{17}$$

if

$$\lim_{q \to \infty} \int \underset{\Delta}{\cdots} \int \widetilde{Y}_{iq}^2 \prod_{j=1}^{m} P_j(\lambda_j)\, d\lambda_j = \int \underset{\Delta}{\cdots} \int Y_i^2 \prod_{j=1}^{m} P_j(\lambda_j)\, d\lambda_j \tag{18}$$

and

$$\lim_{q \to \infty} \int \underset{\Delta}{\cdots} \int Y_i \widetilde{Y}_{iq} \prod_{j=1}^{m} P_j(\lambda_j)\, d\lambda_j = \int \underset{\Delta}{\cdots} \int Y_i^2 \prod_{j=1}^{m} P_j(\lambda_j)\, d\lambda_j. \tag{19}$$

By substituting, in (18), the expanded expression for the interpolation polynomial, and by taking into account the orthogonality of the polynomials $H_{j,q+1}(\lambda_j)$, we obtain, after a number of transformations,

$$\lim_{q\to\infty} \int \underset{\Delta}{\cdots} \int \widetilde{Y}^2_{iq} \prod_{j=1}^{m} P_j(\lambda_j)\, d\lambda_j = \tag{20}$$

$$= \lim_{q\to\infty} \sum_{k_1k_2\ldots k_m} y_i(t, \mu_{1k_1}, \mu_{2k_2}, \ldots, \mu_{mk_m}) \prod_{j=1}^{m} \rho_{jk_j}$$

$$(i = 1, 2, \ldots, n)\,(k_1 = 0, 1, 2, \ldots. q;$$

$$k_2 = 0, 1, 2, \ldots, q; \ldots; \quad k_m = 0, 1, 2, \ldots, q),$$

where $\rho_{jk_j} = \int\limits_{a_j}^{b_j} \frac{H_{j,q+1}(\lambda_j)(P_j(\lambda_j)\, d\lambda_j}{H'_{j,q+1}(\mu_{jk_j})(\lambda_j - \mu_{jk_j})}$ are Christoffel numbers.

Formula(20) is a Gauss type mechanical quadrature formula with weights $\prod_{j=1}^{m} P_j(\lambda_j)$ for computing the integral $\int \underset{\Delta}{\cdots} \int Y_i^2 \prod_{j=1}^{m} P_j(\lambda_j)\, d\lambda_j$.

It is well known* that the mechanical quadrature process converges for any Riemann-integrated function if the domain of integration is bounded. If the region is unbounded,the same state of affairs can be attained if, in constructing the interpolation polynomial, one does not take into consideration nodes which lie at a sufficiently great distance from the origin of coordinates, a process which can only have a beneficial effect in calculations with electronic computers (since cases of overflow are avoided).

Since (19) follows from (18), it can be asserted that, when the solution of (2) is such that the second moments in (4) exist, then the interpolation process constructed on Chebyshev type nodes tends in probability to the solution of this system.

3. Calculated Formulas for Computing the Moments

The approximate formulas for computing the moments are obtained from the ordinary formulas expressing these moments in general form if, in these formulas, the exact solution of (2) is replaced by approximate ones in the form of interpolation polynomials constructed from Chebyshev type nodes.

We now obtain the formulas for computing the first- and second-order moments:

$$M[Y_i(t, \lambda_1, \lambda_2, \ldots, \lambda_m)] = \int \underset{\Delta}{\cdots} \int Y_i \prod_{j=1}^{m} P_j(\lambda_j)\, d\lambda_j \approx$$

$$\approx \int \underset{\Delta}{\cdots} \int \widetilde{Y}_{iq} \prod_{j=1}^{m} P_j(\lambda_j)\, d\lambda_j \qquad (i = 1, 2, \ldots, n).$$

$$M[Y_i(t_1, \lambda_1, \lambda_2, \ldots, \lambda_m)\, Y_k(t_2, \lambda_1, \lambda_2, \ldots, \lambda_m)] \approx$$

$$\approx \int \underset{\Delta}{\cdots} \int \widetilde{Y}_{iq}(t_1, \lambda_1, \lambda_2, \ldots, \lambda_m)\, \widetilde{Y}_{kq}(t_2, \lambda_1, \lambda_2, \ldots, \lambda_m) \tag{21}$$

$$\prod_{j=1}^{m} P_j(\lambda_j)\, d\lambda_j$$

$$(i = 1, 2, \ldots, n; \quad j = 1, 2, \ldots, n).$$

By substituting in these formulas the expanded expressions for $\widetilde{Y}_{iq}$ and $\widetilde{Y}_{iq}$ and carrying out a number of transformations, we get

$$M[Y_i] \approx \sum_{k_1k_2\ldots k_m} y_i(t, \mu_{1k_1}, \mu_{2k_2}, \ldots, \mu_{mk_m}) \prod_{j=1}^{m} \rho_{jk_j}.$$

$$M[Y_i(t_1, \lambda_1, \lambda_2, \ldots, \lambda_m)\, Y_k(t_2, \lambda_1, \lambda_2, \ldots, \lambda_m)] \approx$$

$$\approx \sum_{k_1k_2\ldots k_m} y_i(t, \mu_{1k_1}, \mu_{2k_2}, \ldots, \mu_{mk_m})$$

$$y_k(t_2, \mu_{1k_1}, \mu_{2k_2}, \ldots, \mu_{mk_m}) \prod_{j=1}^{m} \rho_{jk_j}$$

$$(i = 1, 2, \ldots., n; \quad j = 1, 2, \ldots, n)$$

$$(k_1 = 0, 1, 2, \ldots, q; \quad k_2 = 0, 1, 2, \ldots, q; \ldots;$$

$$k_m = 0, 1, 2, \ldots, q).$$

where the ρ_{jk_j} are Christoffel numbers.

The approximate formulas for computing higher-order moments have an analogous form.

In computing the moments of the solution of (2) by (21), it is most convenient to determine the functions $y_i(t, \mu_{1k_1}, \mu_{2k_2}, \ldots, \mu_{mk_m})$ $(i = 1, 2, \ldots, n)$ by numerical methods, carrying out the computations on electronic digital computers, since the accuracy of analog computers is, in many cases, inadequate; moreover, the final computations by (21) equally require discrete (digital) technology. The Chebyshev type nodes and the Christoffel numbers $\rho_{jk_1}, \rho_{jk_2}, \ldots, \rho_{jk_m}$ are computed from the given probability density functions. However, in many practical cases this is not necessary, since one can use prepared tables [10] of roots of orthogonal polynomials and the Christoffel numbers corresponding to these polynomials.

For example, let the random variable λ_j be distributed normally, $P_j(\lambda_j) = \frac{1}{\sqrt{2\pi}\sigma_{\lambda_j}} \exp\left[-\frac{(\lambda_j - \overline{\lambda}_j)^2}{2\sigma^2_{\lambda_j}}\right]$. We set

*From the Steklov-Polya theorem.

$\lambda_j = \bar{\lambda}_j + x\sigma_{\lambda_j}\sqrt{2}$. The distribution density of the random variable x will be $P(x) = e^{-x^2}/\sqrt{\pi}$. The Chebysnev-Hermite polynomials

$$H_n(x) = \left(-\frac{1}{2}\right)^n e^{x^2} \frac{d^n}{dx^n}[e^{-x^2}]$$

form a system of polynomials which are orthogonal on the interval $(-\infty, \infty)$.

Let $x_{k,\,q+1}^{q+1}$ $(k = 0, 1, 2, \ldots, q)$ be the roots of the Chebyshev- Hermite polynomial of degree q + 1. In this case, the Chebyshev type interpolation nodes and the Christoffel numbers are computed by the formulas

$$\lambda_{jk_j} = \bar{\lambda}_j + x_k^{(q+1)}\sigma_{\lambda_j}\sqrt{2}$$

$$(k = 0, 1, 2, \ldots, q),$$

$$\rho_{jk_j} = \int\limits_{-\infty}^{\infty} \frac{H_{q+1}(x)\,P(x)\,dx}{H'_{q+1}(x_k^{(q+1)})\,(x - x_k^{(q+1)})} = \rho_k^{(q+1)} \tag{22}$$

$$(k = k_j).$$

For uniform distributions on the intervals $[a_j, b_j]$, the Chebyshev type nodes and the Christoffel numbers are computed by the formulas

$$\lambda_{jk_j} = \frac{b_j - a_j}{2}\,x_k^{(q+1)} + \frac{b_j + a_j}{2}$$

$$(k = 0, 1, 2, \ldots, q), \tag{23}$$

$$\rho_{jk_j} = \rho_k^{(q+1)} = \int\limits_{-1}^{1} \frac{U_{q+1}(x)\,dx}{U'_{q+1}(x_k^{(q+1)})\,(x - x_k^{(q+1)})},$$

where $U_{q+1}(x) = \frac{(q+1)!}{(2q+2)!}\frac{d^{q+1}}{dx^{q+1}}(x^2 - 1)^{q+1}$ is the Legendre polynomial of degree q + 1 and the (k = 0, 1, 2,..., q) are its roots.

Since the method proposed here, for q = 1, gives a linear approximation to the solution of (2), it can be used in that case as one of the possible linearization methods which does not require that the equations of system (2) be transformed.

CONCLUSIONS

The method presented here can be used in the investigation of the accuracy of operation of an automatic control system described by a system of ordinary differential equations for which, with given initial conditions and for any choice of the random variables entering into the system's right members, there exists a unique solution with finite second moments. Thus, the method can also be used for the investigation of systems with essentially nonlinear characteristics.

In conclusion, the author wishes to express his deep appreciation for the friendly aid, valuable advice, and comments, which were advanced during the discussion of certain questions touched upon in the present paper, to E. P. Popov, V. I. Zubov, I. Ya. Diner, A. A. Sveshnikov and A. D. Maksimov.

Example. An automatic control system is described by equations of the form

$$\frac{dY}{dt} + Y^2 = (\lambda + 1)^2, \quad t = 0, \quad Y(0) = 0,$$

where λ is a random variable with zero mathematical expectation, and dispersion $M[\lambda^2] = 0.01$;

$$P(\lambda) = \frac{1}{\sqrt{2\pi}\,0{,}1}\,e^{-\frac{\lambda^2}{0{,}02}}.$$

It is required to determine the mathematical expectation and dispersion of the output coordinate Y.

By using (21) and (22) and making use of tables [10], we find that, for q = 1, M[Y] = 0.949 and D[Y] = 0.0164, while for q = 2, M[Y] = 0.964 and D[Y] = 0.0123.

The exact solution, obtained by solving the given equation with the given initial conditions, is that

M[Y] = 0.963, D[Y] = 0.0123.

Thus, in the given example, for q = 2 the approximate values of the mathematical expectation and the dispersion, computed by the interpolation method, coincide with the exact values to within one unit in the third decimal place.

THEORY OF IDEAL MODELS OF AN EXTREMAL CONTROLLER*

V. V. Kazakevich

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 4, pp. 489-505, April, 1960
Original article submitted July 6, 1959

By means of the theory of point transformations, an analysis is made of the operation of an extremal control system with a commutator. In the discussion, no essential limitations are imposed on the form of the nonlinearities. The existence of a limiting cycle is proven, and the character of its establishment is determined; the possibility of multiple oscillations, and the conditions for their generation, are investigated. The effect of asymmetry on the extremal function is determined, and an estimate of the accuracy of controller operation is made.

Existing automatic control systems solve the problem of maintaining a controlled quantity either constant or else changing in accordance with a previously prescribed law (in the case of so-called "programmed" control).

After a disturbing factor has acted, the controlled quantity changes its value, and the automatic controller must, by means of its action on the controlling parameter, take it to some given level in some interval of time.

If the problem to be solved by the automatic controller consists in maintaining a given program, then the control system just sketched is theoretically valid for its solution. Thus, for example, we have the problems of maintaining the number of rotations of a machine's principal shaft, steam or gas pressure in a trunk, voltage or current in a circuit, the problem of maintaining a given ratio of components, etc.

However, as technology developed, a number of problems arose which differed in principle from those just cited, these being the problems of the automatic search for, and maintaining of, extremal values of the controlled quantity, either at its upper or its lower boundary.

Such problems arise in the most diverse domains of technology (aviation, motor design, etc.).

Naturally, such problems can be solved only approximately by the ordinary control systems.

Several years ago the author of the present paper developed the automatic control principle which solves these problems, the principle which one may call that of extremal control.

Some of the questions in the theory of operation of extremal controllers were already considered previously by the author [1,2].

In the present paper, using the methods of point transformation theory, we investigate the operation of one of the extremal control schemes.

1. Principle of Operation of the Extremal Controller

In view of the fact that the form of the functional relationship between the controlled and the controlling quantities is not known and, moreover, varies in the course of time by a completely unknown law, to give this relationship in advance is not possible.

It is in relation to this that the idea of introducing an artificial disturbance is made basic to the principle of operation of the extremal controller.

All the motions arising in the system as a result of this disturbance are divided into two classes: a) the class of admissible motions, b) the class of inadmissible motions.

To the class of admissible motions are assigned all those which move the controlled quantity closer to the required extremum or boundary, while the motions which take the controlled quantity further away are assigned to the class of inadmissible motions.

By means of a special device, the direction of the process is verified, and if this direction causes the controlled quantity to approach the required extremum, then the disturbance is accepted; if the quantity moves away from the extremum, then the sign of the disturbance is reversed, and motion in the required direction then commences.

To provide stability of control, the variations of the controlled quantity during the establishment process are carried out nonmonotonically.

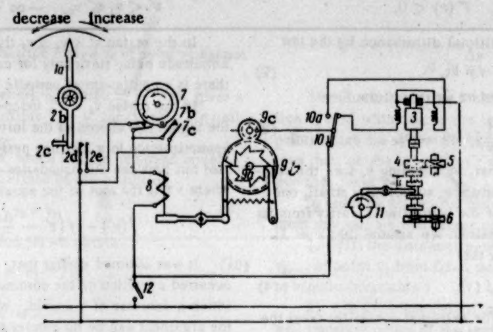
Basic to the scheme is a special device which provides selectivity in choosing an admissible disturbance and which transfers the motion from the class of inadmissible motions to that of admissible ones. This device is a relay which takes into account the direction (sign) of the velocity of the disturbed motion. It is because of this that we shall henceforth call it a signum-relay.

The signum-relay is made up of lever 2b (Fig. 1) friction-coupled to the axis of indicating instrument 1a which measures the controlled quantity p, so that the lever is dragged along by the pointer as p varies.

However, lever 2b can move only within the limits of a certain zone between contacts 2c and 2d. This will be called the insensitivity zone. As the pointer of the instrument moves to one side or the other, lever 2b will touch one of the contacts (2c or 2d) and will stop, while the pointer will continue its motion.

---

* This work was first published in the Trudy TsIAM in 1949; it is reprinted here without change.



In addition to the signum-relay, the following basic elements enter into the extremal controller scheme (Fig. 1):

1. The instrument which measures the controlled quantity.

2. Reversible device 10 which is connected to the organ which acts on the controlling parameter.

3. A contact device (a commutator) which provides the periodic character of the artificial disturbance.

If the controlled quantity, whose extremum the controller seeks, depends on several parameters, then these latter are switched in by turn by means of device 4-5-6 in such manner that, during the control time for one of the parameters, the remaining ones either remain free, or are kept constant, or are varied in accordance with a given program.

Control is effected in the following manner. We assum that the controller is not switched in; then, the position of pointer 1a will not be changed (under the assumption that natural disturbances are absent), i.e., the parameter v, acting on the quantity p, does not change. With this, let it be assumed that the quantity p does not attain a maximum.

We now switch in knife switch 12. This starts the rotation of motor 3 (to one side or the other) and commutator disk 7.

With this, let the change of parameter v give rise to a decrease of p. With this, instrument pointer 1a, in rotating counterclockwise, drags along lever 2b which, after traversing part of the insensitivity zone, closes contacts 2d and 2e which causes the operation of electromagnet 8 and stepping mechanism 9 which reverse motor 3 and change the direction of parameter v. Thanks to this, the quantity p increases and, if the rotational speed of the disk of contact devic 7 is sufficiently small, the quantity p attains an extremum and begins to move about a maximum.

To eliminate the possibility that the stimuli of disturbing forces would disrupt controller operation, contact device 7 (a commutator) was introduced.

Let the permissible deviation of parameter v from the value v_0 which corresponds to a maximum be some Δv. Then, the number of rotations of disk 7 is so chosen that, during one rotation, the change in the quantity v due to the action of motor 3 does not exceed Δv.

If, with such a choice for the number of rotations of disk 7, there now begins the action of disturbing forces, then two cases are possible:

a) The effect of the disturbance on either side is greater than the effect of variations in v. In this case, changes in v from increasing p cease when $v_1 - \Delta v \leq v \leq v_1 + \Delta v$, where v_1 corresponds to the beginning of the disturbance.

b) The effect of the disturbance on either side is less than the effect of variations in v. In this case, control proceeds normally until one reaches the value of $v^* + \Delta v$ (for disturbances which increase p) or $v^* - \Delta v$ (for the opposite case), where v^* is the quantity attainable in the absence of disturbing forces.

If the rotational speed of the commutators can not be considered small, and if a number of other design requirements do not hold, then the value of v^* attainable by the controller may differ from the optimal value v_0.

2. Investigation of the Establishment Process in the Extremal Controller

An extremal controller is a special nonlinear oscillatory system with one, two, or more degrees of freedom as a function of the character of the idealization.

With a number of far-reaching simplifications, in many cases the motion of the controlled system in the absence of external disturbances, i.e., for fixed values of v (in other words, with the extremal controller switched out), may be described by a linear differential equation

$$\frac{dp}{dt} = f(v) - p. \tag{1}$$

We shall assume that the function $f(v)$ is continuous in the interval $-\infty < v < +\infty$ and

$$f'(v_0) = 0, \quad f''(v) < 0.$$

We introduce the artificial disturbance by the law

$$v = kt. \tag{2}$$

Equation (1) may then be written in the form

$$\frac{dp}{dv} = \frac{1}{k}[f(v) - p]. \tag{3}$$

It is clear from (3) that, by choosing k, i.e., the velocity of the artificial disturbance, sufficiently small, one can make the deviation of the controlled quantity from its static value as small as desired. We assume that $k \ll 1$; with this, we may consider that

$$p = f(v). \tag{4}$$

With this condition, the extremal controller takes the form of a system with one degree of freedom. We denote by δ the magnitude of the signum-relay's insensitivity zone, and by Δt the commutator time (the size of the artificial disturbance's period).

Then, $\Delta v = k\Delta t$ is the quantity by which the argument v can change during the commutator time. We shall assume that, for the value $v = v_1$, the commutator operates and reversal occurs, after which the argument begins changing in one direction or the other.

We now show that the entire line of initial values is divided into a number of regions, where this decomposition depends on the relationship of δ and Δv, and also on the sign of k. The character of the control process is essentially different for each of these regions.

We shall later have occasion to use the following, almost self-evident lemma: if the continuous function $p = f(v)$ satisfies the condition $f'(v_0) = f''(v) < 0$ for $v \leq v_0$ then, for each pair of values v_a and v_b such that $v_a < v_b \leq v_0$, the following inequalities hold:

a) if we are given two numbers C_1 and C_2 $(0 < C_1 \leq C_2)$, then

$$f(v_b) - f(v_b - C_1) < f(v_a) - f(v_a - C_2), \tag{5}$$

b) if we are given numbers d_1 and d_2 such that

$$f(v_a) - f(v_a - d_1) = f(v_b) - f_1(v_b - d_2), \tag{6}$$

then

$$d_1 < d_2 \tag{6a}$$

and

$$v_a - d_1 < v_b - d_2. \tag{6b}$$

The proofs of these inequalities are given in the Appendix.

We shall consider the initial value $v \leq v_0$, assuming that reversal to a decreasing argument occurs for the value $v = v_1$. We assume that there exists a $v' < v_0$ such that

$$f(v') - f(v' - \Delta v) = \delta. \tag{A}$$

This can always be achieved by choosing a sufficiently small Δv or a sufficiently large δ.

We now show that, if (A) holds, the semiline of initial values $v_1 \leq v_0$ can be partitioned into the two regions:

$$v' < v_1 \leqslant v_0, \quad -\infty < v_1 < v'.$$

In the region $v' < v_1 \leq v_0$ the motion is stable, the amplitude being stationary for each initial value (i.e., there is a continuum of periodic motions).

In the region $v_1 < v'$, independently of which point of the region was chosen as the initial value, there occurs an approximation to a limiting periodic motion which is carried out between the boundaries of $v^* - \Delta v/2 \leq v \leq v^*$, where v^* is the root of the equation

$$f(v^*) - f\left(v^* - \frac{\Delta v}{2}\right) = \delta. \tag{B}$$

It was assumed earlier that, at the value $v = v_1$, there occurred operation of the commutator and reverser, after which a decrease of v ensued. With this, the decrease of the argument can be no greater than Δv: if the signum-relay operates, then the variation of the argument will be less than Δv, while if it does not operate the variation of the argument will equal Δv.

As a consequence of the decrease of the argument, the quantity p begins to decrease.

We now show that, if $v_1 < v'$ then, with a decrease of v by a certain definite amount a $(0 < a < \Delta v)$ given by (7) down to a value $v_2 = v_2(v_1)$, the signum-relay must operate; the controlled quantity will thereby decrease by the amount δ.

Indeed, the quantity a is defined by the condition that, with a decrease of the argument v by a, the insensitivity zone be traversed, i.e., that p be decreased by δ:

$$f(v_1) - f(v_1 - a) = \delta \tag{7}$$

or

$$f(v_1) - f(v_2) = \delta, \tag{7a}$$

where $v_2 = v_1 - a$.

We use the lemma at this point. By comparing (7) with (A), we note that (6a) holds if we take

$$v_1 = v_a, \quad v' = v_b, \quad a = d_1, \quad \Delta v - d_2;$$

consequently, $a < \Delta v$.

At the moment of operation of the signum-relay,

$$v = v_2 = v_1 - a.$$

Immediately after this, the argument begins to increase, continuing to do so until the next operation of the commutator.

The increase of the argument is by the quantity $\Delta v - a = \Delta v - (v_1 - v_2)$. At the moment of the next operation of the commutator, the argument has reached the value

$$v_3 = v_2 + [\Delta v - (v_1 - v_2)] = 2v_2 + \Delta v - v_1. \tag{8}$$

After this, the control cycle starts repeating.

Thus, as the result of one complete control cycle, the point v_1 on the axis of abscissas is translated to the point v_3 and, correspondingly, the point p_1 of the curve $p = f(v)$, with abscissa v_1, is translated to point p_3, with abscissa v_3.

It will be shown below that the image v_3 of point v_1 cannot leave the region $v < v'$.

Consequently, (8), where v_2 is defined by (7a), gives a transformation of the semiline $v_1 < v'$ into itself. We call this the transformation T.

The invariant points, which remain unmoved under this transformation, are defined by the condition

$$v_3 = v_1. \tag{9}$$

On the basis of (9) and (8) we obtain

$$v_2 = v_1 - \frac{\Delta v}{2} \tag{10}$$

or

$$a = \frac{\Delta v}{2}.$$

If we eliminate a from (7) by means of this last equation, and denote by v^* an invariant point, we obtain the following formula for determining v^*:

$$f(v^*) - f\left(v^* - \frac{\Delta v}{2}\right) = \delta. \tag{B}$$

3. The Establishment Process in the Extremal Controller

We now discuss the question as to the character of the establishment process, as well as the number of invariant points which satisfy Eq. (B).

After commutator operation, there begins the decrease of v down to the value of v_2, in accordance with the equation

$$v_2 = v_1 - a, \tag{8a}$$

where a is defined by (7).

With the reaching of the value $p = f(v_2)$, the signum-relay operates, and the argument begins increasing up to the value

$$v_3 = v_2 + (\Delta v - a) = v_1 - a + (\Delta v - a). \tag{8b}$$

It follows from (8b) that the value of v_3 will exceed v_1 if the difference $\Delta v - a$ is greater than a; for the entire range of values of v_1 in which this is the case, transformation T will translate every point of this region to the right.

If, in some region of values of v_1, the difference $\Delta v - a$ is less than a, then transformation T will here translate each point of this region to the left.

The condition $\Delta v - a > a$ leads to the inequality $\Delta v/2 > a$, while the condition $\Delta v - a < a$ leads to the inequality $\Delta v/2 < a$.

We consider the two cases $v_1 < v^*$ and $v^* < v_1 < v'$.

The quantity a is defined by (7). We compare it with (B) and note that the right members of (7) and (B) are identical. Consequently, in the case $v_1 < v^*$, the conditions of the lemma are met, if we take $v_1 = v_a$, $v^* = v_b$, $a = d_1$ and $\Delta v/2 = d_2$ but, in this case, we have, according to (6),

$$a < \frac{\Delta v}{2}. \tag{11a}$$

If we now consider the case when $v^* < v_1 < v'$, then the conditions of the lemma hold under the assumptions that

$$v^* = v_a, \quad v_1 = v_b, \quad a = d_2, \quad \frac{\Delta v}{2} = d_1. \tag{11b}$$

In this case,

$$a > \frac{\Delta v}{2}.$$

Thus, transformation T shifts all the points of the semiline $v_1 < v'$ which lie to the left of v^* to the right, and all points which lie to the right of v^* to the left. It thus follows that, on the semiline $v < v^*$ there is just the one immovable point v^*.

In order to determine the character of the establishment process, we must clear up still two more questions.

1. Will the distances ρ_1 of the successive images v_3, v_5,... of point v_1 from fixed point v^* decrease, increase, or remain invariable?

2. Are there conditions under which transformation T will translate points of the semiline $v < v'$ lying to the left of v^* into the region lying to the right of v^* and, conversely, can it translate points lying to the right of v^* into the region lying to the left of v^*?

We first prove that, no matter what point $v_1 < v^*$ we choose, its image v_3 will not leave the region $v < v'$.

Indeed, if the point lies to the right of v^* and to the left of v' then, as was proven earlier, transformation T translates it to the left; consequently, it can not move from the region $v^* < v_1 < v'$ into the region $v > v'$

If, now, the point lies to the left of v^* then, by comparing (7) and (B), we see that, on the basis of (6b) of the lemma, $v_1 - a < v^* - \Delta v/2$; consequently,

$$v_3 = v_1 - a + (\Delta v - a) < v^* - \frac{\Delta v}{2} + (\Delta v - a) = \tag{8c}$$

$$= v^* + \frac{\Delta v}{2} - a.$$

But $a > 0$ and, therefore, by strengthening the inequality we get

$$v_3 < v^* + \frac{\Delta v}{2}. \tag{12}$$

We now compare (A) and (B). On the basis of (6b) of the lemma, we conclude that

$$v^* - \frac{\Delta v}{2} < v' - \Delta v \quad \text{or} \quad v^* + \frac{\Delta v}{2} < v'. \tag{13}$$

Thus, we always have $v_3 < v'$.

We now prove that, with successive applications of transformation T, the successive images v_3, v_5,... always approach closer to v^*. Let the distances of points $v_i (i = 1,2,\ldots)$ from v^* be

$$\rho_i = v^* - v_i. \tag{14}$$

We form the function a':

$$a' = v^* - \frac{\Delta v}{2} - v_1 + a. \tag{15}$$

It is easily seen that

$$\rho_1 - a' = \frac{\Delta v}{2} - q. \tag{16}$$

To determine the character of the establishment process, it is necessary to consider the two cases: $\rho_1 > 0$ and $\rho_1 < 0$.

We first consider the case $\rho_1 > 0$. In this case $v_1 < v^*$. It was determined earlier that, for $v_1 < v^*$, $\Delta v/2 \geq a$.

Consequently, from (16),

$$\rho_1 - a' > 0 \quad (\rho_1 > 0).$$

Moreover, it was shown earlier that, if $v_1 < v^*$, then $v^* - \Delta v/2 > v - a$ and, consequently, $a' > 0$.

Therefore, a' can vary within the limits

$$\rho_1 > a' > 0 \tag{17a}$$

We now rewrite (8), taking (16) into account:

$$v_3 = v_1 + 2\left(\frac{\Delta v}{2} - a\right) = \tag{8d}$$

$$= v^* - \rho_1 + 2(\rho_1 - a') = v^* + \rho_1 - 2a'.$$

By bearing in mind that, on the basis of (14), for $i = 3$

$$v_3 = v^* - \rho_3, \tag{14a}$$

and by comparing (14a) and (8d), we obtain

$$\rho_3 = 2a' - \rho_1. \tag{C}$$

By taking (17a) into account, it is simple to conclude from (C) that ρ_3 can vary within the limits $-\rho < \rho_3 < \rho_1$. Whence

$$|\rho_3| < \rho_1 \quad (\rho_1 > 0). \tag{18a}$$

We turn now to the case when $\rho_1 < 0$, whereby $v' > v_1 > v^*$. In this case, $\Delta v/2 - a < 0$ and $v^* - \Delta v/2 < -v_1 - a$. Consequently, $a' < 0$ and $\rho_1 - a' < 0$.

It follows from this that a' can vary within the limits

$$\rho_1 < a' < 0. \tag{17b}$$

From whence, on the basis of (C), we conclude that

$$|\rho_3| < |\rho_1| \quad (\rho_1 < 0). \tag{18b}$$

It follows from (18a) and (18b) that, for any values $v_1 < v'$,

$$|\rho_3| < |\rho_1|. \tag{18}$$

It is thus shown that no matter where the point v_1 lies on the semiline $v < v'$, we always have $|\rho_3| < |\rho_1|$ i.e., repeated iteration of transformation T shifts its image ever closer to v^*. In other words, for any value of $v_1 < v'$, the extremal control process approximates to the limiting motion of period $\tau = \Delta v/k$, in which the argument changes periodically, with the same period τ, within the limits $v^* - \Delta v/2 \leq v \leq v^*$, and the corresponding controlled quantity p varies within the limits

$$f\left(v^* - \frac{\Delta v}{2}\right) \leqslant p \leqslant f(v^*).$$

Having (C), we can easily find the condition for which image v_3 of point v_1 turns out to be on the same side of the invariant point as v_1.

For this condition to be met, ρ_3 must keep the same sign as ρ_1.

We consider, as previously, the two cases: $\rho_1 > 0$ and $\rho_1 < 0$. Let $\rho_1 > 0$. Since, with this, we also have $a' > 0$ then, from (C), it follows that $\rho_3 > 0$ if

$$2a' > \rho_1; \tag{19a}$$

Now let $\rho_1 < 0$, for which $a' < 0$; consequently, $\rho_3 < 0$ if

$$|2a'| > |\rho_1|. \tag{19b}$$

Both conditions (19a) and (19b) reduce to the one:

$$\phi = |2a'| - |\rho_1| > 0. \tag{20a}$$

Thus, if the function $\phi > 0$, transformation T moves the image of point v_1 to the invariant point v^* while keeping it on the same side of v^*; if

$$\phi < 0, \tag{20b}$$

then the image of point v_1 is shifted by transformation T to v^* while simultaneously transferring over to the other side of v^*. If

$$\phi = 0 \tag{20c}$$

then image v_3 coincides with invariant point v^*, and the further successive images remain immovable.

Condition (20a) gives that property of the function $p = f(v)$ for which ρ_3 retains the sign of ρ_1. One may also give the boundaries for the point v_1 such that its image may not under any conditions coincide with v^*. These boundaries are defined by the condition that $\rho_3 \neq 0$.

Let $\rho_1 > 0$. We have from (16) that

$$a' = \rho_1 - \frac{\Delta v}{2} + a. \tag{16a}$$

On the basis of (C), the condition being sought reduces to the inequality $2a' > \rho_1$, i.e.,

$$2\left(\rho_1 - \frac{\Delta v}{2} + a\right) > \rho_1,$$

from whence

$$\rho_1 > \Delta v - 2a. \tag{21a}$$

But if $v_1 < v^*$, then a can vary within the limits $0 < a < \Delta v/2$. Therefore, if $\rho_1 > \Delta v$, then (21a) always holds. With this, $v_1 = v^* - \rho_1 = v^* - \Delta v$.

Now let $\rho_1 < 0$. With this, $v' > v_1 > v^*$ and the number a can vary within the limits

$$\frac{\Delta v}{2} < a < \Delta v.$$

The condition sought reduces to the inequality $2a' < \rho_1$ from whence, on the basis of (16a),

$$\rho_1 < \Delta v - 2a. \tag{21b}$$

Condition (21b) will be met if $\rho_1 < \Delta v - 2\Delta v = -\Delta v$. With this, $v_1 = v^* - \rho_1 > v^* + \Delta v$. Thus, if v_1 is at a distance from v^* whose modulus is greater than Δv, then the image of point v_1 cannot, under any conditions, coincide with v^*.

We now consider the case when $v_1 > v'$. As before, let a decrease of v commence after commutator operation; the decrease of v can continue either until the signum-relay operates or, failing that, until the commutator operates.

In the case under consideration ($v_1 > v'$) the signum-relay does not operate, since the controlled quantity p can change, with a decrease of the argument by Δv, only by the amount m, which is less than the insensitivity zone width δ.

This quickly follows from the lemma. Indeed, $m = f(v_1) - f(v_1 - \Delta v)$.

From a comparison with (A) we note that $v' < v_1 < v_0$ and the variations of the argument are identical; consequently, on the basis of part "a" of the lemma, $m < \delta$. Therefore, the reversal from an increase in v will occur, not by operation of the signum-relay, but by operation of the commutator, which will occur at the value $v_2 = v_1 - \Delta v$.

After commutator operation, the argument increases up to the value $v_3 = (v_1 - \Delta v) + \Delta v = v_1$. After this, there is again a reversal to decreasing v, operation of the signum-relay, but by operation of the commutator, since the signum-relay does not operate, reversal, etc.

Consequently, one full control cycle translates each initial value which lies in the region $v' < v < v_0$ into itself; there is a continuum of stationary amplitudes.

In other words, if the control process starts from a value of v lying in the region $v' < v < v_0$, then there will occur periodic oscillations of period $\tau = 2\ \Delta v/k$ for periodic variations of the argument within the limits $v_1 - \Delta v \geq v \geq v_1$ and a corresponding variation of the controlled quantity within the limits of $f(v_1 - \Delta v) \leq p \leq f(v_1)$.

Until now we have considered all the points of the semiline $v \leq v_0$ except the point $v = v'$, defined by (A).

All the values considered for $v = v_0$ correspond to definite actual oscillatory processes which occur in the extremal controller. This cannot be said of the initial value $v_1 = v'$.

In fact, according to (A), after a reversal to decreasing v occurs for the value v', the controlled quantity changes by δ for a change of argument of exactly Δv.

But with this there must simultaneously occur two actions: reversal due to signum-relay operation, and reversal due to commutator operation.

Such simultaneous operations have no real meaning. One might think that to this there would correspond a switching out of the entire reversing device; this is not admissible, despite the small probability that (A) holds. In practice, even if the initial value turns out to be equal to v', one must provide operation either of the commutator or of the signum-relay. Consequently, it would be possible to assign the value of v' to one of the regions.

We now consider controller operation if the initial value is $v > v_0$. If we assume that, after commutator operation initially, there occurs an increase of the argument then, by assuming that there exists a $v'' > v_0$ such that

$$f(v'') - f(v'' + \Delta v) = \delta,$$

we can transfer over all the results obtained for $v \leq v_0$ to the case when $v \geq v_0$. Instead of transformation T we shall have transformation T', given by the formula

$$v_3 = 2v_2 - \Delta v - v_1,$$

where v_2 is defined by the formula $f(v_1) - f(v_2) = \delta$.

Consequently, in this case one can partition the semiline of initial values $v \geq v_0$ into two regions: $v_0 \leq v_1 < v''$ and $v'' < v_1$. The value of v'' is defined as the root of (A').

In the region $v_0 \leq v_1 < v''$ the motion is stable, there being a continuum of periodic motions.

In the region $v'' < v_1$ there occurs an approximation to a limiting periodic motion, in which the argument varies periodically with period $\tau = \Delta v/k$ between the limits $v'^{*} \leq v \leq v'^{*} + \Delta v/2$, where v'^{*} is the root of the equation

$$f(v'^{*}) - f\left(v'^{*} + \frac{\Delta v}{2}\right) = \delta.$$

In order to exhaust completely all the possibilities which can ensue for values of Δv and δ for which there exist $v = v'$ and $v = v''$, it is necessary to discard the supposition that, at the moment when the controller is switched in, the commutator necessarily is operated by a decrease of the controlled quantity p.

We note first of all, that if the initial value of v_1 for which the commutator operates on an increase in the controlled quantity is at a distance from v_0 equal to or greater than Δv, then this case leads to that already considered if one takes account, not of the value v_1, but of the value $v_1' = v_1 \pm \Delta v$ ("+" for $v_1 < v_0$ and "-" for $v_1 > v_0$).

In fact, with this the following operation of the commutator will occur for a decrease of $p = f(v)$, which is a case already considered; the behavior of the controlled system will thus depend on whether v_1' lies in the region $v' < v_1 < v''$ or in the region $v_1 < v'$ and $v_1' > v''$.

In the first case, there is a continuum of periodic motions; in the second case, there are either periodic motions about v^{*} and v'^{*} if, respectively, $v_1' = v^{*}$ or $v_1' = v'^{*}$, or an approximation to these limiting motions.

There still remains for consideration the case when the initial value of v_1 for which the commutator operates on an increase of the controlled quantity is separated from v_0 by a distance less than Δv. Let

$$v_1 = v_0 + b > v_0 \qquad (0 < b < \Delta v).$$

It is easily seen that, with a decrease of p from the maximum value $p = f(v_0)$, which will occur with decreasing v, down to the value $p = f(v_1 - \Delta v)$, the signum-relay does not operate, since the change in p, $\delta p = f(v_0) - f(v_0 - \Delta v)$ will be less than δ. Consequently, the following commutator operation occurs for the value:

$$v_2 = v_0 + b - \Delta v < v_0, \quad v_0 - v_2 = \Delta v - b < \Delta v.$$

After commutator operation, there begins an increase of v from the value v_2 to the value

$$v_3 = v_2 + \Delta v = v_0 + b - \Delta v + \Delta v = v_0 + b = v_1.$$

With the attainment of $v_3 = v_1$, there occurs a new operation of the commutator, and the cycle begins to repeat. Consequently, one full control cycle will transfer the initial value of v_1 into itself, i.e., there is a continuum of periodic motions. The case when $v_1 = v_0 - b$, $0 < b < \Delta v$, reduces to what has just been considered if one begins the investigation with the following operation of the commutator.

Thus, the partitioning of the line of initial values, $-\infty < v_1 < +\infty$, into regions depends on which side the argument begins to vary on at the moment when the controller is switched in.

Case A. If commutator operation gives rise to a decrease in v, then the v_1 line is divided into three regions:

region L_1
$$v_1 < v'. \tag{22'}$$

region L_2
$$v' < v_1 < v'' + \Delta v. \tag{22''}$$

region L_3
$$v'' + \Delta v < v_1. \tag{22'''}$$

Case B. If commutator operation gives rise to an increase in v, the regions are shifted to the left, and are the following:

region L_1'
$$v_1 < v' - \Delta v, \tag{23'}$$

region L_2'
$$v' - \Delta v < v_1 < v''. \tag{23''}$$

region L_3'
$$v'' < v_1. \tag{23'''}$$

In the first and third regions there occur approximations to the limiting periodic motions while, in the second region, there is a continuum of periodic motions.

4. Effect of Variations of the Parameters Δv and δ

We have thus far assumed that Δv and δ have values such that there exist numbers $v' < v_0$ and $v'' > v_0$.

We now drop this limitation and consider the influence of changes in the parameters Δv and δ.

Let there exist real values of v' and v''. We shall fix $\Delta v = \Delta_1 v$ and we shall vary δ.

The decomposition into regions L_1, L_2, and L_3 depends on the character of the real roots of (A) and (A').

It is easily seen that, as δ_1 increases, the points v' and v'' move further away from v_0 while, for decreasing δ_1, the points v' and v'' move closer to v_0. For some definite values $\delta = \delta_1$ and $\delta = \delta_2$, the points v' and v'' coincide with v_0; the values of these are determined, respectively, from the expressions

$$f(v_0) - f(v_0 - \Delta v) = \delta_1. \tag{24}$$
$$f(v_0) - f(v_0 + \Delta v) = \delta_2.$$

Simultaneously with the change of position of the points v' and v'' on the line there is a change of position of the invariant points v^* and v^*_1, defined by (B) and (B'). These points move away from v_0 with increasing δ and approach v_0 for decreasing δ. Suppose that they coincide with v_0 for the values $\delta = \delta_3$ and $\delta = \delta_4$, defined by (25):

$$f(v_0) - f\left(v_0 - \frac{\Delta v}{2}\right) = \delta_3. \tag{25}$$
$$f(v_0) - f\left(v_0 + \frac{\Delta v}{2}\right) = \delta_4.$$

It is obvious that $\delta_3 < \delta_1$ and $\delta_2 < \delta_4$. We consider the case when the curve $p = f(v)$ is symmetric about the line $v = v_0$. Then, $\delta_1 = \delta_2$ and $\delta_3 = \delta_4$. Let $\delta_3 < \delta < \delta_1$. Consequently, there exists no v' which satisfies (A). Let $f(v_0) - f(v_0 - a_1) = \delta$ and consequently, $a_1 < \Delta v$. Therefore, operation of the signum-relay occurs to the left of v_0 if the initial value lies to the right of v_0 in the region L_1 [Condition (26)].

With this, the regions of (22) are deformed, and assume the forms:

region L_1
$$v_1 < v_0 + \Delta v - a. \tag{26'}$$

region L_2
$$v_0 + \Delta v - a_1 < v_1 < v_0 + a_1. \tag{26''}$$

region L_3
$$v_0 + a_1 < v_1. \tag{26'''}$$

We shall continue to decrease δ. If $\delta = \delta_3$, i.e., if v^* coincides with v_0, then $a_1 = \Delta v/2$; then,

$$v_0 + \Delta v - a_1 = v_0 + \frac{\Delta v}{2}, \quad v_0 + a_1 = v_0 + \frac{\Delta v}{2}.$$

Consequently, region L_2 shrinks to a point. There remain two regions. Region L_1 : $v_1 < v_0 + \Delta v/2$; region L_3: $v_0 + \Delta v/2 < v_1$.

With still greater decrease of δ, the motion loses its simple character and becomes a multiple motion.

It may be shown that the mode of multiple oscillations is not effective in practice here, since oscillations are possible with this that have greater amplitudes than the simple oscillations.

It is therefore meaningful to decrease δ and to increase Δv until v^* gets close to v_0, but not beyond that; this is the more advantageous since, generally speaking, it is quite difficult to obtain a small δ, but a decrease in Δv is very desirable from the point of view of increasing the stability of the control mode with respect to external disturbances.

We have been changing δ with Δv held fixed. It is easily seen that an increase in Δv acts analogously to a decrease in δ.

We can consider the case of asymmetry analogously.

5. Consideration of a Concrete Problem

Let the function $p = f(v)$ have the form

$$p = -v^2. \tag{27}$$

We shall consider initially a value of $v_1 > v_0 = 0$. If Δv and δ are given, then the magnitude of v^* is defined by the equation

$$f(v^*) - f\left(v^* - \frac{\Delta v}{2}\right) = \delta; \tag{28}$$

from which, based on (27),

$$v^* = \frac{\Delta v}{4} - \frac{\delta}{\Delta v} \qquad (v^* \leqslant 0).$$

Equation (28) is meaningful when $\delta \geq \Delta v^2/4$. Region (A) is isolated by the boundaries v' and $v_0 = 0$, where v', in accordance with (A), is defined by the formula

$$v' = \frac{\Delta v}{2} - \frac{\delta}{2\Delta v} \qquad (v' \leqslant 0). \tag{29}$$

We now determine the character of the establishment process in accordance with (20a) and (20b). The character of the process we are seeking depends on the sign of the expression $\psi = |2a'| - |\rho_1|$. We now construct this function. According to (14),

$$a' = \left(v^* - \frac{\Delta v}{2}\right) - (\delta_1 - a),$$

where $\underline{a}$ is the root of (7).

From (7) we obtain the quadratic equation in $\underline{a}$:

$$a^2 - 2v_1 a - \delta = 0;$$

from whence

$$a = v_1 + \sqrt{v_1^2 + \delta}.$$

(The plus sign is chosen so that $a > 0$.)

Consequently,

$$a' = \left(\frac{\Delta v}{4} - \frac{\delta}{\Delta v} - \frac{\Delta v}{2}\right) - \left[v_1 - \left(v_1 + \sqrt{v_1^2 + \delta}\right)\right|$$

Further,

$$\rho_1 = v^* - v_1 = \left(\frac{\Delta v}{4} - \frac{\delta}{\Delta v} - v_1\right).$$

Inequality (20a) takes the form

$$\phi = \pm\left[-\frac{3}{4}\Delta v - \frac{\delta}{\Delta v} + v_1 + 2\sqrt{v_1^2 + \delta}\right| > 0.$$

(The plus sign is taken for $v_1 < v^*$, the minus sign for $v_1 > v^*$; this expression is meaningful for $\delta \geq \Delta v^2/4$.

It is easily shown that this expression cannot be satisfied for any arbitrary v_1. It follows from this that it is impossible to choose values of Δv and δ such that the approximation to v^* occurs for any v_1 on one side only. However, for certain regions of values of Δv and δ, one can cite such a point $v_1 = v_u \neq v^*$ whose image v_3 coincides with the invariant point v^*.

In fact, it follows from (20c) that this point is defined by the condition that $\psi = 0$.

Whence,

$$v_1 = \frac{-\left(\frac{3}{2}\Delta v + \frac{2\delta}{\Delta v}\right) \pm \left(\frac{4\delta}{\Delta v} - 3\Delta v\right)}{6}.$$

The minus sign defines the invariant point v^*. The plus sign gives the point v_u sought:

$$v_u = \frac{3}{4}\Delta v + \frac{1}{3}\frac{\delta}{\Delta v}. \tag{30}$$

Formula (30) gives a negative value of v_u for $\delta < 2.25\Delta v^2$, while it follows from (28) that v^* has a minus sign [the condition for applicability of (28)] if $4\delta > \Delta v^2$.

Consequently, the values of v_u are meaningful in the region

$$0.25\Delta v^2 < \delta < 2.25\Delta v^2. \tag{31}$$

We now consider the entire v_1 line, and construct the regions of initial values given by (23) and (26). So long as there exist values $v' < v_0 = 0$, i.e., so long as $\delta > \Delta v^2$ [this follows from (29)], the line of initial values is partitioned into the following three regions (22):

1) region L_1

$$v_1 < \frac{\Delta v}{2} - \frac{\delta}{2\Delta v};$$

2) region L_2

$$\frac{\Delta v}{2} - \frac{\delta}{2\Delta v} < v_1 < \frac{\delta}{2\Delta v} - \frac{\Delta v}{2} + \Delta v = \frac{\delta}{2\Delta v} + \frac{\Delta v}{2};$$

3) region L_3

$$\frac{\delta}{2\Delta v} + \frac{\Delta v}{2} < v_1.$$

If δ is included in the interval $0.25\,\Delta v^2 < \delta < \Delta v^2$, then the line of initial values is partitioned into the regions of (26) [where the quantity a_1 is defined by the condition $f(v_0) - f(v_0 - a_1) = \delta$, but $v_0 = 0$, and, consequently, $a_1 = \sqrt{\delta}$]:

1) region L_1

$$v_1 < v_0 + \Delta v - \sqrt{\delta};$$

2) region L_2

$$v_0 + \Delta v - \sqrt{\delta} < v_1 < v_0 + \sqrt{\delta};$$

3) region L_3

$$v_0 + \sqrt{\delta} < v_1.$$

As δ decreases from $\delta = \delta_1 = \Delta v^2$ to $\delta = 0.25\Delta v^2$, region L_2 decreases and, for $\delta = 0.25\,\Delta v^2$, shrinks to a point. With further decreases in δ, the motion becomes multiple.

Returning to (31), we note that, in the region of values $\delta > 2.25\,\Delta v^2$, there occurs an asymptotic approach to periodic motions (if v_1 is chosen in regions L_1 or L_3); in the region of (31) the establishment process can be either asymptotic or finite; in the region of $\delta < 0.25\Delta v^2$, there are multiple oscillations.

The character of the possible motions in the system under consideration depends on the two essential parameters Δv and δ.

Figure 2 shows the Δv, δ parameter plane.

In the region bounded by the arc of the parabola $\Delta v^2 = \delta$ and the positive δ semiaxis, there is a rigid excitation mode with a decomposition of the initial values in accordance with the domains of (22).

In the region between the arcs of the parabolas $\Delta v^2 = 4\delta$ and $\Delta v^2 = \delta$, there are rigid modes with decomposition in accordance with the regions of (26).

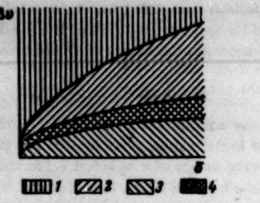


Fig. 2. 1 is the multiple oscillatory mode, 2 is the rigid mode, with decomposition into the regions of (26), 3 is the asymptotic approach to a periodic motion (the decomposition into the regions of (22)), 4 is the finite and asymptotic establishment processes (decomposition into the regions of (22)).

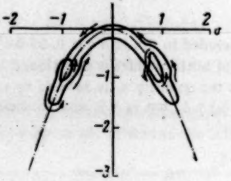

Fig. 3.

The asymptotic approximation to periodic motion occurs in the region bounded by the arc of the parabola $9\Delta v^2 = 4\delta$ and the positive δ semiaxis.

The region $\Delta v^2 > 4\delta$ is characterized by the presence of a multiple oscillatory mode.

Figure 3 shows the phase diagram of the multiple periodic oscillations for $\Delta v = 3$ and $\delta = 1$.

Figure 4 shows the development of the multiple periodic oscillations in time (curve I), where the axis of abscissas is laid out with time in the scale of $1/k$. This same figure gives the development (curve II) in time of the simple periodic oscillations for the limiting value of $\Delta v = 2$ for the chosen value of $\delta = 1$. It is clear, from a comparison of curves I and II, that the multiple oscillations are less suitable, since their amplitudes are greater than those of the simple oscillations.

In conclusion, we consider the question of the influence of the system's parameters on the inaccuracy of the extremal control operation. By "inaccuracy of operation" we shall understand the difference between the value v_0 of the argument corresponding to the true extremal value of the controlled quantity and the limiting value v^* which can be attained as a result of the extremal controller's action.

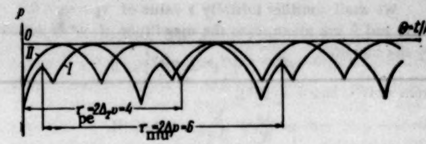

Fig. 4.

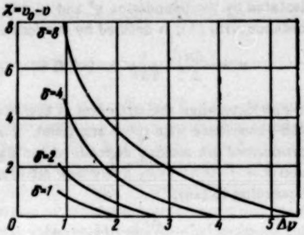

Fig. 5

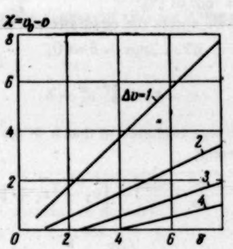

We denote this difference by χ:

$$\chi = v_0 - v^* = \frac{\delta}{\Delta v} - \frac{\Delta v}{4}. \tag{32}$$

Expression (32) is meaningful so long as $\chi \geq 0$, since the case $\chi < 0$ corresponds to the case when the motion becomes multiple, and when (28) can therefore not be applied.

Figure 5 gives graphs of the quantity χ as a function of Δv for different fixed values of δ. It is clear from this figure that each value of δ has its corresponding value of $\overline{\Delta v}$ for which the inaccuracy χ vanishes. With decreasing Δv the inaccuracy increases, this increase not being very large for values of Δv close to $\overline{\Delta v}$; for significant decreases in Δv the magnitude of χ begins to increase more rapidly since, in (32), the first, hyperbolic-type, term begins to play a predominant role.

Figure 6 gives graphs of the quantity χ as a function of δ for different fixed values of Δv. This function is given by a family of straight lines with slopes greater than zero.

A comparison of Figs. 5 and 6 shows that the increases in δ have a lesser effect on the increase of the inaccuracy than do decreases in Δv.

Appendix

Lemma. If the continuous function $p = f(v)$ satisfies the conditions $f'(v_0) = 0$, $f''(v) < 0$ for $v \leq v_0$ then, for each pair of values v_a and v_b ($v_a < v_b \leq v_0$), the following inequalities hold:

a) if there are given two numbers c_1 and c_2 ($0 < c_1 \leq c_2$), then

$$f(v_b) - f(v_b - c_1) < f(v_a) - f(v_a - c_2); \tag{5}$$

b) if there are given two numbers d_1 and d_2 such that

$$f(v_a) - f(v_a - d_1) = f(v_b) - f(v_b - d_2), \tag{6}$$

then

$$d_1 < d_2 \tag{6a}$$

and

$$v_a - d_1 < v_b - d_2. \tag{6b}$$

Proof. We first note that, since $f''(v) < 0$ then, for decreasing v_1, the function $f'(v)$ increases monotonically.

First, we prove (5).

a) We assume initially that $v_a < v_b - c_1$; in this case, the intervals $v_a - c_2 \leq v \leq v_a$ and $v_b - c_1 \leq v \leq v_b$ are nonintersecting.

With this,

$$[f'(v)]_{v < v_a} > [f'(v)]_{v > v_b - c}. \tag{33}$$

Further,

$$f(v_b) - f(v_b - c_1) = \Delta P_1 = \int_{v_b - c_1}^{v_b} f'(v)\, dv, \tag{34a}$$

$$f(v_a) - f(v_a - c_2) = \Delta P_2 = \int_{v_a - c_2}^{v_a} f'(v)\, dv. \tag{34b}$$

On the basis of (33), and bearing in mind that $c_1 \leq c_2$, we conclude that $\Delta P_1 < \Delta P_2$.

b) We now assume that $v_a > v_b - c_2$. In this case, the intervals $v_a - c_2 \leq v \leq v_a$ and $v_b - c_1 \leq v \leq v_b$ partially intersect each other; with this, the segment $v_b - c_1 \leq v \leq v_a$ is common to both intervals. Consequently, on this segment, the changes in the function $f(v)$ will also be identical.

It remains to compare the changes of the function $f(v)$ on the intervals $v_a - c_2 \leq v \leq v_b - c_1$ and $v_a \leq v \leq v_b$. But, for these intervals, we have case "a". Consequently, here also $\Delta P_1 < \Delta P_2$. Thus, (5) is proven.

Now we prove (6a).

We fix the quantity c_1 in the left member of (5), introducing the notation $c_1 = d_2$. We now, in the right member of (5), change c_2 (denoting it by d_1) in such fashion that the inequality becomes an equality.

Since, in (34b), $f'(v)$ retained its sign over the entire interval of integration, the quantity defined by the integral in (34b) can be decreased only by decreasing the length of this interval, whereby, on the basis of (33), equality can be reached only for $d_1 < d_2$.

As for (6b), it is obvious.

ELECTROMAGNETIC CONTROL-ELEMENT DYNAMICS

I. E. Dekabrun, N. P. Kozlov, and I. M. Krassov

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 4, pp. 506-512, April, 1960
Original article submitted June 30, 1959

The equation of motion is derived for a rotary type electromagnetic control element, and a comparison is made with experimental results.

In automatic control and regulation systems, extensive use has been made of electric controlling elements in which electrical quantities are transformed to mechanical ones. Such elements (electromagnetic and electrodynamic) are used in remote control systems, in electrohydraulic servomechanisms and in other devices of automation technology.

Despire the widespread usage of electric controlling elements, their dynamics are still insufficiently explicated. The existing works [1] in this area treat only individual questions, and lack a general character.

In the present paper we consider the dynamics of an electromagnetic polarized controlling element, since it is the most widely used type.

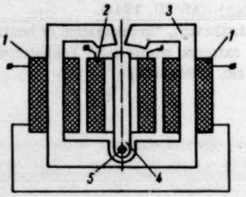

Fig. 1

A schematic drawing of the electromagnetic control element is shown in Fig. 1, where 1 is the excitation coil (superposed magnetization), 2 is the control coil, 3 is the magnetic circuit, 4 is the armature, and 5 is the output shaft. When a controlling signal is applied to coil 2, output shaft 5 is rotated by a definite angle.

We now write the general form of the equation of motion for the electromagnetic control element's armature:

$$J\ddot{\theta} = M_{\mathrm{d}} - M_1 . \tag{1}$$

Here, J is the armature's moment of inertia, θ is the armature's angle of rotation, M_d is the driving torque, and M_1 is the impedance torque of the armature's motion.

The driving torque, equal to

$$M_{\mathrm{d}} = PR \tag{2}$$

(where P is the force engendering the armature rotation and R is the radius of application of the force), depends on the current flowing in the control coil.

The impedance torque is made up of the load torque M_L, the friction torque in the bearings M_F and the damping torque M_v.

In considering the operation of an electromagnetic control element in any actual control scheme, it is necessary to take into account both the form of the load and the frictional force in the bearings arising when an external force is applied to the armature axis [2]. For investigating the dynamics of an inherently electromagnetic control element removed from any control scheme (and these may be very diverse), there is the possibility of not taking the load on the control element's armature into account. In this case, the impedance torque will be determined by the friction in the bearings under the action of the armature's own weight, and by the damping which arises when the armature moves within the surrounding air, i.e.,

$$M_1 = Qrf \operatorname{sign} \dot{\theta} + kq\dot{\theta}, \tag{3}$$

where Q is the armature's weight, r is the radius of the armature shaft, f is the coefficient of friction in the bearings, k is a proportionality factor, and q is the coefficient of viscous friction.

By substituting (2) and (3) in (1), we get

$$J\ddot{\theta} = PR - Qrf \operatorname{sign} \dot{\theta} - kq\dot{\theta}. \tag{4}$$

The work expended in moving the control element's armature, as in every polarized electromagnetic system, is carried out at the expense of two energy sources: the controlling (working) and the polarizing sources. In the general case, the force acting on the armature of the system under consideration can be presented in the form of a sum of three forces [3]

$$P = P_1 + P_2 + P_3,$$

where P_1 is the component due to the polarizing source (or sources), which exists whether or not there is current in the control winding, P_2 is the component due to the controlling (working) source (or sources), P_3 is the component arising from the interaction of the magnetic fluxes of the controlling and polarizing sources which actually determines the direction of armature motion.

For the case when the polarizing and working sources are coils, these components equal

$$P_1 = \Sigma \frac{(i_{\mathrm{e}} w_{\mathrm{e}})^2}{2} \frac{dG_{\mathrm{e}}}{dy}, \quad P_2 = \Sigma \frac{(i_{\mathrm{c}} w_{\mathrm{c}})^2}{2} \frac{dG_{\mathrm{c}}}{dy},$$

$$P_3 = \Sigma \frac{i_{\mathrm{e}} w_{\mathrm{e}} i_{\mathrm{c}} w_{\mathrm{c}}}{2} \frac{dG_{\mathrm{ec}}}{dy},$$

where i_e and i_c are the currents flowing in the excitation and control coils, respectively, w_e and w_c are the number of turns in the excitation and control coils, G_e is the circuit's conductance with respect to the magnetic flux of the excitation coil, G_c is the circuit conductance with respect to the control coil's magnetic flux, G_{ec} is the circuit conductance determining the magnitude of the portion of the excitation coil's magnetic flux in the control winding, y is the linear deviation of the armature from the neutral position*.

As is obvious from these expressions, only the sign of the third component is determined by the polarity of the current in the control winding. The summation signs in all these expressions are indicative of the fact that polarized systems, as a rule, have complicated configurations of magnetic circuits with several controlling and polarizing sources.

The system under consideration is a differential one. In it (Fig. 1) there are two excitation coils on the arms of the magnetic circuit, and one control coil on the cross piece. With no controlling signal present, the electromagnet's armature is acted upon by the forces generated by the first and second excitation coils. In this case, the component P_1 is the sum of these two forces, and equals

$$P_1 = \frac{(i_1 w_1)^2}{2}\frac{dG_1}{dy} + \frac{(i_2 w_2)^2}{2}\frac{dG_2}{dy}, \qquad (5)$$

where G_1 and G_2 are the circuit's conductances with respect to the magnetic fluxes of the first and second excitation coils, respectively, i_1, i_2 and w_1, w_2 are the currents and numbers of turns in the first and second excitation coils, respectively.

Since the coils are identical ($w_1 = w_2 = w_e$) and are connected in series ($i_1 = i_2 = i_e$), the expression may be rewritten in the form

$$P_1 = \frac{(i_e w_e)^2}{2}\left(\frac{dG_1}{dy} + \frac{dG_2}{dy}\right). \qquad (6)$$

The second component P_2, generated by the control coil, can be expressed by the formula

$$P_2 = \frac{(iw)^2}{2}\frac{dG}{dy}, \qquad (7)$$

where i and w are the current and number of turns in the control coil, G is the circuit conductance with respect to the magnetic flux of the control coil.

The third component, created by the interaction of the two counter-directed magnetic fluxes of the first and second excitation coils with the magnetic flux of the control coil, equals

$$P_3 = \frac{iwi_e w_e}{2}\left(\frac{dG_{2c}}{dy} - \frac{dG_{1c}}{dy}\right), \qquad (8)$$

where G_{1c} and G_{2c} are the conductances which determine the magnitude of the magnetic fluxes in the control coil which correspond to the first and second excitation coils.

In order to express P_1, P_2, and P_3 in terms of the controlling element's parameters, we use its replacement circuit (Fig. 2). Figures 3 and 4 show the nomenclature of the basic design parameters of the control element. With this nomenclature, we can write that the impedances of the left and right air gaps equal, respectively,

$$R_{P1} = \frac{\delta}{(c-y)d}, \qquad R_{P2} = \frac{\delta}{(c+y)d}, \qquad (9)$$

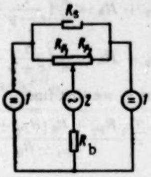

Fig. 2. 1 is the excitation winding's mmf, 2 is the control winding's mmf.

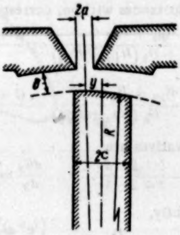

Fig. 3. Basic design parameters of the electromagnetic control element.

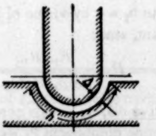

Fig. 4. Design parameters of the armature's bearing portion.

and that the air gap between the bearing and the armature equals

$$R_b = \frac{\delta}{ld}, \qquad (10)$$

where c = b - a, $l = hk_1$, $k_1 = \delta/\Delta$, d is the armature thickness.

We take $R_s = \infty$, and calculate a number of auxiliary quantities:

$$R_{P1} + R_{P2} = \frac{2c\delta}{(c^2 - y^2)d}.$$

$$R_{P1} - R_{P2} = \frac{2y\delta}{(c^2 - y^2)d}.$$

---

*We consider small angular deviations of the armature, within the limits of ± 1 degree.

$$R_{P1}R_{P2}=\frac{\delta^2}{(c^2-y^2)d^2}.$$

$$R_{P1}R_{P2}+R_\delta(R_{P1}+R_{P2})=\frac{\delta^2}{(c^2-y^2)d^2}\left(1+\frac{2c}{l}\right).$$

$$R_{P1}+R_\delta=\frac{\delta}{d}\left(\frac{1}{c-y}+\frac{1}{l}\right).$$

$$R_{P2}+R_\delta=\frac{\delta}{d}\left(\frac{1}{c+y}+\frac{1}{l}\right).$$

To determine P_1 we first find

$$R_1=\frac{1}{G_1}=\frac{R_{P1}R_{P2}+R_\delta(R_{P1}+R_{P2})}{R_{P2}+R_\delta}. \qquad (11)$$

$$R_2=\frac{1}{G_2}=\frac{R_{P1}R_{P2}+R_\delta(R_{P1}+R_{P2})}{R_{P1}+R_\delta}.$$

The conductances will be, correspondingly,

$$G_1=\frac{R_{P2}+R_\delta}{R_{P1}R_{P2}+R_\delta(R_{P1}+R_{P2})}=\frac{(l+c+y)(c-y)d}{(l+2c)\delta}. \qquad (12)$$

$$G_2=\frac{R_{P1}+R_\delta}{R_{P1}R_{P2}+R_\delta(R_{P1}+R_{P2})}=\frac{(l+c-y)(c+y)d}{(l+2c)\delta}.$$

and their derivatives are

$$\frac{dG_1}{dy}=-\frac{l+2y}{l+2c}\frac{d}{\delta}. \qquad \frac{dG_2}{dy}=\frac{l-2y}{l+2c}\frac{d}{\delta}; \qquad (13)$$

Consequently,

$$P_1=-\frac{2(i_e w_e)^2 d}{(l+2c)\delta}y. \qquad (14)$$

The minus sign shows that component P_1 is directed opposite to the translation y.

Component P_2 = 0 by virtue of the fact that the conductance is constant, since

$$R_0=\frac{1}{G}=R_\delta+\frac{R_{P1}R_{P2}}{R_{P1}+R_{P2}}=R_\delta+\frac{\delta}{2cd} \qquad (15)$$

and its derivative dG/dy equals zero.

To determine component P_3 we should find the expressions for G_{1C} and G_{2C}. For this, we sketch the replacement circuit (Fig. 5) and determine which portion of the fluxes engendered by each excitation coil will flow through the control coil. The action of each excitation coil will be considered separately. Based on Ohm's laws and Kirchhoff's laws, we get

$$G_{1C}=\frac{R_{P2}}{R_{P1}R_{P2}+R_\delta(R_{P1}+R_{P2})},$$

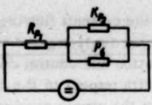
$$G_{2C}=\frac{R_{P1}}{R_{P1}R_{P2}+R_\delta(R_{P1}+R_{P2})}. \qquad (16)$$

Consequently,

$$G_{2C}-G_{1C}=\frac{R_{P1}-R_{P2}}{R_{P1}R_{P2}+R_\delta(R_{P1}+R_{P2})}. \qquad (17)$$

After substituting of the impedance values, we get

$$G_{2C}-G_{1C}=\frac{2dly}{\delta(l+2c)}, \qquad (18)$$



whence

$$\frac{d(G_{2C}-G_{1C})}{dy}=\frac{2ld}{\delta(l+2c)}. \qquad (19)$$

Consequently,

$$P_3=iwi_e w_e\frac{ld}{\delta(l+2c)}. \qquad (20)$$

Thus, the general expression for the force will have the form

$$P=P_3+P_1 \qquad (21)$$

or

$$P=iwi_e w_e\frac{ld}{\delta(l+2c)}-\frac{2(i_e w_e)^2 d}{\delta(l+2c)}y. \qquad (22)$$

As is clear from this expression, the component P_1 of the force on the armature acts as a spring, rotating the armature after cessation of the action of the controlling signal to the original position. It may therefore be called an electrical spring.

Figure 6 shows the family of static characteristics M = f(θ) for various currents i in the control winding, these curves having been obtained experimentally. These graphs substantiate the correctness of our computations.

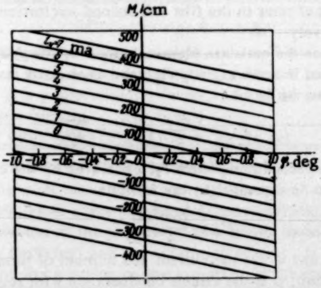


Fig. 6. Static characteristics of the electromagnetic control element.

For small angles of rotor deviation, we may assume that

$$y=\theta R. \qquad (23)$$

Then,

$$P=\frac{iwi_e w_e ld}{\delta(l+2c)}-\frac{2(i_e\omega_e)^2 Rd}{\delta(l+2c)}\theta \qquad (24)$$

or

$$P=Ai-B\theta, \qquad (25)$$

where

$$A=\frac{wi_e w_e ld}{\delta(l+2c)}, \quad B=\frac{2(i_e w_e)^2 Rd}{\delta(l+2c)}.$$

By substituting the expression obtained for the force P in (4), we obtain

$$J\ddot{\theta} = (Ai - B\theta)R - kq\dot{\theta} - Qrf\,\mathrm{sign}\,\dot{\theta}$$

or

$$\frac{J}{AR}\ddot{\theta} + \frac{kq}{AR}\dot{\theta} + \frac{B}{A}\theta + \frac{Qfr}{AR}\,\mathrm{sign}\,\dot{\theta} = i.$$

By going over to dimensionless symbols, we get the equation describing the armature motion in the following form:

$$m\ddot{\varphi} + \gamma\dot{\varphi} + \beta\varphi + \alpha\,\mathrm{sign}\,\dot{\varphi} = I, \qquad (26)$$

where

$$m = \frac{J\delta\,(l + 2c)\,\theta_m}{i_e w_e dlwRi_m}, \quad \gamma = \frac{kq\delta\,(l + 2c)\,\theta_m}{i_e w_e dlwRi_m}, \quad \beta = \frac{2i_e w_e R\theta_m}{lwi_m},$$

$$\alpha = \frac{\theta rf\delta\,(l + 2c)\,\theta_m}{i_e w_e dlwRi_m}, \quad \varphi = \frac{\theta}{\theta_m}, \quad I = \frac{i}{i_m},$$

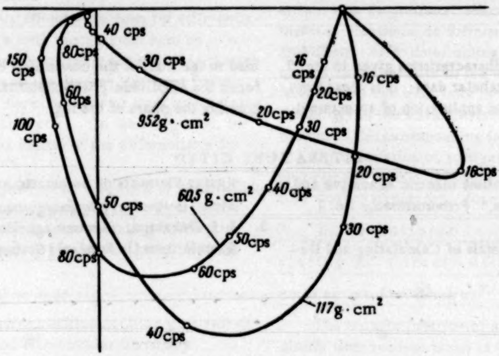

Fig. 7. Experimental amplitude-phase characteristics.

θ_m and i_m are the basic magnitudes of the angle of deviation and the control current.

In (26), the term α sign $\dot{\varphi}$, characterizing the friction in the bearings, is a negligibly small quantity, since the armature axis is supported in ball bearings and operates with flood lubrication. In view of this, the motion of the controlling device's armature can be described by an equation of the form

$$T_2^2\ddot{\varphi} + T_1\dot{\varphi} + \varphi = \frac{1}{\beta}I \qquad (27)$$

where

$$T_2^2 = m/\beta, \quad T_1 = \gamma/\beta.$$

Expression (27) is the usual form for writing the equation of a second-order oscillatory link. Its transfer function can be given in the following form:

$$W(p) = \frac{1}{\beta\left(T_2^2 p^2 + T_1 p + 1\right)}. \qquad (28)$$

The form of the frequency characteristic of such a link is widely known, but the data which characterize the frequency characteristic of an actual electromagnetic controlling device are of definite interest.

The amplitude and phase frequency characteristics of a type REP electromagnetic controlling device were recorded for a controlling current of i = 2 ma and for different inertial loads on the armature axis (for different moments of inertia)†. The armature's inherent moment of inertia J equalled 60.5 g · cm². The table presents the data obtained for a control current of i = 2 ma; the basic magnitude of armature angular rotation was taken to be $\theta_m = 0.4°$. The basic value of control current was taken to be $i_m = 2$ ma.

The quantity N in the table is the ratio of the dimensionless amplitude of armature angle of rotation to the dimensionless control current, i.e.,

$$N = \frac{\theta_a}{\theta_m} \Big/ \frac{i}{i_m},$$

and the quantity ψ is the lag phase.

---

† The experiments were carried out by L. P. Levin, G. Yu. Chubarova, and G. M. Val'kova.

Frequency, cps	Moment of inertia g · cm^2								
	60,5			117			952		
	θ_a, deg	N	ψ, deg	θ_a, deg	N	ψ, deg	θ_a, deg	N	ψ, deg.
16	0.376	0.94	13	0.44	1.11	15	0.64	1.6	24
20	0.372	0.93	20	0.48	1.2	30	0.32	0.8	35
30	0.376	0.94	30	0.53	1.33	42	0.124	0.31	55
40	0.40	1.0	46	0.53	1.33	75	0.05	0.126	85
50	0.42	1.06	60	0.32	0.8	90	0.04	0.1	108

DIFFERENTIATION OF SLOWLY VARYING SIGNALS

S. N. Diligenskii

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 4, pp. 513-524, April, 1960
Original article submitted August 31, 1959

The paper considers methods of differentiating slowly varying electrical signals with respect to time, taking into account the nonlinearities inherent in actual devices, as well as methods of replacing the differentiation operation by a determination of the increments of the input quantity during fixed intervals of time.

Posing of the Problem

In the present work we consider methods for differentiating slowly varying signals with spectra from zero up to several cps. In such a frequency spectrum the signal derivative will be small, and the receiving devices will have finite sensitivities. Therefore, the differentiator must provide amplification of the signal derivative. On the other hand, for slowly varying signals, the inertia of the differentiator itself has a lower value.

It is convenient to open the investigation of possibilities of differentiating slowly varying signals by comparing the frequency characteristics of the corresponding differentiating device with the frequency characteristics of an ideal differentiator

$$\Phi_{id}(j\Omega) = T_{d.id}\, j\Omega,$$

where $T_{d.id}$ is the derivative coefficient (time constant) of the ideal differentiator and Ω is circular frequency.

On the basis of such a comparison one can establish, for the real differentiator, a working range of frequency characteristic in which its distortion will not exceed some established quantity. We adopt the convention in this work that the difference of the phase frequency characteristics of the ideal and the real differentiators $\Delta\varphi$ shall not exceed 20°, and that the ratio of the ordinates of the amplitude frequency characteristics lie within the limits of 0.8 to 1.2. The derivative coefficient T_d of the real differentiator is bounded. Therefore, in addition to the working range of the frequency characteristic, the magnitude of T_d for the given differentiator is determined.

All differentiating devices can be divided into two types: differentiators in which the operation of differentiation is modeled (analog differentiators) and differentiators in which the operation of differentiation is replaced by the determination of the increment of the input quantity during finite intervals of time (we agree to call such devices discrete differentiators). For the differentiation of slowly varying signals, discrete differentiators turn out to be competitive with analog differentiators.

Analog Differentiators

In this section we shall consider two basic types of electronic differentiators, designed for the differentiation of dc signals, and an electric differentiator in the form of a servosystem with proportional velocity control. The basic elements of electronic dc differentiators are RC circuits[*] and amplifiers. After determining the working range of the frequency characteristics in the linear treatment of these differentiators, one must take into account the effect of nonlinearities in the static characteristics of amplifiers and motors on the corresponding frequency characteristics.

Differentiation of ac signal envelopes by means of passive circuits is, due to large errors, efficacious only for rapidly varying signals (cf., for example, [1]).

A. Differentiator in the Form of a Differentiating RC Circuit with an Amplifier Connected at Its Output[†]

The transfer function of an inherently differentiating circuit with account taken of the impedance of the leakage condenser[‡] is written in the form

$$\frac{\bar{U}_{out}(p)}{\bar{U}_{in}(p)} = \frac{Tp + R/R_{le}}{Tp + 1 + R/R_{le}}, \tag{1}$$

where T = RC is the time constant (coinciding with the derivative coefficient when the amplifier is not connected in), R/R_{le} is the ratio of the circuit's active impedance to the impedance of the leakage condenser, $\bar{U}_{in}(p)$ and $\bar{U}_{out}(p)$ are the transforms of the input and output voltages, respectively.

In Fig. 1 there are constructed the relative amplitude and the phase frequency characteristics. The upper boundary of the working range of the frequency characteristics is due to the presence in (1) of the aperiodic link (in accordance with the conditions adopted earlier for the phase frequency characteristic, $(\Omega T)_{max} = 1$). The lower boundary of the working range is due to the static term in the ampli-

---

[*] In differentiating slowly varying signals, an RC circuit is more convenient than an RL circuit since, by means of an RC circuit, one can easily obtain a larger time constant for a lower sensitivity to noise.

[†] An RC differentiator is described, for example, in [2].

[‡] To increase the time constant one uses a condenser with a large capacity, in which the leakage impedance can be commensurable with R.

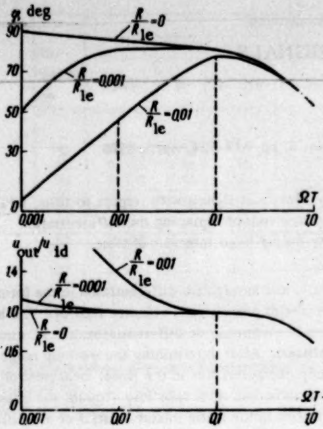

Fig. 1. Phase frequency and relative amplitude frequency characteristics of a differentiating RC link.

fier's transfer function. With this, the magnitude of $(\Omega T)_{min}$, as is clear from the phase frequency characteristics constructed for various R/R_{le}, decreases proportionately to the decrease in R/R_{le}. However, for each type of condenser there exists an absolute magnitude of Ω_{min} which depends only on the coefficient of impedance of the leakage condenser $k_{le} = R_{le}C$.

By substituting $C = k_{le}/R_{le}$ in (1) we obtain

$$\frac{\overline{U}_{out}(p)}{\overline{U}_{in}(p)} = \frac{R/R_{le}(k_{le}p+1)}{R/R_{le}k_{le}p+1+R/R_{le}}. \tag{2}$$

It is clear from (2) that, for low frequencies, the effect of the static term on the transfer function depends only on the magnitude of k_{le}. For example, for $\Delta\varphi = 20°$ and $k_{le} = 3000$ μf·meg, $\Omega_{min} = 0.001$ cps.

It is clear from (1) that the differentiating circuit's time constant coincides with the derivative coefficient. To increase this latter, we connect an amplifier to the differentiating circuit's output.

If we assume that the amplifier has a linear static characteristic, then the derivative coefficient is increased by a factor of $\underline{k}$, where $\underline{k}$ is the amplifier's gain**.

The size of $\underline{k}$ is limited by the increase, at the amplifier's output, of parasitic signals due to internal noise, and also by the decrease in range of variation of the input signal corresponding to the linear portion of the amplifier's static characteristic.

The effect of internal noise on the working range of the frequency characteristic can be estimated by the ratio y_p of the parasitic signal u_p††, as a fraction of the input signal, to the maximum value of the useful signal during one period (for $u_{in}(t) = B \sin \Omega t$):

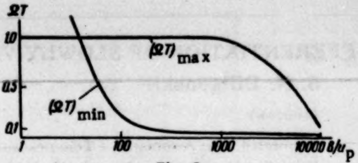

Fig. 2.

$$y_p = \frac{u_p}{B}\frac{1}{\Omega T}. \tag{3}$$

where B is the amplitude of the input signal.

On the other hand, for operation on the linear portion of the amplifier's static characteristic, it is necessary that the following inequality hold for $u_{in.1}$

$$B\Omega T \leqslant u_{in.1}. \tag{4}$$

The aforementioned peculiarities of amplifier operatio will not affect differentiator operation if, in the given frequency range, as B varies within given limits, y_p remains much less than unity and satisfies (4). Figure 2 shows the graphs constructed for $(\Omega T)_{min} = f_I(B/u_p)$ and $(\Omega T)_{max} = f_I(B/u_p)$ for $y_p = 0.05$ and $u_{in.1}/u_{lp} = 1000$ (for k = 1000). It is clear from these graphs that, because of the limitation on the magnitude of $(\Omega T)_{min}$ and the limits of variation of the input signal's amplitude, one can increase the derivative coefficient only by a factor of 1000.

B. Differentiator in the Form of an Amplifier with Aperiodic Feedback

This differentiating device consists of an amplifier, shunted by an aperiodic feedback path, and a subtraction block in which the input signal is subtracted from the amplifier's output signal (Fig. 3). The subtraction block is included so as to eliminate dc components from the amplifier's output signal. If the amplifier's characteristics

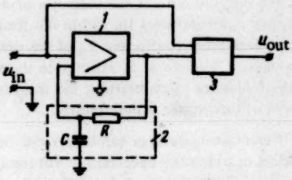

Fig. 3. Block schematic of a differentiator in the form of an amplifier with aperiodic feedback. 1 is the amplifier, 2 is the aperiodic feedback link, and 3 is the subtraction block.

**It is assumed that the amplifier's input impedance is much greater than the RC circuit's output impedance.

†† We understand by u_p an averaged value of the parasitic signal, the magnitude of which depends on the amplifier circuit.

are assumed to be linear, then the transfer function of such a system will have the form

$$\frac{\overline{U}_{\text{out}}(p)}{\overline{U}_{\text{in}}(p)} =$$

$$= \frac{(1+k_1)k}{(k+k_1+k)}\left(\frac{T}{1+k_1}p+1\right)\frac{1}{\frac{Tp}{k+k_1+1}+1} - 1, \qquad (5)$$

where $k_1 = R/R_{\text{in.a}}$ and $R_{\text{in.a}}$ is the amplifier's input impedance.

From (5) one may show that, to eliminate the dc component from u_{out}, k and k_1 must satisfy the relationship

$$k_1 = \frac{1}{k-1}. \qquad (6)$$

By substituting k_1 from (6) in (5), we get

$$\frac{\overline{U}_{\text{out}}(p)}{\overline{U}_{\text{in}}(p)} = \frac{(k-1)^2}{k^2}\,Tp\left(\frac{Tp}{k+k/(k-1)}+1\right)^{-1} \qquad (7)$$

Figure 4 gives the amplitude and phase frequency characteristics of the system. It is clear from these graphs that, as k increases, the magnitude of $(\Omega T)_{\max}$ increases. However, in the given case, the derivative coefficient equals the time constant of the RC circuit. From the expressions $k_1 = R/R_{\text{in.a}}$, $k_1 = 1/(k-1)$, and $T = RC$ for $k \gg 1$, we can obtain

$$T \approx \frac{R_{\text{in. a}}}{k}C. \qquad (8)$$

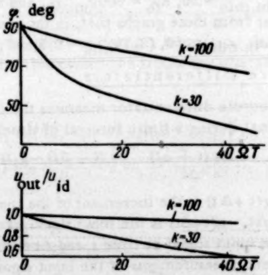

Fig. 4. Phase frequency and relative amplitude frequency characteristics of the differentiator in the form of an amplifier with aperiodic feedback.

Thus, as k increases, T decreases. This decrease can be compensated by increasing the capacity of the condenser until R_{1e} becomes commensurable with $R_{\text{in.a}}$. In practice, even for an amplifier with $R_{\text{in.a}}$ = 10 meg, for k = 100 and C = 500 μf, T = 50 sec. Thus, in a linear system there is a limitation on the size of T_p. From whence, the magnitude of $(\Omega T)_{\max}$ in practice equals 40.

In a linear system no limitation on $(\Omega T)_{\min}$ was obtained, since the dc component due to the condenser leakage was compensated here in the subtraction block. However, in practice the subtraction block has a finite accuracy in implementing the operation of subtraction. We assume that the error with this comprises 0.1% of the dc component of u_{in} ‡‡. As in the previous case, we define the ratio

$$y_s = \frac{0.001}{\Omega T}. \qquad (9)$$

If, as before, we set $y_s = 0.05$, we get that $(\Omega T)_{\min} = 0.02$.

The upper boundary of the working range does not depend on the amplitude of the input signal if $u_{\text{in,1}}/B \geq 1$, where this holds for any frequency***.

C. Servosystem with Proportional Velocity Control as a Differentiating Device

The simplified schematic of the servosystem with proportional velocity control is shown in Fig. 5a. The system consists of electronic amplifier 1, low-power motor 2 controlled by the electronic amplifier, reducer 3, and feedback position transducer 4. In a first approximation, we assume that all links of the system have linear characteristics, and that the time constants of the amplifier and motor may be neglected †††. We write the equations of such a system in the form:

$$u_{\text{m}} = k_{\text{a}}\varepsilon. \qquad (10)$$

$$v = k_{\text{m}}u_{\text{m}} \qquad (11)$$

$$v_{\text{r}} = \frac{v}{k_{\text{r}}}. \qquad (12)$$

$$\overline{U}_{\text{fb}}(p) = k_{\text{fb}}\frac{\overline{V}_{\text{r}}(p)}{p}. \qquad (13)$$

$$\varepsilon = u_{\text{in}} - u_{\text{fb}} \qquad (14)$$

where ϵ is the error signal, u_d is the voltage on the control winding, v is the motor speed prior to the reducer, v_r is the motor speed after the reducer, $\overline{V}_r(p)$ is the transform of v_r, $\overline{U}_{\text{fb}}(p)$ is the transform of the feedback position voltage, u_{in} is the input signal voltage, k_a is the amplifier gain, k_r is the reduction factor, k_{fb} is the position feedback gain, showing the change in u_{fb} for one rotation.

From (10)-(14) we obtain

$$\frac{\overline{V}(p)}{k_{\text{a}}k_{\text{m}}} = \frac{Tp}{Tp+1}\overline{U}_{\text{in}}(p), \qquad (15)$$

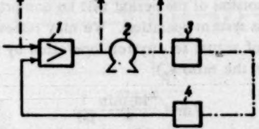

Fig. 5a.

---

‡‡ It is obvious that, for k = 100, the amplifier's background noise will be less than the error from subtraction.

*** This can be verified by defining the signal at the amplifier's input as the difference between $u_{\text{in}} = B\sin\Omega t$ and the feedback signal.

††† The permissibility of this last assumption will be explained below.

where $\bar{U}_{in}(p)$ is the transform of $u_{in}(t)$, $\bar{V}(p)$ is the transform of $v(t)$ and $T = k_r/k_a k_m k_{fb}$.

Expression (15) coincides in form with (1) for the case when $R/R_{1e} = 0$. For the measurement of slowly varying signals, as was established earlier, the value of T should be chosen large (for $R/R_{1e} = 0$). Therefore, for low-power motors, the coefficient $k_r/k_a k_m k_{fb}$ will be larger than the electrical and electromechanical time constants; the working range of frequency characteristics can be found from Fig. 1 (for $R/R_{1e} = 0$, $(\Omega T)_{min} = 0$, $(\Omega T)_{max} \approx 1$).

As the servosystem's output signal, one may use ϵ, u_m, and $\underline{v}$ (a voltage proportional to $\underline{v}$). Measurement of ϵ is equivalent to the case of a passive RC network with an ideal capacitor, while measurement of u_m and $\underline{v}$ is equivalent to the case when an amplifier is connected at the output of the RC network.

The dynamics of the actual servosystem differ from those of the linear system principally because of the nonlinearities of the static motor characteristics and free play in the reducer. It was shown in [3] that the function $v = F(u_m)$ for low-power asynchronous motors has the form

$$\frac{v}{v_{max}} = \frac{2\,\dfrac{u_m - u_{st}}{u_{m.\,max}}}{1 + \dfrac{u_m - u_{st}}{u_{m.\,max}}} \qquad (16)$$

where v_{max} is the maximum motor speed, $u_{m.max}$ is the maximum voltage on the control winding, u_{st} is the voltage corresponding to starting.

For $u_m \ll u_{m.max}$, (16) can be approximated by (11). As shown by experiments, (16) is valid as u_m varies within the limits of $u_{m.min} \leq u_m \leq u_{m.max}$. By $u_{m.min}$ we understand a quantity somewhat larger than u_{st}. The starting voltage is determined by the starting torque, which depends on the load on the motor shaft. The load torque, in its turn, depends on the friction in the bearings, which is not a strictly constant quantity. Therefore, the motor shaft can turn continuously, starting with some velocity v_{min} which we agree to call the minimum velocity of continuous rotation.

If the voltage on the motor winding lies within the limits of $u_{st} \leq u_m \leq u_{m.min}$ there then occurs a discontinuous mode of motor operation. For $u_{in} = B \sin \Omega T$, a definite portion of the period will be comprised of discontinuous system operation. We may reflect this idiosyncrasy of actual servosystem operation by the ratio y_m (similar to the ratio y_p):

$$y_m = \frac{u_{in.\,min}}{B} \frac{1}{\Omega T} \qquad (17)$$

where $u_{in.min}$ is the voltage at the amplifier input which corresponds to $v_{m.min}$; (17) is analogous in form to (3) but, in practice, $u_{in.min}$ is significantly larger than u_p.

For input signals with shallow slopes, the free play in the reducer manifests itself in the servosystem. Because of the presence of the free play, as the sign of the slope of $u_{in}(t)$ changes, the speed of the motor will not correspond to the slope of the input signal during the time that the free play is being taken up. It can be shown (cf. Appendix 1) that the ratio of the motor speed at the moment when the free play has been taken up to the maximum speed during the period (for $u_{in}(t) = B \sin \Omega t$) equals

$$y_f = 1.65 \left(\frac{m_f k_{fb}}{B}\right)^{\frac{2}{3}} \frac{1}{\sqrt[3]{\Omega T}} \qquad (18)$$

where m_f is the free play in the first stage of the reducer.

The upper limit to the working range can be given in the form of (4), where by $u_{in.1}$ we shall understand u_{in} corresponding to the boundary of approximation of nonlinear relationship (16) by the linear static characteristic of (11).

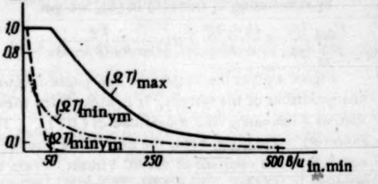

Fig. 5b.

Figure 5b shows the curves constructed for $(\Omega T)_{min}$[‡‡‡] and $(\Omega T)_{max}$ as functions of $B/u_{in.min}$ for $y_m = y_f = 0.05$, $u_{in.1}/u_{in.min} = 50$, $k_{fb} = 500 u_{in.min}$ and $m_f = 0.0001$. It is clear from these graphs that, in the range $20 \leq B/u_{in.min} \leq 50$, $(\Omega T)_{min} \approx 0.5$ and $(\Omega T)_{max} \approx 1$.

Discrete Differentiators

A discrete differentiator measures the increment of the input signal during a finite interval of time:

$$\frac{\Delta g(t + \Delta t)}{\Delta t} = \frac{g(t + \Delta t) - g(t)}{\Delta t}. \qquad (19)$$

where $\Delta g(t + \Delta t)$ is the increment of the input signal at time $t + \Delta t$, $g(t + \Delta t)$ is the input signal at time $t + \Delta t$, $g(t)$ is the input signal at time $\underline{t}$, and Δt is the time interval between measurements of the input signal.

A discrete differentiator may be constructed either on the principle of quantized input signal $g(t)$ or on the principle of quantized time. In measuring the speed of change of a slowly varying input signal, Δg will be small, so that it is more convenient in practice to use the second principle (the value of Δt can be chosen arbitrarily).

The dynamic characteristics of discrete differentiators[1] depend on the method of measuring the increments of the input signal. One can cite two basic methods of measuring Δg:

[‡‡‡] In correspondence with (17) and (18), two curves are given for $(\Omega\ T)_{min}$. For a given value of $B/u_{in.min}$, the lower boundary of the frequency characteristic corresponds to the larger ordinate.

[1] It is understood that we are speaking of discrete differentiators with quantized time.

1. Comparison of the instantaneous values of $g(t+\tau)$ and $g(t)$, where τ is a fixed interval between two measurements [cf. (19)].

In (19) we replace the continuous argument t by the discrete argument $n\tau$ (n corresponds to the moments at which Δg is measured). Then, letting $g(t) = B \sin \Omega t$, we obtain

$$\frac{\Delta g_1(n\tau+\tau)}{B\tau} = \frac{1}{\tau}\left[\sin \Omega (n+1)\tau - \sin \Omega n\tau\right]. \quad (20)$$

By transforming (20), we find that

$$\frac{\Delta g_1(n\tau+\tau)}{B\tau} = \frac{2}{\tau}\sin\frac{\Omega\tau}{2}\cos\left(\Omega n\tau+\frac{\Omega\tau}{2}\right). \quad (21)$$

Expression (21) can be considered as the system's frequency characteristic for a discrete argument. This means physically that (21) shows the difference $\Delta g_1/B\tau$ from the ideal derivative only for the moments of time $n\tau$. The relative amplitude and phase frequency characteristics are given in Fig. 6 (curve 1). As the argument of the frequency characteristics, we have here chosen $\Omega\tau$. It is clear from these graphs that the working range of relative values of $\Omega\tau$ has just the upper boundary of $(\Omega\tau)_{max} \approx 0.6$.

2. Comparison of the results of integrating the input signal over the intervals of time $[t, t+\tau]$ and $[t+\tau, t+2\tau]$, respectively:

$$\frac{\Delta g_2}{B\tau} = \frac{1}{\tau}\left[\int_{t+\tau}^{t+2\tau} g(t)\,dt - \int_{t}^{t+\tau} g(t)\,dt\right]. \quad (22)$$

As in the previous case, it is assumed that $g(t)$ varies sinusoidally. We obtain the frequency characteristic in the form

$$\frac{\Delta g_2(\varphi+2\Omega\tau)}{B\tau} = \frac{4}{\Omega\tau}\sin^2\frac{\Omega\tau}{2}\cos(\varphi+\Omega\tau), \quad (23)$$

where φ is the current value of the argument (analogous to $n\tau$ in number 1 above).

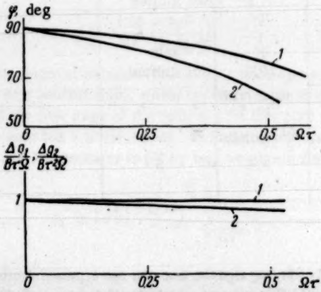

Fig. 6. Phase frequency and relative amplitude frequency characteristics of discrete differentiators. 1 is for a discrete differentiator of the first type, 2 is for a discrete differentiator of the second type.

The relative amplitude and phase frequency characteristics are given in Fig. 6 (curve 2)[2]. It is clear from them that the upper boundary of the working range has been lowered, and that $(\Omega\tau)_{max} \approx 0.45$.

It is clear from (21) and (23) that the derivative coefficient (for small $\Omega\tau$) equals, respectively, 1 and τ[3]. In the first case, T_d can be increased only by connecting an amplifier at the output of the discrete differentiator and, in the second case, at the cost of increasing τ. However, connecting an amplifier reduces the working range (cf. above), and increasing τ decreases Ω_{max} (Fig. 6). Moreover, implementing the necessary operations to determine increments on the basis of analog technology leads to large errors. For example, in the discrete differentiators described in [4-6], there will be large dc components at the output due to the nonideal nature of the elements. The transition to digital technology, as will be shown below, retains the working range of the frequency characteristics with an arbitrarily large derivative coefficient.

We consider a discrete digital differentiator. To measure the results of integrations over the interval τ, it is convenient to present the input signal $g(t)$ in the form of frequencies of trains of pulses (pulse-frequency modulation):

$$f(t) = f_0 + lg(t), \quad (24)$$

where f_0 is the minimum frequency, corresponding to $f(t) = 0$, and is the slope of the analog-digital transformation[4].

Figure 7 shows the block schematic of a discrete digital differentiator. The transformation corresponding to (24) is implemented in device 1. As a reversible counter for the differentiation of slowly varying signals, one may use the low-power pulsed step-by-step motor 2. In switching phase, the rotor of such a motor is rotated by one and the same angle $\Delta\varphi$. The use of a pulsed motor, in addition to simplifying the counter scheme, permits the implementation of a digital-analog transformation by means of inductive transducer 3. The intervals of addition and subtraction are given by synchronous motor 4. The control scheme in 5 provides: a) switching of motor phase

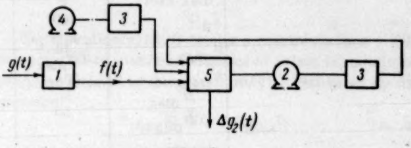

Fig. 7.

---

[2] In Fig. 6, the relative amplitude frequency characteristic was constructed in the dimensionless units $\Delta g_2/B\tau^2\Omega$ instead of $\Delta g_2/B\tau\Omega$.

[3] One can convince oneself of this by expanding $\sin(\Omega\tau/2)$ in a series and retaining just the first term of the expansion.

[4] Such a transformation can be implemented either by means of a special device or by the use of transducers with digital outputs.

with frequency $f(t)$; b) reversal of the direction of phase switching upon transition from addition to subtraction; c) transmission to the differentiator's output of the measured increment of the input signal; d) reset of the system to its initial state.

We now consider what the conditions are which must be satisfied by the digital differentiator's parameters in order to provide the necessary working range of the frequency characteristic (Ω_{min} to Ω_{max}).

The integration time τ can be found, for a given upper boundary of the working range of the frequency characteristic, from the phase frequency characteristic of an ideal discrete differentiator in which $(\Omega\tau)_{max}$ equals 0.45 (Fig. 6, curve 2):

$$\tau = \frac{0.45}{\Omega_{max}}. \qquad (25)$$

In a digital system, Δg will be expressed in the form of some number m of pulses. The general expression for m, as well as the expressions for m_{min} and m_{max} for a given frequency Ω and amplitude B in the case of a sinusoidal input signal, are derived in Appendix 2. The quantity m_{min} characterizes the minimum accuracy in measuring Δg over one period of signal variation. By considering m_{min} to be a given quantity, we obtain from (A.10), after substituting the value of τ from (25), $\Omega = \Omega_{min}$ and $B = B_{min}$, the expression for

$$l = \frac{8m_{min}}{B_{min}}\Omega_{max}\left(\frac{\Omega_{max}}{\Omega_{min}}\right)^2. \qquad (26)$$

With this, the maximum number of pulses necessary to make the transformation from digital form to analog will equal, on the basis of (A.11), $m_{max} = (2B_{max}/B_{min}) \times m_{min}(\Omega_{max}/\Omega_{min})^2$.

Finally, by taking into account the optimal relationship between f_0 and IB(cf., Appendix 2), we find from (A.12) the expression for the maximum capacity of the counter:

$$n_{max} = \frac{8B_{max}}{B_{min}}m_{min}\left(\frac{\Omega_{max}}{\Omega_{min}}\right)^2.$$

Of all the parameters of the digital differentiator, it is the quantity m_{max} which may be limited in practice since, with increasing m_{max} for a given type of digital differentiator, there is a decrease in the magnitude of $\Delta\varphi$ which, in practice, has a lower limit. Therefore, for given m_{min} and m_{max}, a digital differentiator has a bounded working range. For example, $\Omega_{max}/\Omega_{min} = 22$ for $m_{min} = 3$, $m_{max} = 10{,}000$ and $B_{max}/B_{min} = 5$.

In contradistinction to the second type of discrete differentiator which was considered earlier, in the given digital differentiator T_d depends, not only on τ, but also on the proportionality factor between the angle of rotation of the transducer's shaft and the change in voltage at the output of the induction transducer. Here, the proportionality factor does not depend on the working range, and T_d may in fact be made as large as desired.

Comparison of Dynamic Characteristics of Differentiating Devices

The results of a comparison of the three types of analog differentiating devices and the digital discrete differentiator are presented in the following table

	RC network plus ampl.	Ampl. with aperiodic feedback:	Servo system	Digital differentiator
Ω_{min} 1/sec	0,001	0.001	$\frac{0.4}{T}$	Not limited
Ω_{max} 1/sec	$\frac{1}{T}$	0.8	$\frac{1}{T}$	20 Ω_{min}
T_d/T	1000	100	1000	Not limited
B_{max}	$\frac{u_{in.1}}{\Omega T_{max}}$	$u_{in.1}$	$u_{in.1}$	" "
B_{min}	$20u_p$	$20\ u_p$	$20\ u_{in.min}$	" "
$\frac{B_{max}}{B_{min}}$	50	50	2.5	5

It is clear from the table that only the servosystem and discrete digital type differentiators have no limit on the smallness of the quantity Ω_{min}. In the digital differentiator, moreover, the derivative coefficient can be made arbitrarily large. The sole superior feature of the analog differentiator is its greater simplicity vis-a-vis the digital system. However, for the differentiation of slowly varying signals, one can use a pulsed motor in the digital differentiator, which significantly simplifies the entire system.

Summary

Analog differentiating devices with large working ranges (an amplifier at the output of an RC network, or an amplifier with aperiodic feedback) have a limited magnitude of Ω_{min} and of the derivative coefficient. In an electromagnetic differentiator, the quantity Ω_{min} can be made arbitrarily small, and $\Omega_{max}/\Omega_{min}$ can be made less than in electronic differentiators, but the derivative coefficient is of the same order of magnitude.

It is advantageous to construct discrete differentiators in the form of digital systems. A digital differentiator permits one to have an arbitrarily small value of Ω_{min} and an arbitrarily large derivative coefficient.

Appendix 1

For simplicity of computation, we assume that the motor characteristic $v = F(u_m)$ is linear. The free play in the reducer manifests itself when the sign of the input signal's slope changes. We now determine the motor speed at the moment when the free play has all been taken up, given a sinusoidal input signal:

$$v_f = k_a k_m B(1 - \cos \Omega t_f) \approx k_a k_m B \frac{\Omega_f^2 t_f^2}{2}, \qquad (A.1)$$

where v_f is the motor speed at the moment when the free play has all been taken up. Knowing the shaft rotation angle φ_f corresponding to taking up of the free play for a given reducer transfer number, we can, by integrating (A.1) and solving the resulting equation for t_f, determine this quantity in the form

$$t_f = \sqrt[3]{\frac{6\varphi_f}{k_y k_f B\Omega^2}}. \qquad (A.2)$$

By substituting (2) in (1), we find the expression for v_f in terms of φ_f:

$$v_f = k_a k_m B \cdot 1{,}65 \left(\frac{\varphi_f \Omega}{k_y k_m B}\right)^{\frac{2}{3}} \qquad (A.3)$$

We now find the ratio of the maximum speed during one period at a given frequency to the velocity v_f:

$$y_f = \frac{1.65}{\Omega T}\left(\frac{\varphi_f \Omega}{k_a k_m B}\right)^{\frac{2}{3}} \qquad (A.4)$$

The angle of rotation for free play take-up can be presented as a product $m_f k_r$, where m_f corresponds to the free play in the first stage of the reducer (the free play in the other stages has a lower value). By multiplying the numerator and denominator in (4) by k_{fb}, we obtain finally

$$y_f = 1.65\left(\frac{m_f k_{fb}}{B}\right)^{\frac{2}{3}} \frac{1}{\sqrt[3]{\Omega T}}. \qquad (A.5)$$

Appendix 2

The length of the period between two neighboring pulses for a sinusoidal input signal with arbitrary initial phase $\varphi\,[g(t) = B\sin(\Omega t + \varphi)]$ is defined by the equation

$$\int_0^{T_i} [f_0 + lB\sin(\Omega t + \varphi)]\,dt = 1, \qquad (A.6)$$

where T_i is the length of the ith period.

By integrating (A.6) we get

$$f_0 T_i - \frac{lB}{\Omega}\cos(\Omega T_i + \varphi) + \frac{l}{\Omega}\cos\varphi = 1.$$

We now find the expression defining the number $\underline{n}$ of accumulated pulses during the interval $[\varphi, \varphi + \tau]$:

$$f_0 T_1 - \frac{lB}{\Omega}\cos(\Omega T_1 + \varphi) + \frac{lB}{\Omega}\cos\varphi = 1,$$

$$f_0 T_2 - \frac{lB}{\Omega}\cos(\Omega T_1 + \Omega T_2 + \varphi) + \frac{lB}{\Omega}\cos(\varphi + \Omega T_1) = 1, \qquad (A.7)$$

. . . .

$$f_0 T_n - \frac{lB}{\Omega}\cos(\Omega T_1 + \ldots + \Omega T_n + \varphi)$$

$$+ \frac{lB}{\Omega}\cos(\varphi + \Omega T_1 + \ldots + \Omega T_{n-1}) = 1,$$

$$f_0 \sum_i^n T_i - \frac{lB}{\Omega}\cos\left(\Omega\sum_i^n T_i + \varphi\right) + \frac{lB}{\Omega}\cos\varphi = n,$$

$$f_0 \tau - \frac{lB}{\Omega}\cos(\Omega\tau + \varphi) + \frac{lB}{\Omega}\cos\varphi = n.$$

One may show analogously that, during the interval $[\varphi + \tau, \varphi + 2\tau]$, there will, in the general case, be accumulated $(n + m)$ pulses:

$$f_0 \tau - \frac{lB}{\Omega}\cos(2\Omega\tau + \varphi) + \frac{lB}{\Omega}\cos(\varphi + \Omega\tau) = n + m. \qquad (A.8)$$

By subtracting (A.7) from (A.8), we get

$$m = \frac{lB}{\Omega}\,[2\cos(\Omega\tau + \varphi) - \cos(2\Omega\tau + \varphi) - \cos\varphi]. \qquad (A.9)$$

For $\varphi = 3\pi/2$, the number $\underline{m}$ is a minimum:

$$m_{min} = \frac{4lB}{\Omega}\sin^2\frac{\Omega\tau}{2}\sin\Omega\tau \approx lB\tau(\Omega\tau)^2. \qquad (A.10)$$

For $\varphi = \pi$, $\underline{m}$ is maximum. The approximate maximum value of $\underline{m}$ is

$$m_{max} \approx lB\tau(\Omega\tau). \qquad (A.11)$$

Correspondingly, (A.7) attains a maximum for $\varphi = \pi/2$. The approximate maximum number of pulses accumulated during one interval of integration may be estimated by the expression

$$n_{max} \approx \tau(f_0 + B_{max} l). \qquad (A.12)$$

The counter will be used optimally if, for a given $\underline{n}$, the quantity m_{min} is maximal. It can be shown that the ratio m_{min}/n, found from (A.10) and (A.7), will be maximal as $lB/f_0 \to 1$.

CHOICE OF FREQUENCY RANGE FOR INDUSTRIAL PULSE-FREQUENCY TELEMETRY SYSTEM DEVICES

A. M. Pshenichnikov

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 4, pp. 525-529, April, 1960
Original article submitted November 17, 1959

The paper considers the effect of frequency range of pulse-frequency telemetry system devices on the errors and noise resistance of transmission, speed of action, and receiver dynamics.

The following factors influence the choice of frequency range of pulse-frequency telemetry system devices:

1) telemetry error as a function of frequency range;

2) noise resistance of signal transmission along the communications channel, and the effect of noise from the 50 cps power supply;

3) indicating instrument dynamics and speed of system action;

4) bandwidth of the secondary channel.

1. Telemetry Error as a Function of Frequency Range

As a function of the ratio of the frequencies which correspond to zero value and to the nominal value of the measured parameter, the error α in transforming this parameter to a proportional frequency in the transmitter gives rise to the telemetry error [1]

$$\alpha_{te} = \frac{\alpha}{1 - f_0/f_N}. \quad (1)$$

where f_0 and f_N are the frequencies corresponding to the zero value and to the nominal value, respectively, of the parameter being measured.

Analogously, the error β arising in the receiver when the frequency is transformed to a proportional current gives rise to the error

$$\beta_{te} = \frac{\beta}{1 - f_0/f_N}. \quad (2)$$

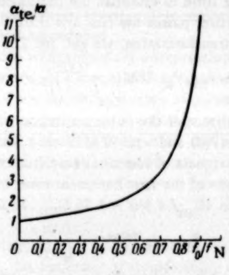
The ratio of the errors is

$$\frac{\alpha_{te}}{\alpha} = \frac{\beta_{te}}{\beta} = \frac{1}{1 - f_0/f_N}. \quad (3)$$

The figure shows the relationship of the ratio of errors, α_{te}/α or β_{te}/β, to f_0/f_N. As is obvious from (3) and from the graphs on the figure, the telemetering error decreases as the ratio f_0/f_N decreases.

2. Noise Resistance of Signal Transmission along the Communications Channel and the Effect of Noise from the 50 cps Power Supply

With weak fluctuation noise, the error is determined by the distortion of the pulse edges of the transmitted signals. This error, as a rule, is a very small quantity.



Dependence of the ratio of the telemetering errors to the ratio of the frequencies corresponding to the zero value and to the nominal value of the parameter being measured.

An analysis of the noise resistance of telemetry signal transmission along a channel with weak fluctuation noise, based on the theory of potential noise resistance, was made by V. A. Kashirin and G. A. Shastova [2]. However, in considering pulse-frequency modulation with a constant mark-space ratio PFM II, the authors of [2] analyzed the transmission of triangular pulses with amplitude $2U_m$. The transmission of triangular pulses negates all the advantages of PFM II, and does not correspond to actual conditions.

The noise resistance of PFM II to fluctuation noise can be determined by expanding rectangular pulses in a Fourier series. The pulse frequency in PFM II can be presented in the following manner as a function of the measured parameter λ:

$$f(\lambda) = f_i + \frac{\Delta f}{2}\lambda, \quad (4)$$

where f_i is the mean pulse frequency, and $\Delta f/2 = (f_N - f_0)/2$ is the frequency deviation.

The expression for a rectangular signal of amplitude $2U_m$, after expansion in a Fourier series, can be written in the form

$$A(\lambda, t) = U_m + \frac{4U_m}{\pi}\left[\sin 2\pi\left(f_1 + \frac{\Delta f}{2}\lambda\right)t + \right. \tag{5}$$

$$\left. + \frac{1}{3}\sin 6\pi\left(f_1 + \frac{\Delta f}{2}\lambda\right)t + \dots\right].$$

The mean square error in transmitting the parameter λ_0 due to fluctuation noise is defined by the expression [2]

$$\delta_{\text{me. sq}}(\lambda) = \frac{\sigma}{2\sqrt{2}\sqrt{\int\limits_0^T \left[\frac{\partial A(\lambda, t)}{\partial\lambda}\right]^2_{\lambda=\lambda_0} dt}}, \tag{6}$$

where σ is the specific intensity of the noise in $v(\text{cps})^{1/2}$ and T is the time to establish the indication.

If the filter passes the first and third harmonics then, after some transformation, we get, for $T \gg 2\pi/f_1$,

$$\delta_{\text{me. sq}}\,\text{PFM} = \frac{0.186\,\sigma}{U_m \Delta f T^{3/2}}. \tag{7}$$

Comparisons of the noise resistance with frequency modulation (FM) and with PFM II must necessarily be carried out for signals of identical amplitudes. With this, the amplitude of the first harmonic must be considered equal, not to $4U_m/\pi$ but $\sim 1.15\ U_m$. In this case,

$$\delta_{\text{me. sq}}\,\text{PFM} = \frac{0.22\,\sigma}{U_m \Delta f T^{3/2}}. \tag{8}$$

For the same amplitude, the error with FM is (cf., [2])

$$\delta_{\text{me. sq}}\,\text{FM} = \frac{0.28\,\sigma}{U_m \Delta f T^{3/2}}. \tag{9}$$

Consequently, if the use of filters provides transmission of the first and third harmonics, with PFM II, then with this the mean square error from fluctuation noise will be less than with FM with filters of the same passband. Low-frequency pulse-frequency systems for transmitting first and third harmonics require the same (and sometimes a smaller) frequency range than the existing frequency telemetry systems.

N. V. Pozin [3] carried out a determination of the error with PFM due to the relatively strong noise when the basic signal distortions are due to the breakdown into pulses and pauses, formulas being derived for approximate determinations of the mean and the mean square errors as functions of the probability of a unit distortion, the filter passband $2F_{pb}$, the frequencies corresponding to the zero and nominal values of the measured parameter, and the establishment time of the indicating instrument:

$$\delta_{\text{me}} = \frac{2P}{\Delta f^2}\left[\left(\frac{F_{pb}}{2} - f_0\right)^2 - \left(f_N - \frac{F_{pb}}{2}\right)^2\right], \tag{10}$$

$$\delta_{\text{me. sq}} = \sqrt{\frac{2P}{T\Delta f^3}\left[\left(\frac{F_{pb}}{2} - f_0\right)^2 - \left(f_N - \frac{F_{pb}}{2}\right)^2\right]}, \tag{11}$$

where P is the probability of unit distortion.

The minus sign between the parenthetical expressions in (10) and (11) is due to the fact that, with PFM II, the subcarrier frequency filter must pass at least the third harmonic and, consequently, $F_{pb} \geq 3 f_N$. This latter determines the choice of the frequency range for PFM II. Otherwise, the probability of unit distortion would not be the same for all pulse durations, as was assumed [3] in the derivation of (10) and (11).

The table gives the results of computing δ_{me} and $\delta_{\text{me.sq}}$ for the telemetry devices of the pulse-frequency devices of TsLEM Mosenergo, IAT AN SSSR and TsNIIKA for operation with filters of passbands of 40 cps (developed by IAT AN SSSR), 80 and 140 cps (telegraph filters), starting from the assumption that the formulas for determining δ_{me} and $\delta_{\text{me.sq}}$, to a first approximation, reproduce the state of affairs when the transition is made from PFM II to FM [3].

In the table, P_{40}, P_{80}, and P_{140} denote, respectively, the probability of unit signal distortion for filter passbands of 40, 80, and 140 cps, with identical signal voltages in all cases.

It is clear from the tabulated data that, for the standard telegraph filters, the very best frequency range of those considered is the range from 4 to 20 cps.

In addition to the considerations already mentioned, the noise from the 50 cps power supply (line) has an effect on the choice of frequency range for the devices of frequency and pulse-frequency telemetry systems. The presence of the frequencies of 25, 50, and 100 cps in the frequency range leads to a strengthening of the effect of noise from the power supply on the operation of the receiving device in the neighborhood of the points cited. In the transmission of the telemetered quantity at a frequency of 25 cps there appears, at the receiving side after some nonlinear transformations, a component of the first harmonic of the industrial frequency (50 cps) which is essentially influenced by the power supply.

Since it is desirable to have the ratio f_0/f_N as low as possible, so as to provide accuracy of transmission, one should choose, for the devices of pulse-frequency telemetry systems, a nominal frequency less than 25 cps. If one takes into account the possible oscillations of the line frequency (under trouble conditions, the frequency in energy systems falls to 46 cps) and the fact that, in using standard telegraph filters with 140 cps pass bands, it is desirable to transmit the third harmonic, then one should take, as the very best nominal frequency, one approximately equal to 20 cps.

3. Dynamics of the Indicating Instrument and the System's Speed of Action

The least (zero) frequency of teletransmission is determined by the highest frequency of variation of the measured parameter, F_m, and, for analog reception, by the indicating instrument dynamics. Since industrial telemetry devices are used, basically, for the measurement of relatively slowly flowing processes, the condition

$$f_0 \geqslant 2F_m, \tag{12}$$

Error	Filter pass-band, cps	Frequency range		
		$f_0=1$ cps $f_N=10$ cps (TsLEM Morénergo) $T=4$ sec	$f_0=5$ cps $f_N=15$ cps (IAT AN SSSR) $T=4$ sec	$f_0=4$ cps, $f_N=20$ cps (TsNIIKA) $T=4$ sec
δ_{me}	40	$2\,P^{40}$	P_{40}	$1.06\,P_{40}$
$\delta_{me.\,sq.}$	40	$0.235\sqrt{P_{40}}$	$0.16\sqrt{P_{40}}$	$0.13\sqrt{P_{40}}$
δ_{me}	80	$6.5\,P_{80}$	$4\,P_{80}$	$2\,P_{80}$
$\delta_{me.\,sq}$	80	$0.424\sqrt{P_{80}}$	$0.316\sqrt{P_{80}}$	$0.177\sqrt{P_{80}}$
δ_{me}	140	$13.1\,P_{140}$	$10\,P_{140}$	$5.75\,P_{140}$
$\delta_{me.\,sq}$	140	$0.8\sqrt{P_{140}}$	$0.5\sqrt{P_{140}}$	$0.27\sqrt{P_{140}}$

flowing from Kotel'nikov's theorem, is always met in practice. Thus, the zero (null) frequency is determined by the indicating instrument's dynamics.

The practical behavior of a pointer indicating electromagnetic galvanometer, measuring mean current of a condenser (or transformer) receiver, becomes completely satisfactory for frequencies at the receiver input of 4 to 5 cps (current pulses of frequencies from 8 to 10 cps flow through the instrument).

The speed of action of a telemetry device is defined as both the time to establish the frequency at the transmitter's output and as the time necessary to transform the frequency to a new indication of the indicating device (for analog reproduction) or, again, as the time necessary to translate the frequency to code (for digital reproduction). In the very fastest transmitter, the maximum time for establishing the output frequency will be when the signal changes from its nominal value to its null value. This time is defined by the formula

$$T_1 \leqslant \frac{1}{2f_0}. \qquad (13)$$

The speed of a telemetering system with analog reception is defined as the time to establish the indication of the indicating instrument and, for a frequency range of 4 to 20 cps, is about 4 seconds.

For digital reproduction, the time necessary to translate the frequencies into code is determined by the receiver error β_{te} and by the frequencies corresponding to the zero value and the nominal value of the measured parameter.

With simple pulse counting,

$$T_2 = \frac{100}{\beta_{te}\%\,(f_N - f_0)}. \qquad (14)$$

With a doubled frequency and a transformation of PFM II to PFM I (pulse-frequency modulation with constant pulse duration),

$$T_2 = \frac{50}{\beta_{te}\%\,(f_N - f_0)}. \qquad (15)$$

4. Secondary Channel Bandwidth

As was mentioned earlier, when signals are transmitted by PFM II, the subcarrier frequency filter must pass at least the third harmonic. However, it is possible to use transmitting and receiving devices of a pulse-frequency telemetry system with narrow-band filter, passing only the first harmonic of the nominal frequency. With this, teletransmission in a large part of the frequency range will be implemented, not by PFM II, but by FM. In this case, thanks to the narrow-band filters, the signal-to-noise ratio at the receiver input will be reduced.

In the devices with secondary compression used today, the narrowest secondary channel is a subchannel of an 80 cps width. Since the receiving device of pulse-frequency telemetry provides normal operation when a sinusoidal signal whose frequency is of the order of 20 cps is applied to its input, telemetry devices with such stations will operate reliably.

Summary

1. Decreasing the f_0/f_N ratio lowers the requirements placed on the accuracy of transforming dc (voltage) to frequency and on the inverse transformation of frequency to current.

2. Increasing the frequency range, f_N to f_0, for the same filter passband, first decreases the mean square error for weak and for strong noise and, second, decreases the conversion (coding) time when digital reproduction is used.

3. The highest teletransmission frequency for PFM II is determined by the noise from the 50 cps line and by the existing standard telegraph filters. For filters with a 140 cps passband, it is desirable to transmit the signal's third harmonic. The highest frequency is about 20 cps.

4. The lowest (null) frequency with analog reproduction is determined by the indicating instrument's dynamics, and is about 4 to 5 cps.

5. For a nominal teletransmission frequency of the order of 20 cps, a telemetering device can operate with the use of any telegraphic filter.

ON THE RELIABILITY OF SCHEMES FOR CONNECTING DISPERSED OBJECTS

V. A. Il'in

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 4, pp. 530-532, April, 1960
Original article submitted July 27, 1959

The paper considers the reliability of schemes for the parallel and series connection of a remote control system's executive points in a communications line. The domain of applicability for each of these schemes is shown.

In [1], the reliability of various remote control line structures for dispersed objects was considered. As a development of this work, we consider here the reliability of schemes for connecting the executive points in communications lines. The choice of some connection scheme or another determines, to a significant degree, the structure, and significantly affects the structural reliability, of remote control systems with dispersed objects (oil and gas industries, pipelines, irrigation systems, transportation, mines and factories, cities' communal economies, etc.). To a certain extent, this also applies to automated systems.

Figures 1, 2, and 3 show schemes for parallel, series, and mixed connections of a group of $\underline{m}$ dispersed executive points (EP) to a common communications bus via distributive devices D which might be parts of the EP's. In a scheme of the mixed type, the individual distributive devices implement, for example, only the functions of switching devices (Fig. 3). Analogous schemes are also used for radio channels.

The executive points on Fig. 1 are connected in parallel via the distributive devices D to a common communications line which joins them to the central point (CP). In many cases, the distributive devices are executed in the form of matching transformers. The parallel connection scheme (Fig. 1) is employed in remote control systems with either frequency or temporal separation of the signals.

With series connections (Fig. 2), the communications line is divided into a chain of segments which are connected in series via the distributive devices D.

In one of the simplest remote control systems with dispersed switching [2], each distributive device contains relay contacts, connected in series in the line, and disconnecting the remaining parts of the system in one of the relay positions. When a series of selection pulses is transmitted, the "next" link is connected to the line at each cycle, and the line is "selected" successively in time.

In remote control systems with dispersed objects, if these systems operate in accordance with the scheme of Fig. 2 and are constructed of contactless elements with rectangular hysteresis loops, the distributive devices are executed in the form of transformers.

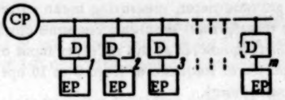

Fig. 1

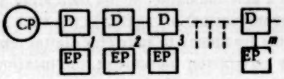

Fig. 2

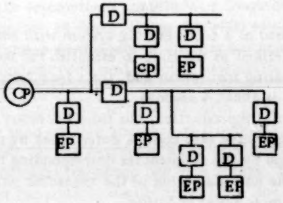

Fig. 3

With a series connection, each distributive device can also implement the function of signal amplification, similar to what takes place in radio relay lines with the same connection scheme.

We now consider the reliability of systems with parallel and with series connections of the EP's in the communications line. Such connection schemes are the fundamental ones.

We make the following assumptions.

1. All distributive devices in one and the same system (scheme) are identical. For each of them there exists a probability of a short-circuited input or output, P_{sc}, and a probability P_{opc} of an opened circuit, for example, from

a winding blowout. The probabilities P_{sc} and P_{opc} for a given EP are mutually independent, and do not depend on the probabilities of short circuits or open circuits of the other EP's.

The probabilities P_{sc} and P_{opc} of a nonoperative state of a given distributive device are related to the mean frequencies of failure due to short circuits f_{sc} and due to open circuits f_{opc} by the following expressions:

$$\bar{f}_{sc} = \frac{P_{sc}}{\bar{T}_{sc}} \text{ and } \bar{f}_{opc} = \frac{P_{opc}}{\bar{T}_{opc}}.$$

Here, $\bar{T}_{sc}$ and $\bar{T}_{opc}$ are the mean nonoperating times of a given distributive device due, respectively, to short circuits and to open circuits during the period of time between maintenance cycles;

$$\bar{T}_{sc} = \frac{1}{n} \lim_{n \to \infty} \sum_{i=1}^{n} T_{i\,sc}, \quad \bar{T}_{opc} = \frac{1}{n} \lim_{n \to \infty} \sum_{i=1}^{n} T_{i\,opc}$$

where n is the number of faults (failures).

2. The communications line itself is considered to be absolutely reliable. Such an assumption simplifies the analysis and can not change the character of the results in any essential way since, when account is taken of the probabilities of short circuits and open circuits in identical links of the line, there is only an increase in the corresponding P_{sc} and P_{opc}.

Then, for schemes with parallel and with series connections, the probability of system failure due to short circuiting of the distributive devices to ground or to the second conductor in a two-conductor line, without taking account of failures due to open circuits, will be expressed by the formula

$$P = 1 - (1 - P_{sc})^m$$

For $mP_{sc} \ll 1$,

$$P \approx mP_{sc}.$$

The probability of a nonoperative state of an object in a system due to open circuits in the distributive devices when parallel connections are employed (Fig. 1) is $P = P_{opc}$, since the open circuiting of any distributive device disrupts the operation only of the EP connected to it.

For a scheme with series connections (Fig. 2), the mean probability of a nonoperative state of an object in the system due to open circuits in the distributive devices, without account being taken of faults due to short circuits, will be

$$P = 1 - \frac{1}{m} \sum_{i=1}^{m} (1 - P_{opc})^{n_i},$$

where n_i is the number of objects connected between the CP and the ith distributive device ($n_1 = 1$) and, for $mP_{opc} \ll 1$, will be

$$P = \frac{m+1}{2} P_{opc}.$$

If an open circuit in a distributive device disrupts only the operation of the EP connected to it in a parallel-connected scheme, the same open circuit in a series-connected scheme will cause failure of an average of $(m+1)/2$ EP's.

It also follows from the expressions obtained that the probabilities of an object's nonoperative state due to a short circuit in a distributive device in systems with parallel and with series connections are equal to each other when the probabilities of short-circuited distributive devices are equal. However, in a parallel-connected scheme, the probability of a nonoperative state of the system due to a short circuit in the distributive devices or in the EP's can be decreased to an arbitrarily small quantity by connecting the EP's to the line via cutouts or limiters similarly to what is done in connecting electric energy users to a power line, or radio relay points to a radio relay network.

For frequency systems of remote control, and for systems which use exponential transformers [3] for the time separation of signals, the EP apparatus is comparatively simple in parallel-connected schemes.

If existing systems of remote control with time separation of signals are connected in accordance with the scheme of Fig. 1, it is necessary to have, at each EP, a one-terminal set (incomplete in many cases) which is frequently unreasonable (for a small number of signals on one EP).

The series-connected scheme can be realized in remote control systems with time separation of signals with contact distributed switches [2] or in contactless systems with elements with rectangular hysteresis loops.

Such systems, even when constructed from contactless elements, have significantly less structural reliability, as our analysis shows.

Frequency systems of remote control can also be constructed in accordance with the series-connected scheme (Fig. 2), but this is unreasonable, in connection with the lower structural reliability of such systems.

The use of series-connected schemes, from the point of view of reliability, may be justified principally in those cases when it is necessary to amplify signals at given points of the line, or it is necessary to switch groups of EP's in communications lines with tree structures, if the solution of such problems gives rise to difficulties when parallel-connected schemes are used.

ON THE QUESTION OF RELAY-CONTACT DEVICE RELIABILITY

K. P. Kurdyukov

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 4, pp. 533-541, April, 1960
Original article submitted February 12, 1958

Methods are considered for increasing the reliability of operation of relay-contact devices by means of spare elements. A new method is suggested for sequential circuits which allows the device's reliability to be increased with the minimum number of spare relays.

In recent years the questions of reliability of electrical devices have received great attention. With this, the problem of increasing reliability is solved by two routes. The first of these is the increase of strength and durability of the elements entering into devices, the replacement of contact elements by contactless ones, for example, by semiconducting and magnetic elements, etc. The second route, independent of the first, is the wide use of stand-by elements, assemblies and blocks, i.e., the use of back-up.

In these cases, the operating parts of the apparatus or of its individual blocks, or even individual elements, are supplied with reserves which are either switched into operation automatically when the basic set fails or operate constantly in parallel with it. Such reserve elements are "redundant," since their introduction adds no new functions to the device.

As an example of the use of the back-up method of increasing reliability, one may adduce the automatic track blocking circuit of the Moscow subway in which, as is well known, a type DSR relay is connected in parallel for every two tracks.

In the engineering and scientific literature devoted to the questions of stand-by capability, one considers principally the reliability of radioelectronic apparatus, constructed from contactless elements and used in a number of special domains, for example, in computing technology, in radio relay communications, for the control of moving objects, etc. In correspondence with the purpose of such apparatus, there arises the requirement that it operate without failures during some interval of time, so that here reliability is defined as the probability that, in the course of a definite time interval, the device will correctly carry out its function.

In industrial devices for automation and remote control, one ordinarily considers a device to be sufficiently reliable if a random failure of its elements does not entail an incorrect functioning which leads to an unsafe state of the object. Operational failures in these cases are considered as "protective", and are ordinarily accompanied by either a blocking device and an alarm indication of the fault, or a transfer of the device to a safer state. Thus, for example, when a railway element fails in the automatic blocking circuit, a red light signal automatically appears, requiring that the train stop.

However, as is understandable, each such case of protective failure disrupts the continuity of the technological process. With the modern tendency to intensify production, it becomes important to increase the reliability and unceasing operation of industrial automation and remote control devices.

In the present paper we consider several questions in the construction of reliable relay-contact devices which permit a single failure to occur without disruption of operation. The principles to be considered in the sequel may be extended also to contactless devices using relay-acting (switching) elements.

The effect achieved when the ordinary method of parallel back-up [1] is used can be illustrated by the example of the simplest relay-contact circuit (Fig. 1a), whose function is to close circuit a-b when relay A1 is excited.

We denote the probability of correct closure of the relay contact by $p(A) = p$, and the probability of the event that circuit a-b will be closed by $p(a\text{-}b)$. In the given case, $p(a\text{-}b) = p$.

Connecting relay A2 in parallel to relay A1 (simple back-up) and connecting the contacts of relay A1 and A2 in parallel (Fig. 1,b) increases the probability of correct closure of circuit a-b up to the value $p(a\text{-}b) = 2p-p^2$, i.e., for $1-p \ll 1$, increases the reliability by almost one order.

Conversely, a series connection of the contacts of relays A1 and A2 (Fig. 1c) lowers the probability of closure of circuit a-b to the value $p(a\text{-}b) = p^2$.

Figure 1 d-f, also gives several variants of the simplest schemes for the two- and three-fold back-up of relay A1, and the corresponding values of the probability of closure of circuit a-b. To determine the expressions for the probabilities, it was assumed that all the relays A1, A2, A3, and A4 were monotypic, as were their contacts, that the probability of contact closure was the same for all, and that cases of incorrect operation were statistically independent.

Fig. 1.

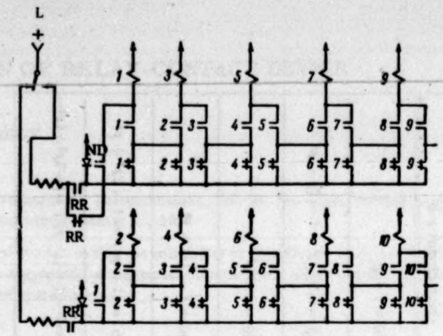

Fig. 2

As is obvious from these examples, by paralleling the corresponding number of relays (with multiple back-up) and by properly connecting their contacts in a circuit which is equivalent in its operation to the action of one contact (or any other more complicated structure), one can attain any previously given degree of reliability, even with the use of elements which are themselves of low reliability. Of course, such back-up leads to a significant increase in complexity and cost of the devices, and to a large expenditure of circuit elements.

For sequential relay-contact circuits, a more economical back-up, which may be called "combined", is possible. The essence of this back-up amounts to this, that the back-up elements, the number of which, as a rule, is less than the number of the basic elements, back each of the basic elements up at that moment (cycle) when the operation of the entire device is determined by the operation of this basic element.

We consider this new back-up method in terms of the example of a centralized control relay distributor of type DVK-3 – DVK-3a. The functional schematic of such a distributor is shown in Fig. 2, and the sequence of its actions is given in Table 1 [2]. One easily convinces oneself that a fault in any one of the counter relays 1-10, or of their contacts, causes the distributor to cease operation, as well as a fault in the action of the entire one-terminal set (and, if this one-terminal set is the central control point, the entire system fails).

We isolate, in Table 1, those cycles which would be terminal points, completing each distributor step, i.e., cycles 0,3,6,9,12,15, etc., and we write the state of the distributor at each of these cycles in the form of a binary number. We adopt the convention that an excited relay state will be denoted by a "1", an unexcited state by a "0". Table 2 gives the sequence of these binary numbers, which completely characterizes the sequence of operations of the distributor relays and which mirrors, by the corresponding binary numbers, their states at each step. Thus, for example, the fifteenth cycle of Table 1 corresponds to the binary number 000001000010 (the fifth cycle of Table 2), while the eighteenth corresponds to 000010000000.

By considering this table of binary numbers as a set defined by given combinations of relay states, and considering all the rest of the set of binary numbers which are not

written in the table as distortions of these combinations, one can try to use, for constructing self-correcting circuits, the same methods which were developed for constructing self-correcting codes, also described by binary numbers which are tabulated in analogous fashion [3,4].

It is well known that, for the construction of error-free codes, it is necessary to create redundant elements of the combinations, and thereby to achieve the result that the code combinations differ from each other by a sufficient number of bits ("distance" between combinations). Thus, to construct a code for the correction of unitary errors, it is necessary that the code combinations differ from each other by at least three bits.

We now extend these propositions to the given combination of relay states. Table 3 gives the values of the "distances" between the combinations of relay states (the binary numbers of Table 2) for the distributor of the circuit in Fig. 2, from which it is clear that, in a number of cases, this condition is not satisfied, so that it is required to introduce auxiliary elements in the combinations (relays) to provide the requisite redundancy.

The number of auxiliary relays can be determined from the well-known expression of Hamming

$$2^{n_0} \leqslant \frac{2^n}{n+1},$$

where n_0 is the number of basic relays in the circuit and n is the total number of relays, including the auxiliary ones.

The value of $m = n - n_0$, i.e., the number of auxiliary relays, can be found from the following table, set up in accordance with this formula:

$n_0 =$	1	2	3	4	5	6	7	8	9	10	11	12
$n =$	3	5	6	7	9	10	11	12	13	14	15	16
$m =$	2	3	3	3	4	4	4	4	4	4	4	4

In the case under consideration, it turns out to be sufficient to add four auxiliary relays. Connecting these relays in the over-all operation of the distributor can be implemented in various ways with the same condition that repeated combinations not occur. As is well known, the number of nonrepeating combinations with this will equal 2^n, i.e., the number of arrangements which differ from each other in at least one place. It is most convenient to construct the table of auxiliary relay operations such that, at each cycle, the minimum number of auxiliary relays, i.e., one relay, will change state. This condition is satisfied by, for example, the Gray code [5], used in a somewhat different form for constructing Table 4, giving the operation of auxiliary relays I-IV. One easily convinces oneself that, with this, the distance between the binary numbers of the combinations of relay states at different cycles of distributor operation in no case is less than three, which is the requirement imposed.

We now consider three cases of constructing self-correcting circuits for relay counters.

1. Circuits for self-correction it there appears, in a binary number characterizing an operate cycle of a given relay, a zero instead of a one (for example, if a prior counter relay did not close its contact in the same operate circuit of the given relay).

2. The same, but for the appearance of a one in the binary number instead of a zero (for example, for the sealing of a contact of the prior relay).

3. The same, but for the appearance in a binary number of a zero instead of a one, or a one instead of a zero.

In the first case, to provide for operation of the given next counter relay, its operate circuit, passing through normally open contacts of the previous counter relay, must be backed up by the contacts of that auxiliary relay which also changed its state at the previous cycle (a normally open contact if it were excited, and a normally closed contact if it were unblocked).

In the second case, protection from a false operation on an incorrect cycle due to a random closing of a contact of a previous relay is attained by introducing into the operate circuit of the given relay the contacts of three auxiliary (back-up) relays which do not change their state at the given cycle, and the combination of whose states at the given cycle differs by the state of at least one relay from

TABLE 4 Binary Numbers for Operation of the Distributor with Auxiliary Relays

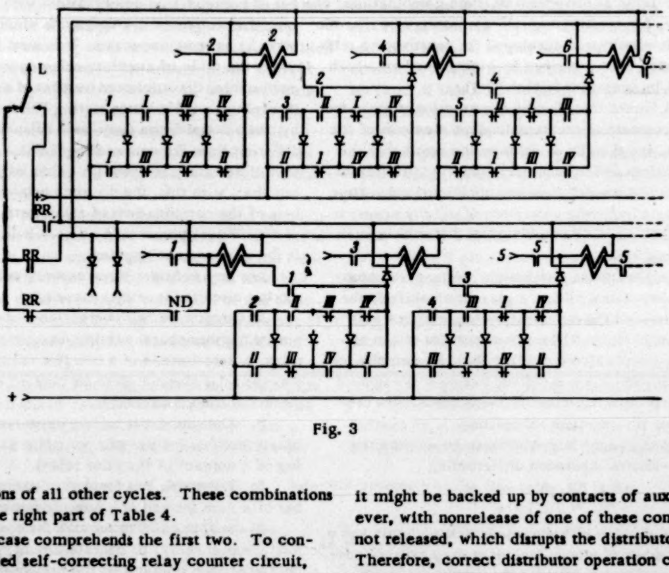

Fig. 3

the combinations of all other cycles. These combinations are given in the right part of Table 4.

The third case comprehends the first two. To construct a protected self-correcting relay counter circuit, it is necessary to create as many back-up operate circuits as there are series contacts of basic and auxiliary relays in the basic operate circuits. Certainly, the contacts of these back-up circuits can be joined by the use of diode elements, as shown in Fig. 3.

It is necessary to dwell on the cut-off relay circuits. As is clear from the scheme of Fig. 2, the blocking and cut-off circuits of the counter relays of an ordinary relay distributor are interconnected, and pass in series through inherently normally open contacts and normally closed contacts of the relay of the next higher ordinal number. For the case of nonclosure of this normally closed contact, it might be backed up by contacts of auxiliary relays. However, with nonrelease of one of these contacts, the relay is not released, which disrupts the distributor's operation. Therefore, correct distributor operation can be achieved only by separating the relays' locking and cut-off circuits, whereby the release of the relays is implemented, not by means of the supply circuit, but by counter flows in the relays' second windings (active unlocking). With this method, unlocking of a given counter relay is obtained by means of the operate circuit of the next relay of the same parity (i.e., even or odd, respectively), and may therefore be identified with it, the differentiation being only by the state of the forcing element, and the cycles on which they are used.

Figure 3 shows the circuit for connecting several of the basic counter relays of a self-correcting distributor, con-

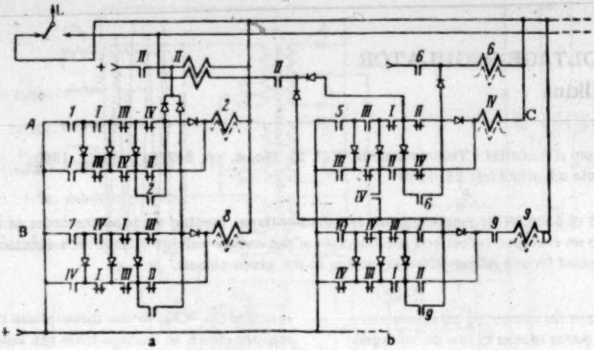

Fig. 4. a is the operate circuit of relay II, b is the release circuit of relay II; A is the operate circuit of relay 2, B is the operate circuit of relay 8, C is the operate circuit of relays 6 and IV, D is the release circuit of relay 9.

structed in accordance with Table 4 and with the conditions to be given now.

As was stated earlier, auxiliary relays I-IV are connected analogously to the basic counter relays in that, at the corresponding cycles of distributor operation, they operate or are released simultaneously with the basic relays. Since auxiliary relays I and II operate and release twice during an operate cycle of the distributor, one then uses for them the binary number of such circuits, as is shown in Fig. 4 for auxiliary relay II.

The difference in the circuits for the basic and the auxiliary relays stems from the fact that there is used, in one of the back-up circuits for operating a basic relay, a proper contact of that auxiliary relay which must also operate (or release) on the same cycle. To obtain coherent operation both of the basic and of the auxiliary relay by this back-up circuit, this circuit is so separated for the basic and the auxiliary relay that the winding of the auxiliary relay is supplied only after the basic relay has operated.

Such a relay distributor provides correct operation for any single fault, i.e., for the failure of any one element, either basic or auxiliary. The distributor's output circuit must, of course, be constructed like an operate circuit, i.e., it must be backed up.

Thus, increasing by almost an order the reliability of distributor operation is attained most economically by adding four relays only, instead of the ten necessary for parallel back-up. It should be mentioned that, according to Hamming's formula, four auxiliary relays can provide back-up for 15 basic relays.*

Using the same principle, one may construct multiple relay contact circuits in which are corrected double, triple, etc. errors, i.e., which will provide correct operation for simultaneous failures of two, three, etc. relays, at the expense of a corresponding increase in redundancy.

* This last sentence is factually (and mathematically) incorrect, as are the data of Table 3 on page 369. The maximum number of basic relays for which four auxiliary relays will suffice is not 15, but 11 [Publisher's note].

RECTIFIED VOLTAGE REGULATOR

O. G. Malkina

(Moscow)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 4, pp. 542-547, April, 1960
Original article submitted July 21, 1959

A new variation of a circuit for regulating low rectified-voltage feeding loads on the order of hundreds of watts is discussed. As an example, curves and oscillograms of the output voltage change as a function of the load change are presented for a regulator wired according to the given circuit.

The use of transistors for computing machines and other devices requires power sources of low dc voltages. These voltages may be obtained by lowering and rectifying the ac power line voltage. The use of ac sources means that filters and voltage regulators must be built. The ac source can be ether single- or three-phase.

One of the advantages of using rectified voltages from three-phase ac sources is that the ripple on the output is less; this simplifies and eases the filter requirements of the voltage regulator. The voltage regulators considered in the article are designed for loads on the order of hundreds of watts, and use saturable reactors for regulation. These regulators permit ac line voltage fluctuations of ± 5-10%, a temperature change of the surrounding medium from -30 to +50°C, and continuous control of the regulated voltage over a range of ±20-25%.

The fluctuations of the regulated voltage are less than ±0.5-1.5% for this type of regulator, and the full regulation time for a step change of load from 100% to 50% and, conversely, from 50% to 100% of the nominal value does not exceed 5-15 msec.

The circuit diagram of the regulator is shown in Fig. 1.

The regulator consists of the following basic elements:

1. Saturable reactors $\overline{Ch}_1$ - $\overline{Ch}_3$, made with an external feedback winding W_0 and one control winding W_y, shunted by the capacitance C_y in order to eliminate the effect of the inductive emf of even harmonics. The reactors can also be made with an internal feedback winding.
2. The three-phase transformer Tr (or three single-phase transformers).
3. Power rectifiers B_1-B_6.
4. The filter, consisting of choke $\overline{Ch}_f$ and capacitances C_{f_1} and C_{f_2}.
5. The meter-amplifier element which, in its turn, consists of: a) voltage divider made of resistances R_1-R_3, and R_2-R_4; b) Zener reference diodes V_{c_1} and V_{c_2}, type D809 or D810; c) rectifiers B_7-B_{10}, type D7D-D7Zh; d) junction transistors Q_1, Q_2, and Q_3 (type P4B); e) resistances R_5, R_6, and R_7, which limit the currents in the control winding and transistors Q_1 and Q_3.

The ac of the three-phase power line, at a 400 cps frequency, is connected through three single-phase saturable reactors $\overline{Ch}_1$-$\overline{Ch}_3$, to the three-phase transformer. The stepped-down ac voltage from the secondary windings of the transformer is rectified by rectifiers B_1-B_6, the variable component is filtered out by the filter ($\overline{Ch}_f$, C_{f_1} and C_{f_2}), and the resultant dc is fed to the load.

In this case, the saturable reactors operate as single-phase magnetic amplifiers, working into a variable load resistance. A simplified equivalent circuit diagram of the load windings of such an amplifier is shown in Fig. 2a.

Commercial transformers have an insignificant leakage reactance, and the quantities x_1 and x'_2 can be neglected. If the load resistance is large, it is also possible to neglect the choke resistance (r_{ch}), and primary and secondary winding resistance (r_1 and r'_2) and the core loss resistance (r_0). Therefore, the simplified equivalent circuit diagram of the load windings of the magnetic amplifier corresponds to the circuit shown in Fig. 2b, for no-load on the regulator.

The amplitude of the output voltage U_{out} will be determined, in this case, by the relation between the choke (magnetic amplifier) reactance x_{ch}, and the transformer reactance x_0. The relation chosen between x_{ch} and x_0 and the given value of the regulated voltage determine the transformation ratio of the transformer.

When the transformer is loaded, $R^1_H \ll x_0$, and the simplified equivalent circuit of the load windings of the saturable reactor corresponds to the circuit shown in Fig. 2c.

The regulation of the output voltage in this type of regulator is based on the fact that the reactance of the saturable reactor x_{ch} depends on the magnitude of the dc excitation ampere-turns.

The main excitation of the circuit is caused by the load current, that is, by the ampere-turns of the feedback winding, which has a coefficient somewhat less than unity (this coefficient can even be equal to unity). The load current is minimum at no-load, and is determined by the currents of the voltage dividers R_1+R_3 and R_2+R_4, and the resistance x_{ch} is maximum (in the circuit of Fig. 2b).

At maximum load, x_{ch} is minimum (in the circuit of Fig. 2c), and the change in x_{ch} due to load current compensates for the change in the output voltage due to the change in the voltage drop across the circuit resistance $R = r_{ch} + r_1 + r_2$.

Fig. 2. Simplified equivalent circuit diagram of the load windings of a single-phase saturable reactor at different loads.

The dc excitation of the saturable reactors is caused not only by the ampere-turns of the feedback winding W_0, but also by the ampere-turns of the control winding W_y. The latter is used to get better stabilization of the output voltage, and to control the amplitude of the regulated voltage over a range of ± 20-25%.

The direction and amplitude of the current in the control winding depend on the states of transistors Q_1 and Q_2 in the metering element.

Voltage reference diodes (B_{c_1} and B_{c_2}) are wired in the base circuit of each transistor (Q_1 and Q_2). Therefore, the circuit in the transistor base will, in practice, flow only when the voltage between the moving arm of the divider and the emitter of the given transistor (U_{e_1} or U_{e_2}) is greater than the sum voltage of the reference diode (U_{r_1} or U_{r_2}) and the rectifiers ($U_{v(7-8)}$ or $U_{v(9-10)}$). The greater the difference in the voltages mentioned, the greater the base current of the transistor will be, and the greater the collector current.

When both transistors are cut off, the circuit diagram of the control winding will be practically analogous to the circuit shown in Fig. 3a. The ampere-turns of the control winding in this case assist the excitation action of the feedback winding, and by the same token, cause additional decrease of the reactance x_{ch}.

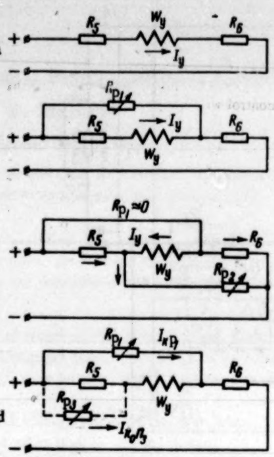

Fig. 3. Simplified equivalent-circuit diagrams of the control winding of the saturable reactor for different states of the transistors in the metering element.

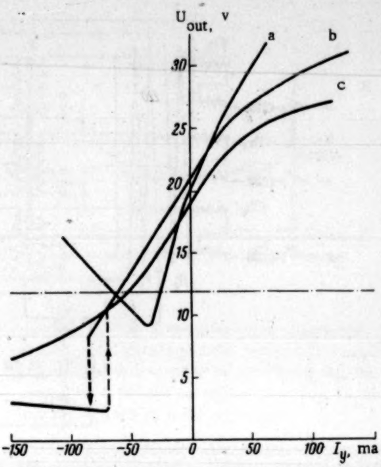

Fig. 4. Dependence of the output voltage of the regulator on the current in the control winding. a) for R_H = 30 ohms, b) 4.2 ohms, c) 1.2 ohms, d) minimum value of the regulator output voltage.

A change in the collector current of transistor Q_1 is equivalent to a change in the resistance R_{p_1}, shown in Fig. 3b. A decrease in the resistance R_{p_1}, that is, an increase in the collector current of this transistor, causes an increase in the voltage drop across resistance R_6 and a decrease of the current in the control winding.

When transistor Q_1 is fully on, the change in the collector current in transistor Q_2 is equivalent to a change in resistance R_{p_2}, shown in Fig. 3c. A decrease in resistance R_{p_2} will cause an increase of an opposing current in the control winding, and therefore these ampere-turns will cause a relative increase in the reactance x_{ch}.

The use of feedback with a coefficient approaching unity ensures an abrupt change in the reactance x_{ch}, and consequently, in the output voltage, when the current in the control winding is changed.

The change in the output voltage of the regulator as the current in the control winding is changed is shown in Fig. 4; the control winding of this regulator has been disconnected from the metering element, and connected to an independent source of dc.

It can be seen from Fig. 4 that to change the output voltage of the given regulator from 12 to 25 v across a load resistance of 30 ohms, it is sufficient to change the control current from -25 to +25 ma, and from -50 to +50 ma for small load resistances. There are 70 turns on the control winding of the reactors of the given regulator. It can also be seen from Fig. 4 that a negative control current exceeding 50 ma is not permitted in this type of regulator. In order to hold the output regulated voltage at 25 v, for example, the control current must be altered within the limits of 22 to 52 ma, and to hold this voltage at 20 v, the control current must be altered between -6 to +8 ma.

All the foregoing determines the choice of the resistances R_5 - R_7 in the metering element.

When the control winding is connected to the metering element, the output voltage is stabilized because a change in the output voltage due to a variation in the load, or power line voltage, causes the base current of a transistor to change; this, in turn, alters the control current so as to counteract the output voltage change.

In principle, it is not possible to compensate completely for the voltage deviation by changing the current in the control winding, since there must always be some voltage difference to cause a new value of the control current. However, the output voltage is maintained quite accurately due to the large amplification factor.

Some curves of the dependence of the output voltage on the load change are shown in Fig. 5 for one of the regulators of the type discussed in this paper. These dependencies are given for different ac source voltages.

The amplitude of the regulated output voltage of this type of regulator is determined by the position of the moving arms of the voltage dividers, which consist of resistances R_1, R_3, and R_2, R_4.

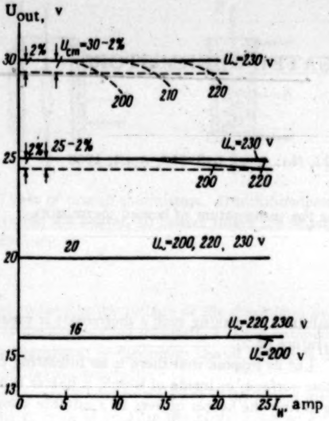

Fig. 5.

The currents in the dividers are significantly greater than the base currents of the transistors; therefore the dividers are only slightly loaded.

The voltage obeys the relation

$$U_{out} = U_{E1}\frac{R_1 + R_3}{R_{x'}},$$

for the first divider, where R_x is the resistance of the divider from point A to the moving arm.

Since the voltage U_{e_1} can be greater under regulation than the sum of the voltages $U_{r_1} + U_{V(7-8)}$ by only a very small amount, an increase in the resistance R_x (that is, a movement of the arm of the divider) will cause a decrease in the output voltage amplitude

The regulated output voltage can be lowered by moving the arm of the first divider from point A to point B, but only to a value which does not require a change in the direction of the current flow in the control winding. Further reduction of the output voltage can be realized by moving the arms of both voltage dividers. For finer control, regulation of the output voltage must be accomplished by moving the arms and the voltage dividers simultaneously, so that the resistance ratios of the dividers

$$\frac{R_1 + R_3}{R_x} \text{ and } \frac{R_2 + R_4}{R_{x_2}}$$

do not differ much.

The change in the collector currents of junction transistors due to a temperature variation leads to a decrease in the control winding current, which in turn causes a change in the output voltage of the regulator. The output voltage change will cause a corresponding variation in the base currents of the transistors, which compensates for the collector current change and practically restores the output voltage amplitude. But when the regulator is heated, the change in the collector current of the transistor due to a temperature increase must be less than the initial collector current, so that the decrease in the transistor base current can compensate for the increase in the collector current. Transistor Q_3 (Fig. 1) is used to prevent ΔI_C from being greater than the initial I_C. With no base connection, the collector current of Q_3 is minimum, and its increase depends on the temperature of the environment.

As the temperature increases, the collector current change of Q_1 leads to a decrease in the control winding current (Fig. 3d), but an increase in the collector current of Q_3, conversely, causes an increase in the control winding current. Thus, the collector current change in Q_3 in this case compensates for the change in the collector current of Q_1.

The output voltage change for a regulator wired according to the circuit discussed is shown on oscillograms (Fig. 6) for various load changes.

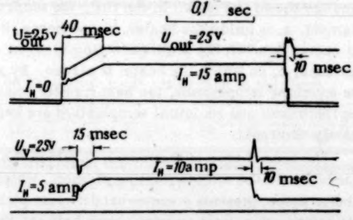

Fig. 6. a) Output voltage change for load current changes from zero to 15 amp and from 15 amp to zero, b) output voltage change for a load current change from 5 to 10 amp, and from 10 to 5 amp.

The recovery time obtained for this particular regulator is not a limit for this type of regulator.

STABILIZING THE TEMPERATURE OF HEATED THERMISTORS

G. K. Nechaev

(Kiev)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 4, pp. 548-554, April, 1960
Original article submitted October 12, 1959

An analytic method of calculating circuits for stabilizing the temperature of heated thermistors used in time delay apparatus is presented.

At present, a number of methods of obtaining time delay with electrical circuits are used. Circuits using the thermal inertia of thermistors are convenient due to their simplicity, reliability, and ability to give long time delays reaching dozens of minutes. However, these circuits are sensitive to a temperature change of the surrounding medium; this limits their use.

In order to eliminate this dependence on the external temperature, Udalov [1] proposed that heated thermistors be used, whose temperature was regulated in a simple manner by changing the current of the heater.

It must be noted that not all heated thermistors are suitable for this use. Two types of heated thermistors exist; they are shown in Fig. 1. In the first, the semiconducting element, a, is inside the heater, b, and hence, heat transfer occurs between the semiconducting element and the envelope, c, on which the heater is placed. By stabilizing the envelope temperature, the heat transfer conditions of the thermistor and its initial temperature are held approximately constant.

The second type of thermistor, in which the heater is placed inside the semiconducting element, which has a tubular shape, presents a somewhat different picture. In this construction, heat transfer occurs between the semiconducting element and the medium; a temperature change of the latter cannot be compensated for by changing the heater current with the aid of the proposed circuit. Only the temperature of the thermistor can be stabilized. Analysis shows that this condition is not sufficient to maintain the delay transient constant when a circuit with the thermistor is turned on, if the temperature of the surrounding medium changes. Consequently, the second type of thermistor will not do for the circuit being considered.

The operation of the circuit can also be made independent from the temperature of the medium by means of thermostation of the thermistor. However, this method is applicable only in those cases where the thermostat is simple in construction. A heated thermistor of the first type can be considered as a microthermostat, inside of which the temperature can be stabilized within certain limits. By analogy, it is possible to make a small-sized thermostat, and place a direct-heated thermistor in it. The possibility of making such a thermostat is mentioned in the literature [2,3].

Let us suppose that there is an insulating cylinder on whose surface, or inside of which, a heater is placed. By regulating the heater current in a suitable manner, the temperature inside the cylinder can be held constant when the medium temperature changes within certain limits. It should be noted that the temperature inside the thermostat must be higher than the temperature of the surrounding medium.

Two satisfactorily simple circuits for controlling the temperature can be proposed; these are shown in Figs. 2 and 3, in which the thermistor acts as the sensing element. In these circuits, R_T is the thermistor in the regulator circuit, $\underline{r}$ is a linear resistance, r_H is the heater resistance, R_{TC} is the semiconducting element of the heated thermistor, and r_b is the barretter. The circuit using the barretter has the advantage over the circuit of Fig. 2, in that it is independent of supply voltage fluctuations, but such a circuit requires somewhat greater power than the circuit with the linear resistance.

The circuit works in the following manner. At a low temperature of the medium, the thermistor resistance has a considerable magnitude, the current in it is small, and a large amount of power is liberated in the heater. As the temperature of the medium is raised, the current in R_T increases, and by the same token, the current in, and power liberated by the heater decrease. Consequently, it is essential to choose the parameters of the circuit so that as the temperature of the medium changes, the temperature inside the thermostat or heated thermistor will remain within given limits.

It has been experimentally established that the heat transfer between the thermistor or thermostat and the surrounding medium follows Newton's formula well within the operating temperature range

$$P = F\alpha(T_T - T_0) = H(T_T - T_0) = K(T - T_0), \tag{1}$$

where P is the power dissipated by the thermistor or thermostat into the surrounding medium, F is the area of the external surface of the thermistor or thermostat, α is the surface heat emission coefficient, H is the overall dissipation factor of the thermistor, T_T and T_0 are the temperatures of the

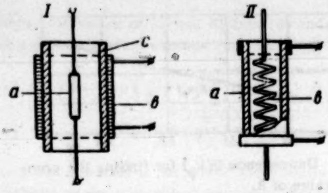

Fig. 1. Types of heated thermistors. I) semiconducting element inside the heater, II) heater inside the semiconducting element.

thermostat surface or the surface of the thermistor heater, and that of the surrounding medium, T is the temperature inside the thermostat or thermistor heater, and K is the over-all heat transfer constant.

Temperature T will be constant if the power dissipated by the resistance r_H is equal to the power emitted by the thermistor or thermostat into the surrounding medium:

$$P_H = I_H^2 r_H = K(T - T_0). \tag{2}$$

If the semiconducting or thermostated element liberates a certain power, it is considered to be a deduction from the computed value of P_H when calculations are made. In time relay circuits, the semiconducting element is ordinarily unexcited before the main circuit is turned on, and thus it is not necessary to account for this power.

Consequently, the power P_H should be a linear function of the medium temperature T_0. The proposed circuits permit one to obtain a dependence $P_H(T_0)$ which is nearly linear in the static mode. In order to have this, it is essential that the curve $P_H(T_0)$ assume values at a number of points in the temperature range which correspond to a linear dependence of $P(T_0)$, that is, so that the difference $\Delta P = P(T_0) - P_H(T_0)$ is zero at these points.

Let us take three such points, which correspond to the limits of the temperature range and its center, as shown in Fig. 4. The curve $P_H(T_0)$ must have an inflection point in order to intersect $P_0(T_0)$ at points 1, 2, and n. This means that d^2P_H/dT_0^2 must be zero at the given point n. Let us consider this condition for the proposed circuit.

For the circuit of Fig. 2, the power liberated in r_H, is determined by the expression

$$P_H = U^2 r_H \frac{P_T^2}{[R_T(r + r_H) + rr_H]^2}, \tag{3}$$

where U is the power supply voltage of the circuit.

Then

$$\frac{d^2P_H}{dT_0^2} = 2U^2 rr_H \tag{4}$$

$$\left\{\frac{[(R_T')^2 + R_T R_T''][R_T(r + r_H) + rr_H] - 3(r + r_H)R_T(R_T')^2}{[R_T(r + r_H) + rr_H]^4}\right\},$$

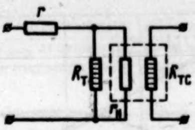

Fig. 2. Circuit for controlling the temperature of a heated thermistor.

whence,

$$\frac{rr_H}{r + r_H} = \frac{R_T[2(R_T')^2 - R_T''R_T]}{(R_T')^2 + R_T''R_T}. \tag{5}$$

The temperature dependence of the thermistor is defined by the expression

$$R_T = R_{T_H}\exp\left(\frac{B}{T} - \frac{B}{T_H}\right) = \gamma R_{T_H}, \tag{6}$$

where R_{T_H} is the thermistor resistance at temperature T_H, and B is a constant defining the properties of the semiconductor from which the thermistor is made.

Then

$$R_T' = -\frac{B}{T^2}R_T,$$
$$R_T'' = \frac{B}{T^4}(B + 2T)R_T. \tag{7}$$

Putting expression (7) into formula (5), we get

$$\frac{rr_H}{r + r_H} = \frac{R_{T_p}}{2}\frac{B - 2T_p}{B + T_p} = R_{T_p}\gamma. \tag{8}$$

The expression for P_H is written in the form

$$P_{H1} = \frac{U^2R_{T_1}^2 r_H}{[R_{T_1}(r + r_H) + rr_H]^2}, \quad P_{H2} = \frac{U^2R_{T_2}^2 r_H}{[R_{T_2}(r + r_H) + rr_H]^2} \tag{9}$$

for temperatures of the medium T_1 and T_2, corresponding to the limits of the working range.

The ratio $\frac{P_{H1}}{P_{H2}}$ must be equal to the ratio P_1/P_2, which is computed or determined in the ordinary manner.

Consequently,

$$k_p = \frac{P_1}{P_2} = \frac{P_{H1}}{P_{H2}} = \frac{R_{T_1}^2\left[R_{T_2} + \frac{rr_H}{r + r_H}\right]^2}{R_{T_2}\left[R_{T_1} + \frac{rr_H}{r + r_H}\right]^2}. \tag{10}$$

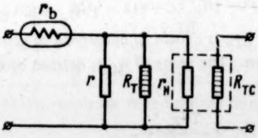

Fig. 3. Circuit for controlling the temperature of a heated thermistor with a barretter.

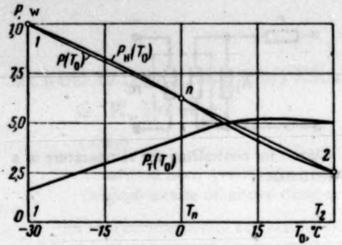

Fig. 4. Dependence of the powers P, P_H, and P_T on the temperature of the surrounding medium.

Then, according to expressions (8) and (10), we get

$$k_p=\left[\frac{R_{T_1}(R_{T_2}+\gamma R_{T_p})}{R_{T_2}(R_{T_1}+\gamma R_{T_p})}\right]^2=\left[\frac{\varepsilon_1(\varepsilon_2+\gamma\varepsilon_p)}{\varepsilon_2(\varepsilon_1+\gamma\varepsilon_p)}\right]^2, \qquad (11)$$

where

$$R_{T_к}=R_{T_н}\exp\left(\frac{B}{T_к}-\frac{B}{T_н}\right)=R_{T_н}\varepsilon_к.$$

The unknown B, which characterizes the thermistor, can be determined from (11). But since this equation is exponential, and is not analytically solved for B, then the curve $k_p(B)$ is plotted, and B, corresponding to a given k_p, is determined from it. Then the resistances r and r_H are determined. However, there is only one expression, (8), which relates these quantities. The second equation can be obtained from the condition of maximum efficiency of the circuit at one of the points in the temperature range. The circuit efficiency is defined by the expression

$$\eta=\frac{P_н}{P}=\frac{R_т^2 r_н}{(R_т+r_н)[R_т(r+r_н)+rr_н]} \qquad (12)$$

where P is the power needed by the whole circuit.

The quantity r, corresponding to a maximum η, is determined from the equality $d\eta/dr_H = 0$:

$$r=\frac{r_н^2 R_т}{R_т^2-r_н^2}. \qquad (13)$$

T_p is chosen as the temperature at which the efficiency is maximum. Then the equation for determining r is obtained from (8) and (13):

$$(1-\gamma^2)r^2-\gamma R_{T_p}(2-\gamma)r-\gamma^2R_{T_p}^2=0. \qquad (14)$$

The quantity R_{T_p} is chosen to correspond to existing types of thermistors. The value of r_H is defined by the expression

$$r_н=\frac{\gamma R_{T_p} r}{r-\gamma R_{T_p}}. \qquad (15)$$

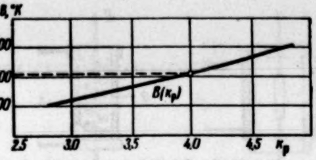

Fig. 5. Dependence $B(k_p)$ for finding the computed value of B.

Then the power supply voltage of the circuit is determined. The power, liberated in r_H at the temperature T_p is found from the formula

$$P_{н.p}=\left[\frac{Ur_н}{R_{T_p}(r+r_н)+rr_н}\right]^2R_{T_p} \qquad (1$$

or after transformation,

$$P_{н.p}=\frac{U^2r_н}{(r+r_н)^2}\left(\frac{1}{1+\gamma}\right)^2. \qquad (17$$

Next the supply voltage is determined:

$$U=(r+r_н)(1+\gamma)\sqrt{\frac{P_{н.p}}{r_н}}. \qquad (18$$

The next step in the calculation is to determine the maximum power dissipated in the thermistor. The power liberated in the thermistor is defined by the expression

$$P_т=\left[\frac{Ur_н}{R(r+r_н)+rr_н}\right]^2R_т. \qquad (19$$

R_T is found from the condition $dP_T/dT = 0$; it corresponds to maximum P_T:

$$R_{T_м}\doteq\frac{rr_н}{r+r_н}=\gamma R_{T_p}. \qquad (20$$

Then

$$P_{т.\max}=\frac{U^2r_н}{4r(r+r_н)} \qquad (21$$

The temperature corresponding to $P_{T\max}$ is found from (8) and (20):

$$T_м=\frac{BT_p}{T_p\ln\gamma+B}. \qquad (22)$$

If T_M proves to be outside of the working temperatur range, the maximum P_T is taken as that for temperature T_2.

To conclude the computation, the maximum static error of the circuit is determined. In order to do this, the temperature at which $\Delta P = P(T_0) - P_H(T_0)$ has extreme values is found. The expression

$$2U^2R_тR_т'rr_н^2=-K[R_т(r+r_н)+rr_н]^3. \qquad (23)$$

is found from the condition $d(\Delta P)/dT_0 = 0$.

Putting the values of R_T and R_T^{+} from (6) and (7) into (23), we get the equation necessary to find T_{OM}:

$$2\frac{U^2 r_H^2 r}{K} = \frac{T_{OM}^2}{B} \frac{\left[R_{T_H} \exp\left(\frac{B}{T_H} - \frac{B}{T_{OM}}\right)(r + r_H) + r r_H\right]^3}{\left[R_{T_H} \exp\left(\frac{B}{T_H} - \frac{B}{T_{OM}}\right)\right]^2}. \quad (24)$$

Since this equation is not solved analytically for T_{OM}, one is obliged to use a graphical method. The maximum static error of the circuit is found from the formula

$$\Delta T_M = \frac{P_H(T_{OM})}{K} - (T - T_{OM}). \quad (25)$$

Let us examine the computation for a circuit with a barretter. It is characterized by constancy of the current flowing through the barretter. This current is defined by the expression

$$I = U_{12}\frac{R_T(r + r_H) + r r_H}{R_T r_H r}. \quad (26)$$

The power liberated in r_H will be

$$P_H = I^2\left[\frac{R_T r}{R_T(r + r_H) + r r_H}\right]^2 r_H. \quad (27)$$

By analogy with the foregoing, an expression similar to (8) corresponds to the condition for obtaining an inflection point on the curve $P_H(T_0)$. If $r = \infty$ in the circuit, we get from (8)

$$r_H = \gamma R_{T_p}. \quad (28)$$

It is possible only in rare cases to make a circuit which will fulfill this condition. By connecting a resistance r in the circuit, one can change the total current and make it equal to the nominal current of the barretter.

The quantity B of the required thermistor is determined from the given ratio of the powers at the edges of the temperature range.

This ratio corresponds to (11) for the first circuit.

If the temperature of the heated thermistor is regulated, then r_H is the given quantity. Choosing a value for R_{T_p}, we find r:

$$r = \frac{\gamma R_{T_p} r_H}{r_H - \gamma R_{T_p}}. \quad (29)$$

The power voltage for the circuit is determined from the values of the lower limit of barretration and from the nominal current of the barretter:

$$U = I\left[\frac{R_{T_1}(r + r_H) + r r_H}{R_T r r_H}\right] + U_{L.B.} \quad (30)$$

In this expression, the thermistor resistance is taken at the lower limit of the temperature range. When the thermistor temperature is raised, the operating point on the volt-ampere characteristic of the barretter will be shifted to the middle of the barretration zone.

The power liberated in the thermistor will be

$$P_T = I^2 R_T\left[\frac{r r_H}{R_T(r + r_H) + r r_H}\right]^2. \quad (31)$$

The amount of thermistor resistance which corresponds to $P_{T\max}$ is determined by an expression similar to (20). The maximum power liberated in the thermistor will be

$$P_{T_M} = I^2\frac{r r_H}{4(r + r_H)}. \quad (32)$$

Hence, the parameters of all the elements in the circuit can be determined. In order to illustrate the method presented, the calculation of the circuit shown in Fig. 2 is presented as an example.

Example. Compute the circuit elements of the temperature regulator of a heated thermistor operating in the temperature range from $\theta_{\theta_1} = -30$, to $\theta_{\theta_2} = +30$°C. The temperature of the semiconducting element $\theta = 50$°C. The power dissipated by the heater at -30°C is $P_{H_1} = 10$ watts.

It is assumed that the best transfer between the thermistor and the medium obeys Newton's formula.

Let us find the power dissipated by the thermistor at temperatures $\theta_{\theta_2} = 30$°C and at $\theta_{\theta p} = 0$°C:

$$P_{H2} = P_{H1}\frac{\theta - \theta_{02}}{\theta - \theta_{01}} = 2.5 \text{ w},$$

$$P_{L.L.} = P_{H1}\frac{\theta - \theta_p}{\theta - \theta_{01}} =$$

$$= 6.25 \text{ w and } k_p = \frac{P_{H1}}{P_{H2}} = 4.$$

Table 1

B,° K	2500	3000	3500
k_p	2,83	3,92	4,8

In order to determine B corresponding to $k_p = 4$, the function $k_p(B)$ is computed from (11) in some range of change in B. The results of the calculation are presented in Table 1.

Having plotted a curve through these points (Fig. 5), we find from it that B = 3025°K, corresponding to $k_p = 4$. We will take a thermistor having $R_{20} = 20$ ohms at $T_H = 293$°K.

Then the values of the thermistor resistance at three points in the temperature range will be

$$R_{T_1} = 165 \text{ ohms} \quad R_{T_2} = 14.2 \text{ ohms} \quad R_{T_p} = 42.8 \text{ ohms}$$

Using (8), we find

$$\gamma = 0.376.$$

The quantity r = 38.5 ohms is found from (14), written in the form

$$r^2 - 30.5\,r - 305 = 0.$$

The heater resistance is determined from (15):

$$r_H = 27.8 \text{ ohms}.$$

The power circuit voltage is computed from (18):

$$U = 43.3 \text{ volts}.$$

Table 2

θ_e, °C	—30	—15	0	15	30
ε	8.25	3.97	2.14	1.17	0.71
P, w	10.0	8.13	6.25	4.38	2.5
P_{H}, w	9.9	8.22	6.25	4.24	2.58
P_{T}, w	1.65	2.86	4.05	5.13	5.0
θ, °C	49.2	50.8	50.0	48.8	50.6

The maximum power dissipated in the thermistor will be $P_{T\max} = 5.13$ w, according to (21).

The thermistor resistance which corresponds to $P_{T\max}$ is found from (20):

$$R_{T_M} = 16.1 \text{ ohms}.$$

The temperature corresponding to R_{T_M} is found from (22): $T_M = 287$°K or 14°C.

The quantities P_H and P_T, and the temperature of the semiconducting element of the heated thermistor are determined on the basis of resistance values, the temperature dependence $R_T(T)$, and U. The results of the calculations are shown in Table 2.

The data of Table 2 confirm the correctness of the proposed method of calculation, and show that such a circuit can be successfully used for regulating the temperature of the semiconducting element in a heated thermistor.

USE OF HEATER RESISTANCES FOR CURRENT AND VOLTAGE STABILIZATION

V. S. Popov

(Leningrad)

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 4, pp. 555-557, April, 1960

Original article submitted October 8, 1959

A new type of electrical stabilizer with metal heater resistance is considered and analyzed. Results of experimental investigation are given, and technical characteristics are noted.

Bridge stabilizers with nonlinear resistances – incandescent lamps, thermistors, and barretters – are widely used as low-power electric current stabilizers [1].

Bridge stabilizers have a number of advantages – simplicity, wide frequency response, and the absence of moving parts. On the other hand, such instruments have a comparatively low stabilization coefficient; furthermore, they cannot be used in circuits where the load and the supply source are commoned.

In the stabilizer developed by the author the basic advantages of bridge stabilizers are retained, and the stabilization coefficient is increased. The stabilizer is suitable for applications in circuits where the load and the supply source are commoned.

The stabilizer consists of a shunt and a metallic resistance with indirect heating. The heater resistance is represented by a platinum heater in a glass insulating tube, around which a platinum spiral is wrapped (Fig. 1). The heater and spiral are placed in an unevacuated brass container serving to protect the heater resistances from mechanical damage. The diameter of the heater is usually within the limits of 10 to 50 μ; the inner diameter of the insulating tube is approximately double that of the heater. The diameter of the spiral wire varies within the range of 5 to 30 μ. The heater resistance is attached to a socket from a type 6N8S radio tube.

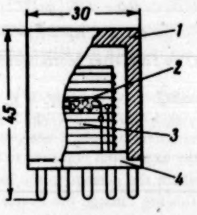
The time constant τ of the heater resistances as a function of heater and spiral dimensions is within the limits 0.03 to 0.80 sec.

As indicated by the investigation, the variation of the spiral resistance R_1 with concurrent action of the heating current I and the current flowing directly through the spiral I_s is of the form

$$R_1 = R_{10} + cI^\alpha + c_1 I_s^\beta, \qquad (1)$$

where R_{10} is the initial resistance of the sensing element (spiral), c and c_1 are constants depending upon the configuration of the heater resistance, α and β are constants within wide limits independent of the lay of winding and of the spiral diameter.

For platinum heaters $\alpha \approx 2.2$, where the temperature rise of the heater due to the heating current is within the



View without cover

Fig. 1. Metallic resistance with indirect heater. 1) Cover; 2) heater resistance; 3) compensating resistance; 4) socket.

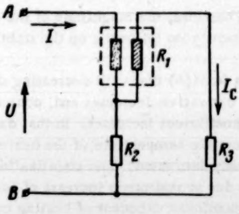


Fig. 2. Circuit diagram of the stabilizer.

limits of 40 to 400°. For heater resistances with nichrome or constantan heaters, $\alpha \approx 1.7$ under the same conditions.

With a platinum spiral, $\beta \approx 2.0$ under the condition that the temperature rise of the spiral due to the current flowing through it does not exceed 20°. With increasing temperature β does increase somewhat.

The arrangement of the stabilizer with heater resistance is shown in Fig. 2.

The relationship between current I_s in the load R_3 and the heating current I is of the form

$$I_s = I \frac{R_2}{R_1 + R_2 + R_3}. \tag{2}$$

Differentiating (2) while taking (1) into account, we obtain

$$\frac{dI_s}{dI} = \frac{R_2 (R_1 + R_2 + R_3) - I R_2 \left(\alpha c I^{\alpha-1} + c_1 \beta I_s^{\beta-1} \frac{dI_s}{dI} \right)}{(R_1 + R_2 + R_3)^2} \tag{3}$$

From that, we find, after rearrangement,

$$\frac{dI_s}{dI} \left(1 + \frac{c_1 \beta I_s^{\beta}}{R_1 + R_2 + R_3} \right) = \frac{R_2 [(R_1 + R_2 + R_3) - \alpha c I^{\alpha}]}{(R_1 + R_2 + R_3)^2}.$$

Equating the expression obtained to zero, we obtain the condition where the current in the load is independent of the current flowing through the heater*:

$$R_1 + R_2 + R_3 = \alpha\ I^{\alpha}. \tag{4}$$

In this manner the condition for stabilization will appear when the resistance increase of the spiral due to the heating current, multiplied α times, is equal to the sum of the resistances of the spiral, load, and shunt.

We will determine the conditions for the stabilization coefficient of the stabilizer to be a maximum. For that purpose we determine the conditions for a minimum of the second derivative d^2I_s/dI^2 in the operating sector of the stabilizer characteristic, that is, in the region where the first derivative dI_s/dI is equal to zero.

Differentiating equation (3) and setting the first derivative equal to zero, we obtain, after a number of rearrangements,

$$\frac{d^2 I_s}{dI^2} = \frac{R_2 (1 - \alpha)}{I (R_1 + R_2 + R_2) \left[1 + \frac{c_1 \beta I^{\beta}}{R_1 + R_2 + R_3} \right]}. \tag{5}$$

The expression $\frac{c_1 \beta I_s^{\beta}}{R_1 + R_2 + R_3}$ is considerably less than unity. Therefore, the magnitude of the current stabilized has practically no influence on the stabilization coefficient.

It follows from (5) that with decreasing shunt resistance R_2 the second derivative decreases and, consequently, the stabilization coefficient increases. In that case, according to (4), the operating temperature of the heater resistance is simultaneously decreased. The stabilization coefficient also increases, due to resistance increase of load R_3, decrease of the nonlinear exponent of heating current α, and increase of the current stabilized; but in that case the operating temperature of the heater resistance increases, and its overload capacity decreases.

According to (4) a higher load resistance is permissible for larger values of the nonlinear exponent α; the power output of the stabilizer increases simultaneously. Therefore, a platinum wire, which has a higher nonlinear exponent than nichrome wire, is used as a heater in the stabilizer.

It was shown by the experimental investigation of a number of stabilizers devised using various metallic heater resistances that, with an increase of the heater current, the load current initially increases, and, thereafter, after reaching some maximum value, decreases. This is due to current redistribution between the load and the shunt as a result of intense resistance increase of the spiral.

The stabilization coefficient of stabilizers is, on the average, equal to 50 for a 10% change in the heating (stabilizing) current, and about 30 for a 20% change of the stabilizing current.

The resistance of the platinum heater increases significantly upon increase of heater current. Consequently, on varying the voltage applied to the heater, the resistance of the latter changes in such a fashion as to oppose a change of the heater current. As a result the stabilizer will be less sensitive to variations of terminal voltage U_{AB} than to heater-current variations.

The table shows the relationship between the load current I_s and the voltage U, transmitted to the terminals of a stabilizer with heater resistances of the platinum heater being of 50μ in diameter and a platinum spiral with wire diameter of 24 μ, with R_2 equal to 1.0 ohm, R_3 equal to 5.0 ohms, and at an ambient temperature t of 20 and 40°.

As can be seen from the table, the stabilization coefficient of a voltage stabilizer is about 70 for a 20% change in the voltage.

The load current decreases when the ambient temperature changes as a result of resistance increase of the spiral and of the heater. For current stabilization, as well as for voltage stabilization, this error can be almost fully compensated for by winding part of the shunt resistance R_2 with copper.

For current stabilizers the copper resistance is 30% of the total in R_2, and for voltage stabilizers is 50%. The compensating copper resistance, wound on a small plate, is located in the same container as the heater resistance (Fig. 1).

During ambient-temperature changes the region of stabilization is somewhat displaced. This is caused by the fact that whenever the ambient temperature increases, the condition for stabilization (4) is disturbed – resistance R_1 increases, and the heating current within the voltage stabilizer decreases slightly. The temperature error of stabilizers does not exceed 0.2% per 10°.

To protect the stabilizers from large overloads, safety fuses made of platinum wire of a diameter equal to approximately 0.8 of the heater diameter should be connected in series with the heater.

---

*In satisfying equation (4) the expression $\frac{c_1 \beta I_s^{\beta}}{R_1 + R_2 + R_3} \ll 1$.

$t = 20°$

U. v	0.5	1.0	1.2	1.3	1.4	1.5	1.6	1.7	1.8	1.9	2.0
I_{c_3} ma	9.20	13.20	13.85	14.02	14.17	14.23	14.25	14.25	14.24	14.20	14.12

$t = 40°$

U. v	1.3	1.4	1.5	1.6	1.7	1.8	1.9	2.0
$I_{\text{э}}$ ma	13.80	14.00	14.10	14.20	14.22	14.22	14.22	14.21

The stabilizers developed are suitable for stabilization of direct current and alternating current (voltage), in the frequency region of from a few cycles to several hundred kilocycles, without wave-form distortion.

As compared with thermistors, the stabilizer with heater resistance has far lower inertia, higher stability, and insignificant temperature error.

A significant advantage of the stabilizer is that it will, after an interruption in operation, reestablish, with a high degree of accuracy, previous values of stabilized current (voltage). It was shown by an investigation of three months' duration that the voltage change at the stabilizer terminals will not exceed + 0.15% of the initial value.

The main advantages of the stabilizer are simplicity, the presence of a commoned point between the load and the supply source, and a high stabilization coefficient.

LETTER TO THE EDITOR

Translated from Avtomatika i Telemekhanika Vol. 21, No. 4, p. 558, April, 1960

The work of the author [1] cites new equations for basic parameters of the two-point regulation process with a new time correction method. The conclusion is drawn on the basis of introduction of the concept of residual delay $\Delta t'$ so that the method of calculation approaches the method laid out in [2]. However, for practical calculation of a system with the proposed method of correction, it is expedient to express the equations for the regulation process parameters directly in terms of given values Q_{in}, Q_{out}, C, Δt, and T'_{on}. The time of starting the heat influx into the object T'_{on} is rigorously given by the correction device. In that case the equations will be as follows:

$$\Delta\vartheta'_{m(+)} = \frac{T'_{on}(Q_{in} - Q_{out}) - \Delta t Q_{out}}{C}, \tag{1}$$

$$\Delta\vartheta'_{m(-)} = \Delta\vartheta_{m(-)} = -\Delta t \frac{Q_{out}}{C}. \tag{2}$$

The full amplitude of autooscillation

$$\Delta\vartheta'_m = \Delta\vartheta'_{m(+)} + \Delta\vartheta'_{m(-)} = T'_{on} \frac{Q_{in} - Q_{out}}{c}, \tag{3}$$

$$T'_{off} = T'_{on} \frac{Q_{in} - Q_{out}}{Q_{out}} = T'_{on}(n-1), \tag{4}$$

$$T' = T'_{on} + T'_{off} = T'_{off} \frac{Q_{in}}{Q_{out}} = T'_{on} n. \tag{5}$$

Equations (1) to (5) given can be obtained from equations (1) to (5) of [1], if it is considered that

$$\Delta t' = T'_{on} - \Delta t \frac{Q_{out}}{Q_{in} - Q_{out}}.$$

In addition to the concept of degree of correction k, introduced in [1], it is also expedient to introduce a second degree of correction k_1, which represents the relationship of full oscillation amplitudes of the process without correction to the amplitudes of the process with correction, that is,

$$k_1 = \frac{\Delta\vartheta_m}{\Delta\vartheta'_m}.$$

It is apparent that

$$k_1 = \frac{\Delta t}{T'_{on}} \frac{Q_{in}}{Q_{in} - Q_{out}} = \frac{\Delta t}{T'_{on}} \frac{n}{n-1}.$$

Expressing the full period of autooscillations in the system with correction in terms of a new degree of correction k_1 and a power of influx n, we obtain

$$T' = \frac{\Delta t n^2}{(n-1)k_1}.$$

The curves of the relationship between the autooscillation period T' and a power of the influx n for $\Delta t = 1$, and at various values of the degree of correction k_1 will be of a form coinciding with the curves in Fig. 3 of [1].

Ya. Z. Tsypkin

LENIN PRIZE LAUREATE

On April 22, 1960, the Committee for the Lenin prize in the domain of science and technology for the Soviet Ministers of the Union of Soviet Socialist Republics awarded the Lenin prize to Doctor of Mechanics. Professor Yakov Zalmanovich Tsypkin for his work on the theory of sampled-data and relay automatic systems, presented in the monographs, Transient and Steady-State Processes in Sampled-Data Circuits, Theory of Relay Systems of Automatic Control, Theory of Sampled-Data Systems, published during the years 1951-1958.

The editorial board of the journal Avtomatika i Telemekhanika (Automation and Remote Control) warmly congratulates Yakov Zalmanovich Tsypkin for his high honor, and wishes him further creative successes.

The V. I. Lenin prize for works on the theory of relay and sampled-data systems was awarded by the director of the laboratory of the Institute for Automation and Remote Control of the Academy of Sciences of the USSR to Professor Yakov Zalmanovich Tsypkin, member of the editorial board of the journal Avtomatika i Telemekhanika (Automation and Remote Control) and doctor of engineering science.

For the first time, a cycle of theoretical works in the domain of automation has received the highest award. The Institute for Automation and Remote Control of the AN SSSR (Academy of Sciences of the USSR) is rightfully proud that the works singled out for the Lenin prize were executed by one of its leading scientific workers.

The editorial board of the journal Avtomatika i Telemekhanika (Automation and Remote Control) is particularly pleased to state that works of Ya. Z. Tsypkin, awarded this high honor, were published in this journal, starting in 1948.

The biography of Lenin prize laureate Ya. Z. Tsypkin is a typical biography of a young Soviet scientist and patriot of our fatherland.

Ya. Z. Tsypkin's first steps as a scientist were connected with the investigation of continuous control systems. The concept of degree of stability, suggested by him in conjunction with P. V. Bromberg [1, 4, 5, 8, 18, 48], entered into automatic control theory and was widely disseminated in the international literature. His following works were devoted to the dynamics of automatic control systems when lags were taken into account. Ya.Z. Tsypkin developed, and applied to the analysis of stability of these systems, frequency methods [4, 6, 7, 8]. The results which he obtained in this area underlay his doctoral dissertation, "Systems with lagging feedback," [9].

The methods developed by. Ya. Z. Tsypkin for investigating systems with lags received broad recognition, both in the Soviet Union and abroad. It is appropriate to recall here that, in evaluating the work of this period, Academician A. A. Andronov characterized Ya. Z. Tyspkin as one of the most vigorous and promising scientists working in the domain of control theory in the USSR.

The tremendous development of computing technology and radioelectronics in the postwar years engendered a heightened interest in discrete devices for control and communications, in particular, in relay, sampled-data and digital devices. Ya. Z. Tsypkin is one of the first scientists to have properly appreciated the importance of this trend and, more than ten years ago, he applied himself to the development of a general theory of discrete automatic systems. His first work in this direction dates back to 1948 [10].

The fundamentals of sampled-data system theory were first presented by him in [12, 13, 15]. The generality of the developed theories of sampled-data systems was not inferior to the generality of theories of continuous systems. In 1951, Ya. Z. Tsypkin published a monograph on sampled-data circuits, Transient and Steady-State Processes in Sampled-Data Circuit [17]. In [20] there was developed a frequency method of analyzing discontinuous control systems which allowed one to establish in which cases sampled-data control improves the system's dynamic properties as compared to continuous control. A further series of works were devoted to the effect of random stimuli [22], of pulse shapes [33], of forcing actions [40] and of nonlinearities [23, 38] on the dynamic properties of sampled-data systems.

Starting in 1956, he extended sampled-data system theory to cover systems with digital computing devices [39, 44, 46, 47, 49, 50, 51].

The enumerated works were widely used by various organizations, designers, developers, investigators and users of sampled-data systems. The developed theory of sampled-data systems entered into the VUZ (university) curriculum and into courses for advanced engineering [45]. It was widely used and further developed in a number of works by Soviet and foreign scientists.

In 1958, Ya. Z. Tsypkin published the fundamental monograph, Theory of Sampled-Data Systems, [52] which is devoted to the analysis and synthesis of sampled-data systems and contains the fundamental general theory of sampled-data automatic systems, applied in various domains of technology. Together with sampled-data systems, relay systems were investigated by him in a number of works. In the theory of relay systems, Ya. Z. Tsypkin developed general and precise methods of investigation, superficially similar to linear methods but, at the same time, applicable to this class of essentially nonlinear systems. These methods permitted the investigation of various modes of operation in relay systems, the comparison of types of circuits and the development of new, advanced schemes. These works [16, 19, 23, 27, 29, 31] were summarized in the monograph, Theory of Relay Systems of Automatic Control [34].

The monographs of Ya. Z. Tsypkin, and many of this papers, were published in the German Democratic Republic, China, Poland, Rumania, Czechoslovakia, England, France, the German Federal Republic, the United States of America, and Japan, and were given as papers at international congresses [43, 46, 50, 51].

It is necessary to mention the characteristic traits of the creative style of Ya. Z. Tsypkin – clarity and explicitness in posing the problem, simplicity and elegance of the method of investigation, tense and concentrated purposefulness.

It is no coincidence that his last monographs constitute three important successive steps in the solution of a single problem, that of creating a general theory of discrete automatic systems.

Ya. Z. Tsypkin devoted much attention and work to the question of preparing a professional cadre. He is widely known as a superb lecturer. His lectures on automatic control theory have been very popular [14, 21, 28, 45, 54].

Under Ya. Z. Tsypkin's editorship, the fundamental foreign works on automatic control have been translated and published here (McColl, Fundamental Theory of Servomechanism (1947); Lauer, Lesnick, and Matson, Servomechanism Fundamentals (1948); James, Nichols, and Phillips, Theory of Servomechanisms (1949); Flugge-Lotz, Phase Plane Method in Relay System Theory, 1959; and others).

Under Ya. Z. Tsypkin's direction, a large number of dissertations were executed, comprising a broad circle of questions in radio engineering, electronics and automatic control.

Professor Ya. Z. Tsypkin is an important Soviet scientist, creator of a unified theory of sampled-data and relay automatic systems which has found wide practical application and has obtained world-wide recognition.

LIST OF THE BASIC SCIENTIFIC WORKS OF YA. Z. TSYPKIN

1. "On the degrees of stability of linear systems," Izvest. Akad. Nauk SSSR, Otd. tekn. nauk No. 12 (1945). (in conjunction with P. V. Bromberg).

ANALYTIC CONTROLLER DESIGN. II

A. M. Letov
(Moscow)

Translated from Avtomatika i Telemekhanika Vol. 21, pp. 561-568, May, 1960
Original article submitted December 23, 1959

The solution is presented for the problem of analytic controller design in correspondence with a given optimizing functional. The solution is given for a closed region which contains the boundary of excursion of the controlling organ.

1. Optimal Systems, Defined in a Closed Region

Essential in all automatic control systems is the limitation on the excursion of the controlling organs ξ:

$$|\xi| \leqslant \bar{\xi} \tag{1.1}$$

on the limitation on the magnitude of the velocity of this excursion

$$|\dot{\xi}| \leqslant \bar{f}, \tag{1.2}$$

where $\bar{\xi}$, f are positive numbers.

With such limitations, the system becomes essentially nonlinear, since the presence of the equality sign in (1.1) and (1.2) permits the system to remain on the boundary of the region $\bar{N}$ of its definition. This region is closed. Moreover, it is impossible here to seek an optimal solution to the problem among functions of the class C_1, since there can be discontinuities on the boundary of the function which solves the problem. By taking into account what has just been said, we formulate the following variational problem.

We consider a closed system to be controlled, in which the disturbed motion of the controlled object is given by the equations

$$g_k = \dot{\eta}_k - \left(\sum_{\alpha} b_{k\alpha}\eta_\alpha + m_k\xi\right) = 0 \quad (k = 1, \ldots, n). \tag{1.3}$$

The notation in (1.3) has the same meaning as in [1]. It is assumed that (1.3), in conjunction with the controller equations being sought, are defined in the closed region $\bar{N}$, characterized by (1.1). In this region there are given the sole boundary conditions

$$\begin{gathered}\eta_{10} = \eta_1(0), \ \ldots, \ \eta_n(0) = \eta_{n0}, \ \xi(0) = \xi_0; \\ \eta_1(\infty) = \ldots = \eta_n(\infty) = \xi(\infty) = 0\end{gathered} \tag{1.4}$$

They mean simply this: that no matter what transient response arises in $\bar{N}$, it must terminate, for $t^* = \infty$, with the system at the origin of coordinates.

As the criterion of optimality, we take the integral

$$I = \int_0^\infty V dt, \tag{1.5}$$

where V is the positively defined quadratic form

$$V = \sum_k a_k\eta_k^2 + c\xi^2. \tag{1.6}$$

We shall search for such continuous functions ξ, η_1, ..., η_n in Class C (permitting, generally speaking, discontinuities of the first derivatives) which minimize the integral in (1.5).

The problem just formulated belongs to the class of the so-called discontinuous problems of the calculus of variations. To solve such problems there exist various methods of the classical variational calculus, as well as newer methods, presented in the works cited in [1]. Here we shall use the methods of the classical variational calculus, supplemented by a nonlinear transformation which, in optimal problems of the first class [1], was used in [2].*

2. Solution of the Problem

We consider the case when the limitation is as in (1.1), and we set

$$\xi = \varphi(\zeta). \tag{2.1}$$

We define the function $\varphi(\zeta)$ as

$$\varphi(\zeta) = \begin{cases} +\bar{\xi} & \text{for} \quad \zeta \geqslant \zeta^*, \\ \varphi(\zeta) & \text{for} \quad |\zeta| < \zeta^*, \\ -\bar{\xi} & \text{for} \quad \zeta \leqslant -\zeta^*, \end{cases} \tag{2.2}$$

where ζ^* is a given positive number and $\varphi(\zeta)$ is any continuous function whose derivative is continuous for $|\zeta| < \zeta^*$, and which is equal to zero for $\zeta = 0$. In particular, such a condition is satisfied by the function $\varphi(\zeta) = \xi \sin \zeta$ for $\zeta^* = \pi/2$ (Fig. 1).

Transformations (2.1) and (2.2) translate the closed region $N(\xi, \eta_1, \ldots, \eta_n)$ into the open region $\bar{N}(\zeta, \eta_1, \ldots, \eta_n)$ and permit one to use the well-known methods of variational calculus for the solution of ordinary Lagrange problems. The only special feature of this solution is that one must verify that the Weierstrass-Erdmann conditions hold at all points of discontinuity of the derivatives. To begin the solution of the problem, we set

---

* The author's attention was called to the transformation by I. A. Litovchenko, to whom the author expresses his gratitude.

$$H = V + \sum_k \lambda_k \left[\dot{\eta}_k - \sum_\alpha b_{k\alpha}\eta_\alpha - m_k\varphi(\zeta)\right]. \tag{2.3}$$

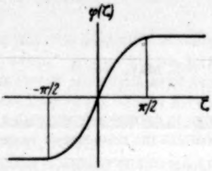

Fig. 1.

On the basis of (2.3), we find that

$$\frac{\partial H}{\partial \dot{\eta}_k} = \lambda_k, \qquad \frac{\partial H}{\partial \eta_k} = 2a_k\eta_k - \sum_\alpha \lambda_\alpha b_{\alpha k},$$

$$\frac{\partial H}{\partial \dot{\zeta}} = 0, \qquad \frac{\partial H}{\partial \zeta} = \left[2c\varphi(\zeta) - \sum_\alpha m_\alpha\lambda_\alpha\right]\frac{\partial\varphi}{\partial\zeta}.$$

The equations of the problem have the form

$$\dot{\eta}_k = \sum_\alpha b_{k\alpha}\eta_\alpha + m_k\varphi(\zeta),$$

$$\dot{\lambda}_k = -\sum_\alpha b_{\alpha k}\lambda_\alpha + 2a_k\eta_k, \tag{2.4}$$

$$0 = \left[2c\varphi(\zeta) - \sum_\alpha m_\alpha\lambda_\alpha\right]\frac{\partial\varphi}{\partial\zeta}.$$

They coincide to within the factor $\partial\varphi/\partial\zeta$ with the equations [(2.1) and (3.3)] of the analogous problem for the open region N(ξ, η_1, ... , η_n) which was formulated in [1].

Therefore, in addition to the solution obtained in [1] for the open region, we should consider the new solution which corresponds to the equation

$$\frac{\partial\varphi}{\partial\zeta} = 0. \tag{2.5}$$

By virtue of the definition given by (2.2), we set

$$\varphi(\zeta) = \pm\bar{\xi} \quad \text{for} \quad |\zeta| \geqslant \zeta^*. \tag{2.6}$$

This latter means that the optimal solution passes over the boundary of the region $\bar{N}$ (ξ, η_1, . . . , η_n).

For interior points of the region, the solution found has the form [1]

$$\xi = \sum_{\alpha=1}^{n} p_\alpha\eta_\alpha. \tag{2.7}$$

Thus, the equation of the controller which corresponds to the functional of (1.5) is written as

$$\xi = \begin{cases} \sum_\alpha p_\alpha\eta_\alpha & \text{for} \quad \left|\sum_\alpha p_\alpha\eta_\alpha\right| < \bar{\xi}, \\ +\bar{\xi} & \text{for} \quad \sum_\alpha p_\alpha\eta_\alpha \geqslant \bar{\xi}, \\ -\bar{\xi} & \text{for} \quad \sum_\alpha p_\alpha\eta_\alpha \leqslant -\bar{\xi}. \end{cases} \tag{2.8}$$

Obviously, this equation corresponds to an ideal nonlinear controller with an infinitely large servomotor speed.

The question of the stability of system (1.3), supplied with the controller defined by (2.8), should be considered separately. It is the subject-matter of an independent problem. As was shown in [1], for a deviation $|\Sigma p_\alpha\eta_\alpha| < \bar{\xi}$, stability is guaranteed; for a deviation $|\Sigma p_\alpha\eta_\alpha| \geqslant \bar{\xi}$ a special investigation is required, leading to the construction of the region of attraction, the boundary of which necessarily lies beyond the limits of $|\Sigma p_\alpha\eta_\alpha| = \bar{\xi}$. Various cases can occur here. Thus, in example 1 of paper [1], where n = 1, b_{11} = b, m_1 = m and, $\eta_1 = \eta$, we had the system of equations

$$\dot{\eta} = b\eta + m\xi,$$

$$\xi = \begin{cases} +\bar{\xi} & \text{for} \quad -\frac{k+b}{m}\eta \geqslant \bar{\xi}, \\ -\frac{k+b}{m}\eta & \text{for} \quad \left|1-\frac{k+b}{m}\eta\right| < \bar{\xi}, \\ -\bar{\xi} & \text{for} \quad -\frac{k+b}{m}\eta \leqslant -\bar{\xi}, \end{cases} \tag{2.9}$$

where the number k is defined by the formula

$$k = +\sqrt{b^2 + \frac{m^2 a}{c}}. \tag{2.10}$$

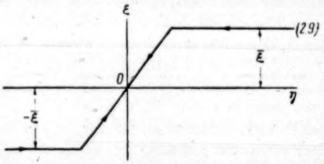

Fig. 2.

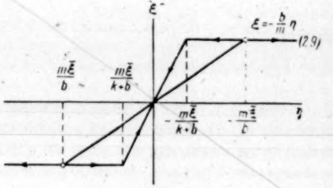

Fig. 3.

Figures 2 and 3 show the system's phase plane for the cases m, b < 0 and m < 0, b > 0. In the first case, the curve $\xi = \xi(\eta)$ (2.9) is the sole integral curve by which the representative point returns to equilibrium for any η_0; in the second case, the system's stability is guaranteed only for $|\eta_0| < -\frac{m\bar{\xi}}{b}$. The features are analogous in the two other cases, in which $m > 0$, $b \gtrless 0$.

It is of interest to note that the choice of sufficiently small weight constants in the function of (1.5) permits an arbitrarily close approach to a relay characteristic of the optimal controller :

$$\xi = \bar{\xi}\,\mathrm{sign}\left(-\frac{k+b}{m}\eta\right). \tag{2.11}$$

However, the execution of the limiting transfer itself requires additional discussion.

3. Possible Generalizations of the Functional of (1.5)

We now consider the case of optimizing a functional of the form

$$I(\xi) = \int_0^\infty (V + \dot{\xi}^2)\,dt. \tag{3.1}$$

In accordance with transformation (2.1), we have

$$I = [\varphi(\zeta)] = \int_0^\infty \left[\sum_k a_k\eta_k^2 + c\varphi^2(\zeta) + \left(\frac{\partial\varphi}{\partial\zeta}\dot{\zeta}\right)^2\right]dt.$$

The boundary conditions remain as before, i.e., (1.4). We set

$$H = \Sigma a_k\eta_k^2 + c\varphi^2(\zeta) + \left(\frac{\partial\varphi}{\partial\zeta}\dot{\zeta}\right)^2$$

$$+\sum_k \lambda_k\left[\dot{\eta}_k - \sum_\alpha b_{k\alpha}\eta_\alpha - m_k\varphi(\zeta)\right]. \tag{3.2}$$

Since

$$\frac{\partial H}{\partial\dot{\zeta}} = 2\left(\frac{\partial\varphi}{\partial\zeta}\right)^2\dot{\zeta},\ \frac{\partial H}{\partial\zeta} = \left[2c\varphi(\zeta) + 2\frac{\partial^2\varphi}{\partial\zeta^2}\dot{\zeta}^2\right]\frac{\partial\varphi}{\partial\zeta} -$$

$$-\sum_k \lambda_k m_k\frac{\partial\varphi}{\partial\zeta}.$$

then the equations of the variational problem will have the form

$$\dot{\eta}_k = \sum_\alpha b_{k\alpha}\eta_\alpha + m_k\varphi(\zeta),$$

$$\dot{\lambda}_k = -\sum_\alpha b_{\alpha k}\lambda_\alpha + 2a_k\eta_k, \tag{3.3}$$

$$\frac{d}{dt}\left[2\left(\frac{\partial\varphi}{\partial\zeta}\right)^2\dot{\zeta}\right] = \left[2c\varphi(\zeta) + 2\frac{\partial^2\varphi}{\partial\zeta^2}\dot{\zeta}^2 - \sum_k\lambda_k m_k\right]\frac{\partial\varphi}{\partial\xi}.$$

Consider the last of these equations. After some obvious simplifications, we find that

$$2\left[\frac{\partial\varphi}{\partial\zeta}\ddot{\zeta} + \frac{\partial^2\varphi}{\partial\zeta^2}\dot{\zeta}^2\right]\frac{\partial\varphi}{\partial\zeta} = \left[2c\varphi(\zeta) - \sum_k m_k\lambda_k\right]\frac{\partial\varphi}{\partial\zeta} \tag{3.4}$$

Therefore, (3.3) should be considered for the two cases

$$\frac{\partial\varphi}{\partial\zeta} = 0, \tag{3.5}$$

when the system's motion occurs on the boundary of region $\bar{N}$, and

$$2\left[\frac{\partial\varphi}{\partial\zeta}\ddot{\zeta} + \frac{\partial^2\varphi}{\partial\zeta^2}\dot{\zeta}^2\right] = 2c\varphi(\zeta) - \sum_k m_k\lambda_k, \tag{3.6}$$

when the system's motion takes place on the interior points of region $\bar{N}$. In the first case we have the solution

$$\varphi(\zeta) = \pm\bar{\xi} \quad \text{for} \quad |\zeta| \geqslant \zeta^*. \tag{3.7}$$

In the second case, since $\frac{\partial\varphi}{\partial\zeta}\dot{\zeta} = \frac{d}{dt}\varphi(\zeta)$, Eq. (3.6) reduces to the form

$$2\ddot{\varphi} = 2c\varphi - \sum_k m_k\lambda_k. \tag{3.8}$$

In conjunction with the first 2n equations of (3.3), this determines the controller equation

$$\dot{\xi} = \sum_\alpha p_\alpha\eta_\alpha - r\xi. \tag{3.9}$$

It is essential to note that, inasmuch as Eqs. (3.3) of the variational problem coincide exactly with (2.1) and (3.3) of [1], the equation just found, (3.9), coincides exactly with (4.5) of [1].

On the $\xi, \eta_1, \ldots, \eta_n$ phase space we sketch the two hyperplanes

$$\sum p_\alpha\eta_\alpha = \pm r\bar{\xi}. \tag{3.10}$$

Then, the controller equation being sought will be written as

$$\dot{\xi} = \begin{cases} +\bar{\xi} & \text{for} \quad \dfrac{\Sigma p_\alpha\eta_\alpha}{r} \geqslant \bar{\xi}, \\ \Sigma p_\alpha\eta_\alpha - r\xi & \text{for} \quad \left|\dfrac{\Sigma p_\alpha\eta_\alpha}{r}\right| < \bar{\xi}, \\ -\bar{\xi} & \text{for} \quad \dfrac{\Sigma p_\alpha\eta_\alpha}{r} \leqslant -\bar{\xi}. \end{cases} \tag{3.11}$$

4. The Weierstrass-Erdmann Conditions

To complete the investigation of the necessary conditions for the existence of an optimal solution of the analytic design problem, one should convince oneself that the Weierstrass-Erdmann conditions hold at the nodal points of function ξ.

In the case when one is considering a functional of the form of (3.1), these conditions reduce to the holding of the following equalities:

$$\frac{\partial H^+}{\partial \dot{\eta}_k} = \frac{\partial H^-}{\partial \dot{\eta}_k}, \qquad \frac{\partial H^+}{\partial \dot{\zeta}} = \frac{\partial H^-}{\partial \dot{\zeta}} \qquad (k = 1, \ldots, n), \tag{4.1}$$

$$H^+ - \sum_k \left(\frac{\partial H}{\partial \dot{\eta}_k} \dot{\eta}_k \right)^+ - \left(\frac{\partial H}{\partial \dot{\zeta}} \zeta \right)^+ = H^- - \sum_k \left(\frac{\partial H}{\partial \dot{\eta}_k} \dot{\eta} \right)^- - \left(\frac{\partial H}{\partial \dot{\zeta}} \zeta \right)^- . \tag{4.2}$$

Here, H is the function in (2.3) or in (3.2), and the "+" and "-" signs denote that the computation of the corresponding functions is carried out to the left or to the right of the nodal points of function ξ.

One easily convinces himself that, if the first n conditions of (4.1) hold, which reduce to the equations

$$\lambda_k^+ = \lambda_k^- \qquad (k = 1, \ldots, n), \tag{4.3}$$

then the two remaining conditions are also satisfied for any functions $\xi, \eta_1, \ldots, \eta_n$ of class C. As for (4.3), it can always be satisfied, as is easily verified, if the optimal system is stable.

Thus, in the example considered in Section 2, the solutions for the optimal controller in the case when have the form $|\xi| \geqslant \bar{\xi}$

$$\begin{aligned} \eta &= c_1 e^{bt} \mp \frac{m\bar{\xi}}{b}, \\ \lambda &= c_2 e^{-bt} \mp \frac{2am}{b^2} \bar{\xi} + \frac{ac_1}{b} e^{bt}, \end{aligned} \tag{4.4}$$

and, in the case when $|\xi| < \bar{\xi}$

$$\begin{aligned} \eta &= \bar{c}_1 e^{-kt} + \bar{c}_2 e^{kt}, \\ \lambda &= \frac{2c}{m^2} [-(k+b) \bar{c}_1 e^{-kt} + (k-b) \bar{c}_2 e^{kt}], \\ \xi &= \frac{1}{m} [-(k+b) \bar{c}_1 e^{-kt} + (k-b) \bar{c}_2 e^{kt}]. \end{aligned} \tag{4.5}$$

From the conditions on the left end (for t = 0)

$$\eta_0 = c_1 \mp \frac{m\bar{\xi}}{b}; \qquad \xi_0 = \pm \bar{\xi}. \tag{4.6}$$

From the conditions on the right end (for t = ∞),

$$\bar{c}_2 = 0. \tag{4.7}$$

The continuity conditions at the nodal points are

$$\bar{c}_1 = c_1 e^{bt_\bullet} \mp \frac{m\bar{\xi}}{b}; \quad -\frac{k+b}{m} \bar{c}_1 = \pm \bar{\xi}. \tag{4.8}$$

The single condition of (4.3) has the form

$$c_2 e^{-bt_\bullet} \mp \frac{2am\bar{\xi}}{b^2} + \frac{ac_1}{b} e^{bt_\bullet} = -\frac{2c}{m^2} (k+b) \bar{c}_1. \tag{4.9}$$

The last equation of (4.1) and (4.2) reduce to identities.

Equations (4.6), (4.7), and (4.9) define the constants c_1, $\bar{c}_7$, and c_2; (4.8) define c_1 and the time $t_\bullet$, corresponding to the nodal point of function ξ. We, hence, find that

$$\pm \frac{k}{b} \frac{m\bar{\xi}}{k+b} = \left(\eta_0 \pm \frac{m\bar{\xi}}{b} \right) e^{bt_\bullet}. \tag{4.10}$$

It is easily established that, for m < 0 and b < 0, (4.10) is solvable for $t_\bullet > 0$ for any $|\eta_0| \geqslant \left| -\frac{m\bar{\xi}}{k+b} \right|$; if this latter inequality does not hold, the system does not go beyond the boundary $|\xi| = \bar{\xi}$ and no nodal point exists. In the case when m < 0 and b > 0, the equation has a solution with respect to $t_\bullet > 0$ for any η_0 which satisfy the inequality

$$\left| -\frac{m\bar{\xi}}{k+b} \right| \leqslant |\eta_0| \leqslant \left| -\frac{m\bar{\xi}}{b} \right|$$

This is again the case shown on Figs. 2 and 3. The analogous features also occur for the other combinations of signs of m and b.

If the functional of (3.1) is used as the criterion of system optimality, then the Weierstrass-Erdmann conditions also are met. Indeed, the solution of the system for $|\xi| = \bar{\xi}$ is as follows:

$$\begin{aligned} \eta &= c_1 e^{bt} \mp \frac{m\bar{\xi}}{b}, \quad \xi = \bar{\xi}, \\ \lambda &= c_2 e^{-bt} \mp \frac{2am\bar{\xi}}{b^2} + \frac{ac_1}{b} e^{bt}. \end{aligned} \tag{4.11}$$

With the boundary conditions at infinity taken into account, the solution of the system for $|\xi| < \bar{\xi}$ is

$$\begin{aligned} \eta &= \bar{c}_1 e^{\mu_1 t} + \bar{c}_2 e^{\mu_2 t}, \\ \xi &= \frac{\mu_1 - b}{m} \bar{c}_1 e^{\mu_1 t} + \frac{\mu_2 - b}{m} \bar{c}_2 e^{\mu_2 t}, \\ \lambda &= -\frac{2a}{\mu_1 + b} \bar{c}_1 e^{\mu_1 t} - \frac{2a}{\mu_2 + b} \bar{c}_2 e^{\mu_2 t}. \end{aligned} \tag{4.12}$$

We find from the initial conditions that

$$\eta_0 = c_1 \mp \frac{m\bar{\xi}}{b}, \quad \xi_0 = \bar{\xi}. \tag{4.13}$$

The continuity conditions for the functions ξ and η at the nodal points are

$$\bar{\xi} = \frac{\mu_1 - b}{m} \bar{c}_1 + \frac{\mu_2 - b}{m} \bar{c}_2, \quad c_1 e^{bt_\bullet} \mp \frac{m\xi}{b} = \bar{c}_1 + \bar{c}_2. \tag{4.14}$$

The Weierstrass-Erdmann conditions reduce to the holding of the two equalities·

$$\lambda^+ = \lambda^-, \quad \left[\left(\frac{\partial \varphi}{\partial \zeta} \right)^2 \dot{\zeta} \right]^+ = \left[\left(\frac{\partial \varphi}{\partial \zeta} \right)^2 \dot{\zeta} \right]^- \tag{4.15}$$

or, what amounts to the same thing, to the equalities:

$$c_2 e^{-bt_\bullet} \mp \frac{2am\bar{\xi}}{b^2} + \frac{ac_1}{b} e^{bt_\bullet} = -\frac{2a}{\mu_1 + b} \bar{c}_1 - \frac{2a}{\mu_2 + b} \bar{c}_2,$$

$$\mu_1 (\mu_1 - b) \bar{c}_1 + \mu_2 (\mu_2 - b) \bar{c}_2 = 0.$$

Equation (4.13) defines the constant c_1; from (4.14) we find that

$$\bar{c}_1 = \frac{1}{\mu_2 - \mu_1}[(\mu_2 - b)\eta^* - m\bar{\xi}],$$
$$\bar{c}_2 = \frac{1}{\mu_2 - \mu_1}[\mu\bar{\xi} - (\mu_1 - b)\eta^*], \quad (4.17)$$

where $\eta^* = \eta(t_*)$. The first equation of (4.16) defines the constant c_2, the second defines the moment of time t_* when the system passes through the nodal point. This last equation, in correspondence with (4.17), takes the form

$$m\bar{\xi}(\mu_1 + \mu_2 - b) = (\mu_1 - b)(\mu_2 - b)\eta^*. \quad (4.18)$$

This last equation means that, at the nodal point, the servomotor speed must vanish, as was also the case with (5.4) of [1].

OPTIMAL PROCESSES IN SECOND-ORDER PULSE-RELAY SYSTEMS

V. N. Novosel'tsev

(Moscow)

Translated from Avtomatika i Telemekhanika Vol. 21, No. 5, pp. 569-574, May, 1960
Original article submitted December 4, 1959

The problem of finding the optimal control law in pulse-relay second-order systems is considered.

Let there be given a physical system which is described by the n-dimensional vector $x_i(t)$ and let the position of the representative point in n-dimensional phase space at the initial moment of time be defined by $x_i(0)$. The representative point must be translated to the given point ξ_i. The process will have been completed after time T, and will be optimal if no other process provides for the attainment of ξ_i in a time less than T.

The optimal control problem for systems described by differential equations of the form

$$\frac{dx_i}{dt} = \varphi_i(x_i, u_l, t) \qquad (i = 0, 1, \ldots, n;\ l = 0, 1, \ldots, r) \tag{1}$$

has been widely investigated in a number of works [1, 2].

In this posing of the problem, time is continuous, and one imposes limitations of the following type on the controlling quantities u_l:

$$|u_l| \leqslant N_l. \tag{2}$$

In [3] the analogous problem is solved for systems described by finite difference equations

$$x_i([k+1]h) - x_i(kh) = \Big[\sum_{j=1}^{n} a_{ij}x_j(kh) + \sum_{l=1}^{r} q_{il}u_l(kh) + f_i(kh)\Big]h. \tag{3}$$

In this problem, time is discrete, t = kh (k = 0,1, . . .) for an arbitrarily chosen h, and conditions of the following type are imposed on the controlling quantities:

$$|u_l(kh)| \leqslant N. \tag{4}$$

Such a system was investigated in [4].

The system of second-order finite difference equations which we consider in this paper, these equations describing planar motion, has the form

$$\begin{aligned} x([k+1]h) - x(kh) &= y(kh)h, \\ y([k+1]h) - y(kh) &= u(kh)h, \end{aligned} \tag{5}$$

where x, y are the point coordinates on the phase plane and u is the point acceleration (controlling action). The behavior of the points is considered under the limitation

$$|u_k| = \text{const}. \tag{6}$$

In this case (a pulse-relay system), it is required to determine the control law $\{u_k^0\}$ which allows the initial point (x_0, y_0) to be translated to the origin of coordinates of phase space in the least possible number of steps K^0. The time here, as in (3), is discrete but, in contradistinction to (1) and to (3), the values of the controlling quantities are also discrete.

The optimal control problem for a system with (5), which we shall solve in the present work, can be classified as a simple number-theoretical problem. It should be mentioned that problems of this type will continue to arise with ever greater frequency in connection with the use of discrete computer technology in automatic control.

It seems advisable to sketch briefly our plan for finding the optimal control law for such a problem. We first find the optimal control law for initial points of the form $(n^2, 0)$, for which we shall use the results of the work of N. N. Krasovskii [3] (the corresponding expressions for the number of steps K^0 and for the control law $\{u^0\}$ can be easily and immediately obtained). We then construct the optimal control for all the integral points of the x axis, x > 0, and we show that the optimal trajectories completely fill up the region of the (x,y) plane defined by the expressions $0 \leq x \leq y(y-1)/2$, $y < 0$. Finally, we shall show that the optimal trajectories of all the other integral points of the (x, y) plane pass through one of the points already considered on the x axis in one of the half planes x > 0 or x < 0. On the basis of the optimal control law obtained, we shall construct an optimal switching line. At the end of this paper we shall discuss questions related to the nonsinglevaluedness of the control law obtained.

We turn now to the solution of the problem, to be carried out in accordance with the plan just given.

The solution obtained in [3] for a second-order system with (4) renders it possible, for a given h, to choose an optimal value of $|u_k|$ which depends on x_{i0} and ξ_i, but does not depend on the number k of steps, and to determine the unique moment for changing the sign of the controlling action (corresponding to a transition from a type N to a P-trajectory [1]).

The peculiar feature of our problem, when (4) been replaced by (6), is that, generally speaking, for a constant modulus of point acceleration, the sign of this acceleration changes more than once during the control process.

Indeed, we consider a point lying on the x axis at a distance x_0 from the origin of coordinates. Let x and y be changed for integer steps, i.e., $|u_k| = 1$, $h = 1$. If $|u_k| = a$ and $h = b$, where $a, b \neq 1$, this leads only to a corresponding change in the scales of the process. In accordance with [3], when (4) holds, K^0 is defined as the least integer which satisfies the inequality

$$\frac{K^2h^2}{4} \geqslant x_0.$$

Replacement of (4) by (6) entails only the change of the inequality sign to an equality sign, i.e.,

$$\frac{K^2h^2}{4} = x_0. \tag{7}$$

In order that (7) have integer solutions in K, it is necessary that x_0 be a perfect square, i.e., $x_0 = n^2$. For such points of the x axis, the optimal control law of [3] remains valid, it taking, in the given case, the form

$$u^0(kh) = -\operatorname{sign}\left[\frac{K^0}{2} - k\right],$$

$$K^0 = 2\sqrt{x_0} = 2n. \tag{8}$$

In the case of (6), for all the remaining points of the x axis, it is not possible to reach the origin of coordinates with a single switching of the acceleration's sign.

We limit ourselves initially to a consideration, for such points, of the half-plane $x > 0$, and to the requirement that one attain in the least number of steps some neighborhood of the origin of coordinates consisting, for example, of the two points (0,0) and (1,0). We define the position of the point on the x axis by the distance p:

$$x_0 = n^2 + p,$$

where

$$0 < p \leqslant 2n + 1.$$

Since the chosen neighborhood is characterized by $y_{K^0} = 0$ then, for $y_0 = 0$, we have the equation

$$\sum_{u_i > 0} u_i = -\sum_{u_j < 0} u_j \quad (i, j = 1, 2, \ldots, K^0), \tag{9}$$

i.e., the neighborhood of zero may be reached only in an even number of steps. It can be shown that

$$K^0 = \begin{cases} 2n, & \text{if} \quad p = 1 \\ 2n + 2, & \text{if} \quad p = 2, 3, \ldots, 2n + 1. \end{cases} \tag{10}$$

In fact, for a zero initial velocity, the path taken by the point in $2n$ steps is maximal for the choice of $u_0(kh)$, according to (8), and is equal to n^2. With this, the point is at the distance p from the origin of coordinates, so that, for $p = 1$, the point falls in the neighborhood of the origin of coordinates, and (8) defines its optimal control law. When (9) is taken into account, for $p \neq 1$, the magnitude of K^0 cannot be less than $2n + 2$.

We now assume that the optimal control law has the form:

$$u_k^0 = -\operatorname{sign}\left[\frac{K^0}{2} - k - 1\right] - 2\delta_{kz},$$

$$\delta_{kz} = \begin{cases} 1 & \text{for} \quad z = k \\ 0 & \text{for} \quad z \neq k \quad (k = 1, 2, 3, \ldots, K^0), \end{cases} \tag{11}$$

where K^0 is defined by (10).

Now we show that one can choose a z corresponding to an optimal control.* As the end point for an even $p = 2l$, we choose the point $x_{K^0} = 1$; for $p = 2l + 1$, let such a point be $x_{K^0} = 0$ ($l = 1, 2, \ldots$). Then z must be so chosen that, for any parity of p ($p \neq 1$), the following equation holds:

$$S_{K^0} + E\left[\frac{p}{2}\right] - E\left[\frac{p-1}{2}\right] = n^2 + p,$$

where S_{K^0} is the path taken by the system during the control process in K_0 steps; $E(\alpha)$ denotes the integral part of α. At the same time, by adding the segments of path taken by the system for the controlling actions of (11), we obtain

$$S_{K^0} = n^2 + 2[2n - 1 - (z - 1)] - 1.$$

By comparing the two last formulas, we obtain the expression for z:

$$z = K^0 - E\left[\frac{p+1}{2}\right]. \tag{12}$$

Consequently, if z is defined by (12), then (11) defines the optimal control law.

The optimal law just obtained is easily extended to any integral point of the phase half plane $x > 0$. In fact, the initial points $x_0 = \operatorname{sign} y_0$ for $x_0 \geq y_0(y_0-1)/2$ (the boundary of this region is the N-trajectory which terminates in the origin of coordinates, i.e., $x_0 = y_0(y_0-1)/2$) lie on one of the optimal trajectories considered. One easily convinces himself that at least one optimal trajectory passes through each point of this region. This follows from the fact that the optimal control law, up until the first switchings (i.e., for $k \leq K^0/2-1$), does not depend on p. The points $\operatorname{sign} x_0 = \operatorname{sign} y_0$ and $\operatorname{sign} x_0 = -\operatorname{sign} y_0$, with the condition that $x_0 < y_0(y_0-1)/2$, are taken over into the case just considered after y_0 steps $u_k = -\operatorname{sign} x_0$ in the right-and left-hand planes respectively. It is easily seen that the "initial translation" of points moving along P- or N-trajectories are also optimal. If necessary, the optimal control law can be written for arbitrary initial conditions. For example, for the case of initial points defined by the conditions

$$\operatorname{sign} x_0 = -\operatorname{sign} y_0, \quad x > {}^1/_2\, y_0(y_0 - 1) \quad (p \neq 1),$$

$$K^0 = 2(n + 1) - |y_0|,$$

$$u_k^0 = -\operatorname{sign}[n - |y_0| - k] - 2\delta_{kz},$$

---

* We adopt the convention that sign 0 = 1.

we have

$$z = K^0 - E\left[\frac{p+1}{2}\right] - |y_0|,$$

$$p = x_0 + {}^1/_2\, y_0(y_0+1) - n^2.$$

The control law just found corresponds to a translation of points to the neighborhood of zero, but it is easily verified that if K^0 remains invariant, and for any number of switchings, if (9) is met then the parity of S_k is unchanged. Therefore, the law that translates the point directly to the origin of coordinates must be supplemented by two steps (when $u_{K^0+1} = -u_{K^0+2} = 1$) to all the trajectories which terminate in the point (1,0). Then, the optimal control law, in the form of (11 and (12), will be valid for all points and, for all p, we shall have $K^* = 2n + 2$.

The control law in the form of (11) and (12) allows us to find the optimal switching line.

We consider the phase half-plane $x > 0$ and the half-line $y = y^*$ on it. It is obvious that the optimal stimulus for all points with integral coefficients on the half-line $y = y^* > 0$ will be $u^0 = -\text{sign}\, x = -1$. Now let $y^* < 0$ and $v = |y^*|$ (Fig. 1). The line under consideration intersects the N-trajectory $x = v(v-1)/2$ at point $\{a[v(v-1)/2, y^*]\}$. Then, for all points with coordinates $0 \leq x \leq v(v-1)/2$; $y = y^*$, we have that $u^0 = \text{sign}\ x = +1$. It remains to consider the points $x > v(v-1)/2$, $y = y^* > 0$. We select an interval of the x axis which contains $2v + 1$ points $v^2 \leq x_0 < (v+1)^2$. For all points, according to (10), $K^0 = 2v^2 + 2$ (in the sense of a translation to the neighborhood of the origin of coordinates) and (11), it is required that $u^0 = \text{sign}\ x = 1$, since a point of such a segment falls on the line after v steps. For points on the x axis such that $x_0 \geq (v+1)^2$, the first change of sign occurs on the step whose ordinal number is known to be greater than v, and for these points $u^0 = -\text{sign}\ x$. Thus, for $y_0 = -v$, the optimal control is these points $u^0 = -\text{sign}\ x$. Thus, for $y_0 = -v$, the optimal control is

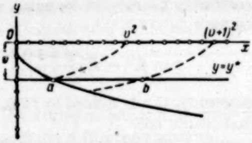

Fig. 1.

$$u^0 = \begin{cases} -\,\text{sign}\, x_0, & \text{if} \quad x \geqslant b, \\ +\,\text{sign}\, x_0, & \text{if} \quad x < b. \end{cases}$$

The abscissa of point b is obviously equal to $v(v-1)/2 + (2v+1) = (v+1)(v+2)/2$. Since the argument did not depend on the choice of v, one may assert that the expression just found defines the optimal switching line on the half-plane $x > 0$.

By carrying out an analogous argument for the half-plane $x < 0$, we can obtain the complete expression for the optimal switching line:

$$u^0 = \begin{cases} -1, & \text{if} \quad x \geqslant f(v, x), \\ +1, & \text{if} \quad x < f(v, x), \end{cases} \tag{13a}$$

where $v = |y|$,

$$f(v, x) = \begin{cases} f_1(v) = \dfrac{(v+1)(v+2)}{2}, & \text{if} \quad x > 0, \\ f_2(v) = \dfrac{v(v+3)}{2}, & \text{if} \quad x < 0. \end{cases} \tag{13b}$$

In the half-plane $x < 0$, to retain the "≥" and "<" signs unchanged, the switching line must be translated by unity toward the y axis.

The switching line just obtained is optimal in the sense that the representative point is translated either to the origin of coordinates or to a neighborhood of it.

The optimal control law, which we have found in the form of (11) and (12), is not unique. We now show that it is possible to define other forms of the control law. We consider the control of points on an expanse of $2n + 2$ steps. A control for which the sign of the stimulus is constant (for example, a negative stimulus) on the first $n + 1$ steps ($i = 1, 2, \ldots, n+1$) and, for $i = n+2, \ldots, 2n+2$, the sign is reversed, we shall call a "canonical" control. With canonical control, there are $(n+1)^2$ points on the path. Since, according to (9), the numbers of steps with "+" and with "−" signs are equal, then all possible controls can be obtained from the canonical one by permutations of signs pairwise between both sign-invariant portions. If, for example, we change the signs of the two terms with ordinal numbers m_1 and m_2

$$1 < m_1 \leqslant n+1,\ n+2 \leqslant m_2 \leqslant 2n+2,$$

then the points passed through on the path will be fewer than with the canonical control, and will be defined by the expression

$$S_{2n+2} = (n+1)^2 - 2(m_2 - m_1) \tag{14}$$

If the initial point is defined by the conditions $x = n^2 + p$, $y = 0$, then we can obtain the expression for its "optimal" control laws by equating $S_{2n+2} = n^2 + p$. From this, we obtain the relationship for m_1 and m_2:

$$m_2 - m_1 = \frac{2n-p}{2}. \tag{15}$$

Fig. 2.

In this work, we fixed the value of $m_1 = n + 1$, and m_2 varied as a function of p. Such an approach made it possible to obtain the optimal switching line.

A typical form of controlling stimulus is illustrated on Fig. 2. Here, $x_0 = -19$ and $y_0 = 0$.

Figure 3 shows the optimal trajectory for the point ($x_0 = 12$, $y_0 = 0$) which corresponds to n = 3 and p = 3. Trajectory 1 is formed in accordance with optimal switching line 3, and trajectory 2 (dashed lines) is obtained from the control of (15) for $m_1 = n$.

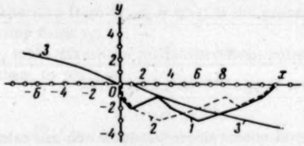

Fig. 3.

Figure 4 shows one of the simplest variants of a realization of an optimal control system using switching lines. The system's action is based on the determination of the mutual positioning of the representative point and the switching line in the half-plane where x > 0.

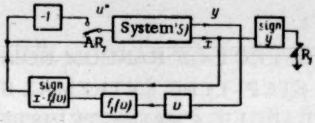

Fig. 4.

THE EFFECT OF RANDOM NOISE ON THE STEADY-STATE OPERATION OF A STEP-TYPE EXTREMAL SYSTEM FOR AN OBJECT WITH A PARABOLIC CHARACTERISTIC

T. I. Tovstukha
(Moscow)

Translated from Avtomatika i Telemekhanika Vol. 21, No. 5, pp. 575-584, May, 1960
Original article submitted October 21, 1959

The optimal parameters of the controlling portion of the extremal system under consideration are calculated. These parameters must be determined from estimates of the deviations from the minimum characteristics in the steady state.

It is shown that, in the particular case of uniformly distributed noise increments, it is most advantageous to operate with small steps, to be determined below.

1. Posing of the Problem

In this paper we consider the case of a step-type extremal system whose object has a parabolic characteristic $y = x^2$. The system's task is the automatic search for, and maintenance of, the minimum of the characteristic. The following posing of the problem, as well as the notation, are the same as in [1] of A. A. Fel'dbaum. All quantities are considered at discrete moments of time $t = nT$ ($n = 0, 1, 2, \ldots$), where T is the time between two successive working steps, or the duration of one cycle. Figure 1 is a block schematic of the extremal system under consideration; O is the object of control, its input and output being related by the function

$$y[n] = x^2[n]. \tag{1}$$

Random noise z[n] acts at the object's output. The noise increments $v = z[n + 1] - z[n]$ are assumed to be statistically independent quantities with probability density $\rho(v)$ and zero mean value. The noise z[n] can be identified, for example, with the random noise in the measuring block of an actual system. Slow shifts of the characteristic, or input noise of the object, will not be considered here. The action of noise retards the automatic search for the minimum of the object's characteristic, where the minimum itself is determined with a certain error.

The actual object output, which can be measured, is the sum of the output y[n] and the random noise, i.e., the quantity

$$w[n] = y[n] + z[n]. \tag{2}$$

The quantity w[n] is applied to the input of the controlling portion of the system C.

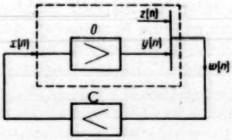

Fig. 1

The search for a minimum is implemented by means of successive cycles; each cycle includes a test to determine the direction of motion toward a minimum, and a working operation which implements this motion. The controlling portion, with its testing motions, disturbs the object's regimen. In the system under consideration, at the beginning of each half cycle, the object's input x [n] receives a stepwise increment of $(\Delta x)_1 = a$ (at the beginning of the cycle) and $(\Delta x)_2 = -a$ (in the middle of the cycle). At the object's output, at the end of each half cycle, one measures the corresponding disturbances $w_1 = y_1 + z_1$ and $w_2 = y_2 + z_2$ and compares them. Thus, one determines the direction of motion toward a minimum, or the sign of the working step (the magnitude of the working step, as of the test step, is a):

$$\begin{aligned} \Delta x[n] &= -a \operatorname{sign} \Delta w[n], \\ \Delta w[n] &= w_1 - w_2. \end{aligned} \tag{3}$$

It is possible with this to make a false step, on moving away from the minimum, since the quantity w is made up of the true output of the object plus noise. If one know the distribution law of the noise increments, $\rho(v)$, then the probability of a false step from the point x equals

$$p(x) = P\{v > \Delta y\},$$

where $\Delta y = y_1 - y_2$, $v = z_1 - z_2$, or

$$p(x) = \int_{-\infty}^{-|\Delta y|} \rho(v)\, dv. \tag{4}$$

The probability of a correct step (one directed toward the minimum) from point x equals

$$q(x) = 1 - p(x).$$

Possible neighboring points $\underline{x}$ are at a distance equal to the working step $\underline{a}$ from each other. We renumber the possible discrete states of the system, assigning the subscript zero to the state which corresponds to the minimum of the characteristic, i.e.,

$$x = ia \qquad (i = -\infty, \ldots, -1, 0, 1, \ldots, \infty). \tag{5}$$

We introduce the notation: $p_i = p(x_i)$ is the probability of a false step from x_i, $q_i = q(x_i)$ is the probability of a correct step from x_i.

If p_{jk} is the transition probability from point x_j to point x_k then, in our case,

$$p_{k,\,k+1} = \begin{cases} p_k & (k > 0), \\ q_k & (k < 0), \end{cases}$$
$$p_{k,\,k-1} = \begin{cases} q_k & (k > 0), \\ p_k & (k < 0), \end{cases}$$
$$p_{k,\,l} = 0 \qquad (l \neq k-1,\ k+1). \tag{6}$$

Thus, the process of seeking a minimum can be considered as a discrete Markov process.

We denote by the "weight" of state x_i the mean value of the object's outputs for the two tests, using the notation $(\overline{\Delta y})_i$ for this quantity. In correspondence with (1) and (5),

$$(\overline{\Delta y})_i = a^2(i^2 + 1) \qquad (i = 0, \pm 1, \pm 2, \ldots). \tag{7}$$

The difference of the values of $\underline{y}$ in the test, $\Delta y =$ $= y_1 = y_2$, is defined as

$$(\Delta y)_i = 4ia^2 \qquad (i = 0, \pm 1, \pm 2, \ldots). \tag{8}$$

The probabilities of false and of correct steps from state x_i are

$$p_i = \int_{-\infty}^{-4|i|a^2} \rho(v)\,dv, \qquad q_i = 1 - p_i. \tag{9}$$

The steps from the minimum, both at the point $x_{+1} = a$ and at the point $x_{-1} = -a$ are false, with a probability of $p_0 = 1/2$.

For convenience and clarity of the exposition, we can construct an equivalent scheme of the discrete Markov process [2]. Such a scheme is shown in Fig. 2. The points on it represent the possible states of the system. The arrows show the transitions from state to state. The probabilities of these transitions are shown. Z is the operator for translation in time, showing that the transition is carried out during a working cycle.

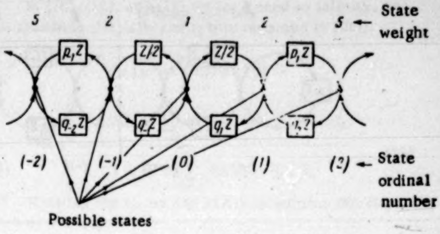

Fig. 2

We denote by $P_i[n]$ the probability that the system is in state x_i at time $t_n = nT$. Then, the mathematical expectation of the output quantity is

$$M_n[y] = \sum_{i=-\infty}^{\infty} (\overline{\Delta y})_i P_i[n] = a^2 \sum_{i=-\infty}^{\infty} (i^2 + 1) P_i[n]. \tag{10}$$

It is necessary to determine $\lim\limits_{n\to\infty} M_n[y]$, if this limit exists, and also to find the $\underline{a}$ for which this limit is a minimum.

The case of an extremal control system with the piecewise-linear characteristic $y = |x|$ was devoted in work [1]. It was shown there that, in the steady state, the minimum value of the mean error in $\underline{y}$ corresponds to a step of size $a \approx 0$ for normally or uniformly distributed output noise.

2. Determination of the Mathematical Expectation and the Dispersion of the Object's Output Variable in the Steady State

We write the equations for the probabilities of the system's states:

$$\begin{aligned}
&\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \\
&P_{-2}[n] = P_{-3}[n-1]\,q_3 + P_{-1}[n-1]\,p_1, \\
&P_{-1}[n] = P_{-2}[n-1]\,q_2 + P_0[n-1]\,\tfrac{1}{2}, \\
&P_0[n] = P_{-1}[n-1]\,q_1 + P_1[n-1]\,q_1, \\
&P_1[n] = P_2[n-1]\,q_2 + P_0[n-1]\,\tfrac{1}{2}, \\
&P_2[n] = P_3[n-1]\,q_3 + P_1[n-1]\,p_1, \\
&\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots
\end{aligned} \tag{11}$$

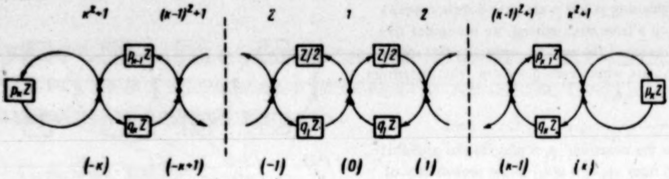

Fig. 3

We have taken into account here that, in correspondence with (9), $p_i = p_{-i}$ and $q_i = q_{-i}$.

We now consider the finite system of 2k + 1 states, shown on Fig. 3. The equations of such system are written in the form

$$
\begin{aligned}
P_{-k}[n] &= P_{-k+1}[n-1]\,p_{k-1} + P_{-k}[n-1]\,p_k,\\
P_{-k+1}[n] &= P_{-k+2}[n-1]\,p_{k-2} + P_{-k}[n-1]\,q_k,\\
&\dots\dots\dots\dots\dots\dots\\
P_{-2}[n] &= P_{-1}[n-1]\,p_1 + P_{-3}[n-1]\,q_3,\\
P_{-1}[n] &= P_0[n-1]\,\frac{1}{2} + P_{-2}[n-1]\,q_2,\\
P_0[n] &= P_{-1}[n-1]\,q_1 + P_1[n-1]\,q_1,\\
P_1[n] &= P_0[n-1]\,\frac{1}{2} + P_2[n-1]\,q_2,\\
P_2[n] &= P_1[n-1]\,p_1 + P_3[n-1]\,q_3,\\
&\dots\dots\dots\dots\dots\dots\\
P_{k-1}[n] &= P_{k-2}[n-1]\,p_{k-2} + P_k[n-1]\,q_k,\\
P\ [n] &= P_{k-1}[n-1]\,p_{k-1} + P_k[n-1]\,p\,.
\end{aligned}
\tag{12}
$$

We consider the limiting system for n → ∞, assuming that the $\lim\limits_{n\to\infty} P_i[n] = r_i$ exists. In this case,

$$
\begin{aligned}
r_{-k} &= r_{-k+1}p_{k-1} + r_{-k}p_k,\\
r_{-k+1} &= r_{-k+2}p_{k-2} + r_{-k}q_k,\\
&\dots\dots\dots\dots\\
r_{-2} &= r_{-1}p_1 + r_{-3}q_3,\\
r_{-1} &= r_0\,\frac{1}{2} + r_{-2}q_2,\\
r_0 &= r_{-1}q_1 + r_1q_1,\\
r_1 &= r_0\,\frac{1}{2} + r_2q_2,\\
r_2 &= r_1p_1 + r_3q_3,\\
&\dots\dots\dots\dots\\
r_{k-1} &= r_{k-2}p_{k-2} + r_kq_k,\\
r_k &= r_{k-1}p_{k-1} + r_kp_k.
\end{aligned}
\tag{13}
$$

It is obvious that

$$\sum_{i=-k}^{k} r_i = 1. \tag{14}$$

We always have 2k + 2 equations in 2k + 1 unknowns. We consider the system of the first 2k equations of (13) and (14), and we determine the r_i which satisfy this system. It will easily be shown that they also satisfy the last equation of (13).

If we also take into account that, by virtue of symmetry, $r_i = r_{-i}$, we shall consequently consider the system

$$
\begin{aligned}
r_0 &= 2r_1q_1,\\
r_1 &= r_0\,\frac{1}{2} + r_2q_2,\\
r_2 &= r_1p_1 + r_3q_3,\\
&\dots\dots\dots\dots\\
r_{k-1} &= r_{k-2}p_{k-2} + r_kq_k\\
r_0 &+ 2\sum_{i=1}^{k} r_i = 1.
\end{aligned}
\tag{15}
$$

We shall successively express all the r_i in terms of r_1:

$$
\begin{aligned}
r_0 &= 2q_1r_1,\\
r_2 &= r_1\,\frac{p_1}{1}\,\frac{1}{q_2}\,,\\
r_3 &= r_1\,\frac{p_1}{1}\,\frac{p_2}{q_2}\,\frac{1}{q_3}\,.\\
&\dots\dots\dots\dots
\end{aligned}
$$

It is easily shown that, in general,

$$r_i = r_1p_1\lambda_2\lambda_3\dots\lambda_{i-1}\zeta_i \qquad (2 \leqslant i \leqslant k), \tag{16}$$

where

$$\lambda_m = \frac{p_m}{q_m}, \quad \zeta_m = \frac{1}{q_m} \quad (m = 1, 2, \dots, k). \tag{17}$$

By substituting, in the last equation of (15), the expression for r_0 from the first equation and the expression for r_i from (16), we obtain

$$r_1 = \frac{1}{2\left(1 + q_1 + \sum\limits_{i=2}^{k} p_1\lambda_2\lambda_3\dots\lambda_{i-1}\zeta_i\right)}\,. \tag{18}$$

The value of r_0 is defined in terms of r_1 from the first equation of (15)

$$r_0 = 2r_1q_1. \tag{19}$$

It is easily verified that the thus determined r_i satisfy the last equation of (13), i.e., the one we didn't consider. Thus, the state probabilities in the steady state are completely given by (16)-(19).

We now turn back to (10). We need to determine the magnitude of the mathematical expectation in the steady state, i.e.,

$$\lim_{n\to\infty} M_n[y] = a^2 \sum_{i=-\infty}^{\infty} (i^2+1)\, r_i. \qquad (20)$$

In (16), (18), and (19) we let k tend to infinity, and we substitute the values of r_i thus obtained in (20):

$$M[y] = \lim_{n\to\infty} M_n[y] =$$

$$= a^2 \frac{1 + 2\zeta_1 + \sum\limits_{i=2}^{\infty} (i^2+1)\, \lambda_1\lambda_2 \ldots \lambda_{i-1}\zeta_i}{1 + \zeta_1 + \sum\limits_{i=2}^{\infty} \lambda_1\lambda_2 \ldots \lambda_{i-1}\zeta_i}. \qquad (21)$$

Knowing the r_i, we can easily determine the dispersion of the quantity y:

$$D[y] = \sum_{i=-\infty}^{\infty} (\overline{\Delta y})_i^2 r_i - M^2[y] =$$

$$= a^4 \left\{ \frac{\zeta_1 + \sum\limits_{i=2}^{\infty} i^4 \lambda_1\lambda_2 \ldots \lambda_{i-1}\zeta_i}{1 + \zeta_1 + \sum\limits_{i=2}^{\infty} \lambda_1\lambda_2 \ldots \lambda_{i-1}\zeta_i} + 2\frac{M[y]}{a^2} - 1 \right\} - M^2[y]. \qquad (22)$$

3. The Case of a Uniform Distribution Law for $\rho(v)$

In this particular case, the computations of M[y] and D[y] by (21) and (22) are easily reduced to numerical results. Let (cf., Fig. 4, a)

$$\rho(v) = \begin{cases} \dfrac{1}{2\eta} & (|v| \leqslant \eta), \\ 0 & (|v| > \eta). \end{cases} \qquad (23)$$

In correspondence with (9), the probabilities of false and correct steps are found from the formulas

$$p_i = \begin{cases} \dfrac{1}{2} - i\dfrac{4a^2}{2\eta} & \left(i < \dfrac{\eta}{4a^2}\right), \\ 0 & \left(i > \dfrac{\eta}{4a^2}\right); \end{cases} \qquad (24)$$

$$q_i = \begin{cases} \dfrac{1}{2} + i\dfrac{4a^2}{2\eta} & \left(i < \dfrac{\eta}{4a^2}\right), \\ 1 & \left(i > \dfrac{\eta}{4a^2}\right) \end{cases} \quad (i = 0, 1, \ldots).$$

We denote by k the integral part of the expression $(\eta - 4a^2)/4a^2$, $\eta = 4a^2 k + \beta$, $\gamma = \beta/4a^2$ (Fig. 4,b)

Then, from (21),

$$M[y] = a^2 \frac{1 + 2\zeta_1 + \sum\limits_{i=2}^{k+1} (i^2+1)\, \lambda_1\lambda_2 \ldots \lambda_{i-1}\zeta_i}{1 + \zeta_1 + \sum\limits_{i=2}^{k+1} \lambda_1\lambda_2 \ldots \lambda_{i-1}\zeta_i},$$

where λ_m and ζ_m are determined from (17), with account being taken of (24).

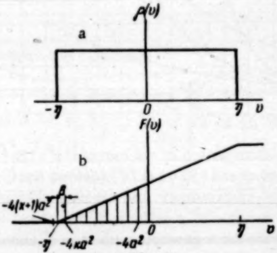

Fig. 4

To simplify the computations, we shall consider, not all a, but only those for which

$$\frac{\eta}{4a^2} = m, \qquad (25)$$

where m is an integer.

We easily obtain from (20), (23), and (24) (cf., the appendix)

$$M[y] = \begin{cases} \dfrac{\eta}{8} + a^2 & \left(\dfrac{\eta}{4a^2} > 1\right), \\ 1.5a^2 & \left(\dfrac{\eta}{4a^2} \leqslant 1\right). \end{cases} \qquad (26)$$

Here, since M[y] is a continuous function of a, $\eta/4a^2$ can take any value, either integral or fractional.

We compute the dispersion D[y] analogously (cf., the appendix)

$$D[y] = \begin{cases} \dfrac{\eta}{16}\left(\dfrac{\eta}{2} - a^2\right) & \left(\dfrac{\eta}{4a^2} > 1\right), \\ \dfrac{a^4}{4} & \left(\dfrac{\eta}{4a^2} \leqslant 1\right), \end{cases} \qquad (27)$$

or we compute the mean-square deviation

$$\sigma[y]=\begin{cases}\frac{1}{4}\sqrt{\eta\left(\frac{\eta}{2}-a^2\right)} & \left(\frac{\eta}{4a^2}>1\right),\\ \frac{a^2}{2} & \left(\frac{\eta}{4a^2}<1\right).\end{cases} \tag{28}$$

The dependence of M[y] and σ[y] on a for several different values of η is given on Fig. 5. For a comparison on the same graph, we give the dependence of the mathematical expectation and the mean-square dispersion on the size of the working step for the case of the piecewise-linear characteristic $y = |x|$, considered in [1], for the same noise distribution law. The corresponding computations are given in the appendix.

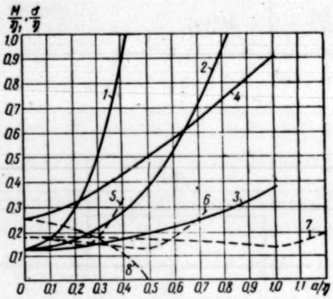

Fig. 5. Comparison of the curves $(M/\eta)(a/\eta)$ (solid lines) and $(\sigma/\eta)(a/\eta)$ (dashed lines) for parabolic characteristic and modulus characteristic in the case of a uniform distribution: curves 1 and 5 are for a parabola with $\eta = 4$, curves 2 and 6 are for a parabola with $\eta = 1$, curves 3 and 7 are for a parabola with $\eta = 0.25$, curves 4 and 8 are for the modulus.

It is clear from the graphs that, for the characteristic $y = x^2$, the optimal (from the point of view of simultaneous smallness of the mathematical expectation and the dispersion) working step a is close to a = 0. A small increase of the step decreases the mean-square deviation insignificantly, but increases the mathematical expectation of the output. In the modulus case, $y = |x|$, it is better to make the step larger than for the relationship $y = x^2$ since, for the modulus, an increase in the step (for small values of the step a) gives an insignificant increase of M[y] accompanied by a decrease of the dispersion.

In conclusion, the author wishes to thank A. A. Fel'dbaum for posing the given problem and for his useful advice. Thanks also to S. Ya. Raevskii for discussing the results obtained.

APPENDIX

1. Determination of the Mathematical Expectation and the Dispersion of the Output Variable for Uniformly Distributed Noise

By substituting (25) in (24) we get

$$p_i=\begin{cases}\frac{1}{2}-\frac{i}{2m} & (i<m),\\ 0 & (i\geqslant m);\end{cases}\qquad q_i=\begin{cases}\frac{1}{2}+\frac{1}{2m} & (i<m),\\ 1 & (i\geqslant m).\end{cases} \tag{I}$$

We find from (21), for m > 1,

$$M[y]=a^2\frac{1+2\zeta_1+\sum_{i=2}^{m}(i^2+1)\lambda_1\lambda_2\ldots\lambda_{i-1}\zeta_i}{1+\zeta_1+\sum_{i=2}^{m}\lambda_1\lambda_2\ldots\lambda_{i-1}\zeta_i},$$

where λ_l and ζ_l are determined from (17) with account being taken of (I).

After some transformations, we obtain the expression

$$M[y]=a^2\frac{2\sum_{i=0}^{m}(i^2+1)\frac{m!^2}{(m-i)!(m+i)!}-1}{2\sum_{i=0}^{m}\frac{m!^2}{(m-i)!(m+i)!}-1}.$$

We let $A(m)=\sum_{i=0}^{m}\frac{1}{(m-i)!(m+i)!}$. Then, since

$$\sum_{j=0}^{2m}\frac{(2m)!}{j!(2m-j)!}=2^{2m} \text{ then } A(m)=\frac{2^{2m-1}}{(2m)!}+\frac{1}{2m!^2},$$

and the denominator of M[y] is written as

$$2m!^2\frac{1}{2}\left[\frac{2^{2m}}{(2m)!}+\frac{1}{m!^2}\right]-1=\frac{2^{2m}m!^2}{(2m)!}.$$

We now consider the numerator of M[y]

$$2\sum_{i=0}^{m}(i^2+1)\frac{m!^2}{(m-i)!(m+i)!}-1=$$

$$=2m!^2(m^2+1)\sum_{i=0}\frac{1}{(m-i)!(m+i)!}-$$

$$-2m!^2\sum_{i=0}^{m}\frac{m^2-i^2}{(m-i)!(m+i)!}-1=\frac{2^{2m-1}m!^2}{(2m)!}(m+2).$$

Whereupon $M[y] = a^2(m + 2)/2$ for $m > 1$.

By taking into account that $m = \eta/4a^2$, we obtain finally,

$$M[y]=\frac{\eta}{8}+a^2 \text{ for } \frac{\eta}{4a^2}>1.$$

For m = 1, we easily get from (21) and (24) that $M[y] = 1.5a^2$; the same result is also obtained for noninteger m less than unity.

The dispersion is computed from (22), with account being taken of (24), (25), and (26).

$$D[y] = a^4 \left\{ \frac{\zeta_1 + \sum_{i=2}^{m} i^4 \lambda_1 \lambda_2 \ldots \lambda_{i-1} \zeta_i}{1 + \zeta_1 + \sum_{i=2}^{m} \lambda_1 \lambda_2 \ldots \lambda_{i-1} \zeta_i} + 2 \frac{M[y]}{a^2} - 1 \right\} - M^2[y],$$

where, as before, λ_l and ζ_l are determined from (17) with account being taken of (I).

We transform the first term in the braces. Then we denote it by B(m). It is easily taken to the form

$$B(m) = \frac{2 \sum_{i=0}^{m} i^4 \frac{m!^2}{(m-i)!(m+i)!}}{2 \sum_{i=0}^{m} \frac{m!^2}{(m-i)!(m+i)!}}.$$

The denominator is the same as in the analogous expression for M[y], andequals $2^{2m} m!^2 : (2m)!$.

We now consider the series in the numerator.

$$\sum_{i=0}^{m} \frac{i^4}{(m-i)!(m+i)!} = m^4 A(m) -$$

$$- (2m^2 - 2m + 1) A(m-1) + A(m-2).$$

By substituting this expression in B(m) we get

$$B(m) = \frac{m(3m-1)}{4}.$$

It is obvious that all these formulas are valid for m > 1.

Finally, for m > 1 ($\eta / 4a^2 > 1$), we find that

$$D[y] = \frac{\eta}{16} \left(\frac{\eta}{2} - a^2 \right).$$

For all $\eta / 4a^2 \leq 1$, we immediately obtain from (22) and (24) that

$$D[y] = \frac{1}{4} a^4$$

2. Mathematical Expectation and Dispersion of the Output Variable for a Uniform Distribution Law in the Case of a Piecewise-Linear Object Characteristic

For the case when the object characteristic is y = |x|, the general expression for the mathematical expectation of the output is found in [1]. We recall that

$$(\overline{\Delta y})_i = (i + \delta_{i,0}) a, \qquad (i = 0, 1, \ldots), \qquad \delta_{i,0} = \begin{cases} 1, \text{ if} & i = 0, \\ 0, \text{ if} & i \neq 0; \end{cases}$$

$$|(\overline{\Delta y})_i| = 2a; \; p_i = p = \int_{-\infty}^{-2a} \rho(v)\, dv;$$

$$r_1 = \frac{1}{2\left(q + \frac{1}{1-\lambda}\right)}; \qquad r_0 = 2qr_1; \qquad r_i = r_1 \lambda^{i-1},$$

where

$$\lambda = \frac{p}{q}; \qquad M[y] = a \frac{q + \frac{1}{(1-\lambda)^2}}{q + \frac{1}{1-\lambda}}.$$

In the case of the uniform distribution of (23)

$$p = \begin{cases} \frac{1}{2} - \frac{a}{\eta} & \left(\frac{1}{2} > \frac{a}{\eta}\right), \\ 0 & \left(\frac{1}{2} \leqslant \frac{a}{\eta}\right); \end{cases} \qquad q = \begin{cases} \frac{1}{2} + \frac{a}{\eta} & \left(\frac{1}{2} > \frac{a}{\eta}\right), \\ 1 & \left(\frac{1}{2} \leqslant \frac{a}{\eta}\right); \end{cases}$$

$$\frac{M[y]}{\eta} = \begin{cases} \frac{4\left(\frac{a}{\eta}\right)^2 + \frac{a}{\eta} + \frac{1}{2}}{4\frac{a}{\eta} + 2} & \text{for} \quad \frac{a}{\eta} < \frac{1}{2}, \\ \frac{a}{\eta} & \text{for} \quad \frac{a}{\eta} \geqslant \frac{1}{2}. \end{cases}$$

We compute the dispersion

$$- a^2 \left[\frac{q + \frac{1}{(1-\lambda)^2}}{q + \frac{1}{1-\lambda}} \right]^2 =$$

$$D[y] = \sum_{i=-\infty}^{\infty} (\overline{\Delta y})_i r_i - M^2[y] = a^2 \frac{q + \sum_{i=1}^{\infty} i^2 \lambda^{i-1}}{q + \frac{1}{1-\lambda}} =$$

$$= a^2 \frac{q\lambda(1-\lambda^2) + \lambda}{(1-\lambda)^4 \left(q + \frac{1}{1-\lambda}\right)^2}.$$

By substituting p and q, we get

$$D[y] = \begin{cases} \frac{\eta^2}{4} \frac{\frac{1}{4} + \frac{a}{\eta} - 3\left(\frac{a}{\eta}\right)^2}{\left(1 + 2\frac{a}{\eta}\right)^2} & \text{for} \quad \frac{a}{\eta} < \frac{1}{2}, \\ 0 & \text{for} \quad \frac{a}{\eta} \geqslant \frac{1}{2}; \end{cases}$$

$$\frac{\sigma[y]}{\eta} = \begin{cases} \frac{1}{2} \frac{\sqrt{\frac{1}{4} + \frac{a}{\eta} - 3\left(\frac{a}{\eta}\right)^2}}{1 + 2\frac{a}{\eta}} & \text{for} \quad \frac{a}{\eta} < \frac{1}{2}, \\ 0 & \text{for} \quad \frac{a}{\eta} \geqslant \frac{1}{2}. \end{cases}$$

THE ACTION OF RANDOM PROCESSES ON DISCONTINUOUS CONTROL SYSTEMS

G. I. Pyatnitskii
(Moscow)

Translated from Avtomatika i Telemekhanika Vol. 21, No. 5, pp. 585-594, May, 1960
Original article submitted April 13, 1959

Questions of the statistical calculations of discontinuous (sampled-data) control systems are considered, these systems being acted upon by stationary random processes. We also consider one particular case when a nonstationary random process acts. It is shown that the method of statistical linearization can be used for the approximate calculation of nonlinear systems in the same form in which it is used for the calculation of continuous nonlinear systems.

INTRODUCTION

Today there is a heightened interest in sampled-data, or discontinuous, control systems. These include systems containing sampled-data elements of one form or another [1, 2], extrapolating devices [3, 4], and digital computers [5, 6].

Discontinuous control systems are superior to continuous ones in those cases when it is necessary to control a slowly varying process, since they require less energy for their operation.

Sampled-data systems can successfully be employed, and are employed, for the purpose of measurement, particularly telemetry; with this, they may easily be made multichannel devices.

Sampled-data systems can be used for the control of several objects by means of the same apparatus which a continuous system must use to control just one object.

The use of digital computers in control systems transforms them into discontinuous control systems since, by their nature, digital machines have to do with discrete information, with digits. Control systems with digital devices are very flexible since, by a simple change of program, they can be made capable of solving their problem under different conditions.

Discontinuous control systems of a quite broad class can be described from a single point of view. In this class fall those systems whose behavior is determined by the values of the input signals at discrete equispaced moments of time.

In [7] a method is given for describing the operation of sampled-data elements with arbitraty pulse forms. The essence of the method is that the actual sampled-data element is presented in the form of a series connection of ideal sampled-data elements which process pulses in the form of Dirac δ-functions (following one another at equally spaced moments of time with norms equal to the values of the element's input signal at the corresponding moments of time) and which form a link which transforms the δ-pulses to pulses of the necessary forms. The shaping link is linear, and is described by a certain weight function and transfer function.

Fig. 1.

The series connection of the sampled-data element with a linear system forms a linear sampled-data circuit. The shaping link with the linear portion of the circuit forms the equivalent continuous portion (ECP) of the circuit (Fig. 1). The transfer function of the ECP is, obviously, the product of the transfer functions of the shaping link and the linear continuous portion of the circuit, and the weight function of the ECP is the convolution of the weight functions of the shaping link and the continuous portion.

If x(t) is the signal acting on the sampled-data circuit's input y (t) is the output signal and g(t) is the weight function of the ECP then, in the steady state of the circuit, the following relationship holds::

$$y(k\Delta t+\varepsilon\Delta t)=\sum_{n=-\infty}^{k} x(n\Delta t)\,g[(k-n)\Delta t+\varepsilon\Delta t]. \tag{1}$$

Here, the time $\underline{t}$ is given in the form $t = k\Delta t + \epsilon\Delta t$, where $\underline{k}$ is an integer, $\epsilon<1$ and Δt is the interval ~~of dis~~creteness (quantization).

Application of the discrete Laplace transform [1] to (1) gives

$$Y^{*}(p,\ \varepsilon)=G^{*}(p,\ \varepsilon)\,X^{*}(p), \tag{2}$$

where Y^{*}, G^{*}, and X^{*} are the transforms of y, g, x, respectively. For example,

$$G^{*}(p,\ \varepsilon)=\sum_{m=0}^{\infty} g(m\Delta t+\varepsilon\Delta t)\,e^{-pm\Delta t}.$$

By analogy with continuous systems, $G^*(p, \epsilon)$ is called the transfer function of the sampled-data circuit. It may be shown that $G^*(p, \epsilon)$ is related to the transfer function (in the usual sense) of the ECP, $G(p)$ by the relationship [8]

$$G^*(p, \varepsilon) = \frac{1}{\Delta t} \sum_{m=-\infty}^{\infty} G\left(p + i\frac{2\pi m}{\Delta t}\right) e^{\varepsilon\Delta t\left(p+i\frac{2\pi m}{\Delta t}\right)}. \tag{3}$$

If p is replaced by $i\omega$, one obtains the frequency characteristic of the sampled-data circuit, which may be interpreted as the ratio of the output signal to the input signal if the input signal is a function of the form $e^{i\omega n\Delta t}$.

Relationships (1) and (2) also hold for systems with feedback, except that, instead of $G^*(p, \epsilon)$ in (2), the system's transfer function enters and, instead of $g(t)$ in (1), the properly defined weight function of system enters.

In the sequel, a time-domain function will always be denoted by a lower-case Latin letter, while its transform will be denoted by the corresponding upper-case letter; to distinguish discrete from continuous transforms, the discrete transforms will always be marked with a star.

1. Stationary Random Processes with Discrete Arguments and Their Actions on Linear Sampled-Data Systems

For the following exposition we shall need certain results from the theory of stationary (in the broad sense) random processes with discrete arguments. This theory is presented in great detail in the book of J. L. Doob [9]. In [10], the theory of discrete random processes is applied to a probabilistic computation of sampled-data systems. In contradistinction to [10], we shall here take as basic the spectral representation of stationary processes given in [9].

Each stationary random process $x(n\Delta t)$ with zero mathematical expectation, permits of a spectral representation

$$x(n\Delta t) = \frac{\Delta t}{2\pi} \int_{-\pi/\Delta t}^{\pi/\Delta t} e^{i\omega n\Delta t} du(\omega), \tag{4}$$

where the random process $u(\omega)$ has orthogonal increments, i.e.,

$$M\left[du(\omega_1)\overline{du(\omega_2)}\right] = \begin{cases} 0 & \text{for} \quad \omega_1 \neq \omega_2; \\ \dfrac{\Delta t}{2\pi} dF(\omega) & \text{for} \quad \omega_1 = \omega_2 = \omega. \end{cases} \tag{5}$$

Here, M is the symbol for mathematical expectation, and a superscript bar denotes the complex conjugate.

The correlation function of a discrete process can be represented in the form

$$R(n\Delta t) = \frac{\Delta t}{2\pi} \int_{-\pi/\Delta t}^{\pi/\Delta t} e^{i\omega n\Delta t} dF(\omega). \tag{6}$$

The function $F(\omega)$ [the same function as in (5)] is called the spectral function of the process, and its derivative with respect to ω, i.e., $S^*(\omega) = F'(\omega)$, is called the spectral density.

The spectral density can be presented in the form of a Fourier series whose coefficients are the values of the correlation function

$$S^*(\omega) = \sum_{n=-\infty}^{\infty} R(n\Delta t)\, e^{i\omega n\Delta t}. \tag{7}$$

It follows from (7) that the spectral density of a discrete process is a periodic function of ω with a period of $2\pi/\Delta t$.

A discrete random process may be obtained from a continuous one if one consider its values at discrete, equally spaced, moments of time.

If $x(t)$ is a continuous stationary random process, then its values for $t = n\Delta t$ comprise a stationary discrete process. Let $S(\omega)$ be the spectral density of the continuous process. The spectral density $S^*(\omega)$ of the discrete process obtained from it can be computed by means of the relationship [11]

$$S^*(\omega) = \frac{1}{\Delta t} \sum_{m=-\infty}^{\infty} S\left(\omega + \frac{2\pi m}{\Delta t}\right), \tag{8}$$

which is easily obtained from (7).

If the stationary random process $x(n\Delta t)$, which can be presented in the form of (4), acts on the input of some linear sampled-data system with constant parameters, then the system's steady-state output, i.e., after damping of the transient response in the system, can be computed by taking account of (1) and (4). The output process will have the spectral representation

$$y(k\Delta t + \varepsilon\Delta t) = \frac{\Delta t}{2\pi} \int_{-\pi/\Delta t}^{\pi/\Delta t} e^{i\omega k\Delta t} G^*(i\omega, \varepsilon)\, du(\omega), \tag{9}$$

where $G^*(i\omega, \epsilon)$ is the system's frequency characteristic.

It follows from (9), when (5) is taken into account, that the output process' correlation function is

$$R_y(n\Delta t, \varepsilon\Delta t) = \frac{\Delta t}{2\pi} \int_{-\pi/\Delta t}^{\pi/\Delta t} e^{i\omega n\Delta t} S_y^*(\omega)\, d\omega. \tag{10}$$

where $S_y^*(\omega)$ is the spectral density of the process y, related to the spectral density of process $x(n\Delta t)$ by the relationship

$$S_y^*(\omega, \varepsilon) = |G^*(i\omega, \varepsilon)|^2 S_x^*(\omega). \tag{11}$$

The dispersion of the process y can obviously be computed from the formula

$$\sigma_y^2(\varepsilon) = \frac{\Delta t}{2\pi} \int_{-\pi/\Delta t}^{\pi/\Delta t} |G^*(i\omega, \varepsilon)|^2 S_x^*(\omega)\, d\omega. \tag{12}$$

Formulas (10) and (12) were obtained from [10].

We turn nowto (8). It immediately follows from it th that the ideal sampled-data element transforms the high-frequency region of the spectrum to a low-frequency one. This leads to the consequence that the introduction of a sampled-data element into a continuous system increases the random errors. This fact is seen particularly clearly in the following example.

Let there be some continuous system, and let there act on it a stationary random process x(t) with spectral density S(ω). Let the system's frequency characteristic K(iω) be such that for | ω | > ω_0, its modulus is so small that the dispersion of the output process can be computed by the formula

$$\sigma_C^2 \approx \frac{1}{2\pi} \int_{-\omega_0}^{\omega_0} S(\omega) \,|\, K(i\omega)\,|^2 \, d\omega. \tag{13}$$

Let us now connect this system to some sampled-data element whose pulse repetition period Δt satisfies the inequality

$$\Delta t < \frac{\pi}{\omega_0},$$

The dispersion of the output random process from the sampled-data circuit thus obtained is computed from (12). With the assumptions made relative to K(iω) and Δt, the frequency characteristic of such a circuit will, according to (3), be

$$G^*(i\omega, \varepsilon) = \frac{1}{\Delta t} F(i\omega)\, K(i\omega)\, e^{i\omega\varepsilon\Delta t}, \tag{14}$$

where F(iω) is the frequency characteristic of the sampled-data element's shaping link.

We assume that over the entire frequency range where | K(iω) | still differs markedly from zero, | F(iω)| / Δt differs little from unity. In fact, this assumption can be satisfied by choosing either a low-frequency part or a sufficiently small Δ t, because | F(iω)| / Δt → 1 for ω → 0 and differs greatly from unity only close to the frequencies ω = ± π/ Δt.

Starting from this, we can write the following expression for the dispersion at the sampled-data circuit's output:

$$\sigma^2 \approx \frac{1}{2\pi} \int_{-\pi/\Delta t}^{\pi/\Delta t} |\, K(i\omega)\,|^2 \sum_{m=-\infty}^{\infty} S_x\left(\omega + \frac{2\pi m}{\Delta t}\right) d\omega. \tag{15}$$

By comparing (15) with (13), and taking into account that $\omega_0 < \pi/\Delta t$, we can infer that $\sigma_S^2 > \sigma_C^2$.

2. Action of a Nonstationary Signal on a Linear Sampled-Data System

Let a nonstationary signal of the following form act on a linear sampled-data system

$$\xi(t) = r(t)\, x(t), \tag{16}$$

where x(t) is a stationary random process and r(t) is a function of time.

The output process can be found by (1):

$$y(k\Delta t + \varepsilon\Delta t) = \sum_{n=-\infty}^{k} \xi(n\Delta t)\, g\,[(k-n)\,\Delta t + \varepsilon\Delta t]. \tag{17}$$

The process ξ (nΔt) can obviously be presented in the form

$$\xi(n\Delta t) = r(n\Delta t)\, \frac{\Delta t}{2\pi} \int_{-\pi/\Delta t}^{\pi/\Delta t} e^{i\omega n\Delta t} du(\omega). \tag{18}$$

By substituting (18) in (17) we get

$$y(k\Delta t + \varepsilon\Delta t) = \frac{\Delta t}{2\pi} \int_{-\pi/\Delta t}^{\pi/\Delta t} du(\omega)\, e^{i\omega k\Delta t} \sum_{m=0}^{\infty} r\,[(k-m)\,\Delta t]\, g\,(m\Delta t + \varepsilon\Delta t)\, e^{-i\omega m\Delta t}. \tag{19}$$

Expression (19) is the spectral representation of the output process. It is a nonstationary process, since k enters into the integrand, and not only into the exponential factor.

We obtain the dispersion of the process y in the following form.

$$\sigma_y^2(k, \varepsilon) = \frac{\Delta t}{2\pi} \int_{-\pi/\Delta t}^{\pi/\Delta t} d\omega S_x^*(\omega) \left| \sum_{m=0}^{\infty} r\,[(k-m)\,\Delta t]\, g\,(m\Delta t + \varepsilon\Delta t)\, e^{-i\omega m\Delta t} \right|^2. \tag{20}$$

We consider two particular cases:

1. Let r(t) be a linear function of time:

$$r(t) = a + bt. \tag{21}$$

Then,

$$\sum_{m=0}^{\infty}[a+b(k-m)\Delta t]\,g[(m+\varepsilon)\Delta t]\,e^{-i\omega m\Delta t}=$$

$$=(a+bk\Delta t)\,G^*(i\omega,\ \varepsilon)+ib\frac{d}{d\omega}G^*(i\omega,\ \varepsilon).$$

If the system's frequency characteristic $G^*(i\omega,\ \epsilon)$ is presented in the form

$$G^*(i\omega,\ \varepsilon)=P(\omega)\,e^{i\varphi(\omega)},$$

then, for the square of the modulus of the sum under the integral sign in (20), we obtain the expression

$$P^2[(a+bk\Delta t)+b\varphi']^2+b^2P'^2,$$

where the "prime" denotes differentiation with respect to ω.

We obtain the following final expression for the dispersion:

$$\sigma_y^2(k,\ \varepsilon)=\frac{\Delta t}{2\pi}\int_{-\pi/\Delta t}^{\pi/\Delta t}d\omega S_x^*(\omega)\,\{P^2[(a+bk\Delta t)+$$

$$+b\varphi']^2+b^2P'^2\}. \qquad (22)$$

For computations by (22), it is necessary to differentiate the modulus and phase frequency characteristics with respect to ω. These operations may be implemented graphically.

2. Let

$$r(t)=e^{at}. \qquad (21a)$$

In this case,

$$\sum_{m=0}^{\infty}e^{\alpha(k-m)\Delta t}g[(m+\varepsilon)\Delta t]\,e^{im\omega\Delta t}=e^{\alpha k\Delta t}G^*(\alpha+i\omega,\ \varepsilon)$$

and, consequently,

$$\sigma_y^2(k,\ \varepsilon)=e^{2\alpha k\Delta t}\frac{\Delta t}{2\pi}\int_{-\pi/\Delta t}^{\pi/\Delta t}d\omega S_x^*(\omega)\,|G^*(\alpha+i\omega,\ \varepsilon)|^2. \qquad (23)$$

In order to compute the dispersion by this formula, it is necessary to reconstruct the system's frequency characteristic, since the presence of α would change all the time constants of the system's continuous part.

A formula analogous to (23) for the case of continuous systems was obtained by V. S. Krapivin [12].

Computations by the formulas obtained can be carried out in the case when the function f(t) is neither linear nor exponential. For this, it is necessary that r(t), in the neighborhood of the moment of time t_0 of interest, can be approximately presented in the form of a linear or exponential function. The size of this neighborhood can be estimated on the basis of the sum entering into (20). It must be such that the magnitude of the quantity under the summation sign outside of this neighborhood be so small that it would be possible to neglect it; at the same time, inside the neighborhood, r(t) must differ only slightly from a straight line or an exponential.

By using general relationship (20), one can compute the dispersion in cases when r(t) varies by a more general law than (21) or (21a).

3. Action of a Stationary Random Process on a Sampled-Data System which Contains a Nonlinear Element

We assume that the stationary random process of the form

$$x(n\Delta t+\varepsilon\Delta t)=\frac{\Delta t}{2\pi}\int_{-\pi/\Delta t}^{\pi/\Delta t}e^{i\omega n\Delta t}Q^*(\omega,\ \varepsilon)\,du(\omega) \qquad (24)$$

acts on some continuous linear system with weight function k(t). The steady-state output process can be presented in the form

$$y(m\Delta t+\eta\Delta t)-\sum_{m=0}^{\infty}\Delta t\int_0^1 x[(m-n)\Delta t+$$

$$+\varepsilon\Delta t]\,k[n\Delta t+(\eta-\varepsilon)\Delta t]\,d\varepsilon. \qquad (25)$$

By substituting (24) therein, we obtain the spectral representation of the output process

$$y(m\Delta t+\eta\Delta t)=\frac{\Delta t}{2\pi}\int_{+\pi/\Delta t}^{\pi/\Delta t}du(\omega)\,e^{im\omega\Delta t}P^*(\omega,\ \eta), \qquad (26)$$

where

$$P^*(\omega,\ \eta)=\Delta\int_0^1 K^*(\omega,\ \eta-\varepsilon)\,Q^*(\omega,\ \varepsilon)\,d\varepsilon, \qquad (27)$$

$$K^*(\omega,\ \eta-\varepsilon)=\sum_{m=0}^{\infty}k[m\Delta t+(\eta-\varepsilon)\Delta t]\,e^{-i\omega m\Delta t}. \qquad (28)$$

We now consider the sampled-data circuit shown on Fig. 2. This circuit contains a nonlinear element. Such an element might be, for example, a relay element, an element with a limited linear zone, and other elements

Fig. 2. Nonlinear sampled-data circuit. 1 is an ideal sampled-data element, 2 is a linear link, 3 is a nonlinear element, 4 is a linear link.

[13]. At the circuit's input acts a stationary random process $v(t) = m_v + v_0(t)$, where m_v is the mathematical expectation of the process $\underline{v}$ and $v_0(t)$ is a process with zero mathematical expectation. By using the results of section 1, we can easily find the spectral representation and, consequently, the correlation function $R_z(n\Delta t, \epsilon\Delta t)$ of the process $\underline{z}$ at the nonlinear element's input. It is also easy to compute the mathematical expectation m_z of the process $\underline{z}$. We shall assume that the process $v(t)$ is normally distributed. In this case, the correlation function $R_x(n\Delta t, \epsilon\Delta t)$ of the process $\underline{x}$ at the nonlinear element's output can be presented in the form of a series [14]

$$R_x(n\Delta t,\ \varepsilon\Delta t) = \sum_{l=1}^{\infty} \frac{a_l}{l!} \rho_z^l (n\Delta t,\ \varepsilon\Delta t). \tag{29}$$

Here, $\rho_z = R_z/\sigma_z^2$, σ_z^2 is the dispersion of process $\underline{z}$, and a_l are coefficients which depend on σ_z and m_z. In its turn, the mathematical expectation m_x of process $\underline{x}$ can be presented in the form

$$m_x = \chi(\sigma_z,\ m_z)\, m_z. \tag{30}$$

A simple and elegant method of calculating the coefficients a_l and χ, based on the use of the δ-function, is presented in [14].

For an element with a limited linear zone,

$$\chi = \frac{b}{a}\left\{1 + \frac{\sigma_z}{m_z}\left[\frac{a - m_z}{\sigma_z}\left(1 - \Phi\left(\frac{a - m_z}{\sigma_z}\right)\right) - \varphi\left(\frac{a - m_z}{\sigma_z}\right) - \right.\right.$$

$$\left.\left. - \frac{a + m_z}{\sigma_z}\left(1 - \Phi\left(\frac{a + m_z}{\sigma_z}\right)\right) + \varphi\left(\frac{a + m_z}{\sigma_z}\right)\right]\right\},$$

$$a_l = \sigma_z^2 \frac{b^2}{a^2}\left[\Phi^{(l-1)}\left(-\frac{a + m_z}{\sigma_z}\right) - \Phi^{(l-1)}\left(\frac{a - m_z}{\sigma_z}\right)\right]^2,$$

where $\underline{a}$ is the magnitude of the element's linearity zone, $\underline{b}$ is the limitation level and b/a is the slope of the linear part of the element's characteristic.

For a relay element,

$$\chi = \frac{1}{m_z} b\left[2\Phi\left(\frac{m_z}{\sigma_z}\right) - 1\right],$$

$$a_l = 4b^2\left[\Phi^{(l)}\left(-\frac{m_z}{\sigma_z}\right)\right]^2,$$

where $\underline{b}$ is the signal level at the relay element's output.

Here, everywhere $\Phi(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{x} e^{-\frac{t^2}{2}} dt$,

and $\Phi^{(l)}(x)$ is the lth derivative of $\Phi(x)$ with respect to $\underline{x}$; $\varphi(x) = \Phi'(x)$.

The spectral density of process $\underline{x}$, starting from (29), can obviously be given in the form of a series

$$S_x^{\bullet}(\omega,\ \varepsilon) = a_1 S_z^{\bullet}(\omega,\ \varepsilon) + \sum_{l=2}^{\infty} \frac{a_l}{l!} \frac{1}{\sigma_z^{(2l+2)}} S_z^{\bullet(l)}(\omega,\ \varepsilon), \tag{31}$$

where $S_z^{\bullet}(\omega, \epsilon)$ is the spectral density of process $\underline{z}$, and $S_z^{\bullet}(l)$ is the lth-order spectrum of the function $S_z^{\bullet}(\omega, \epsilon)$.

Tables 1 and 2 give the values of the coefficients $a/l!$ for an element with a limited linearity zone and a relay element for $a = b = 1$, for various values of m_z and σ_z.

It is clear from the tables that in the overwhelming majority of the cases there holds the inequality $a_l/l! \ll a_1$, for $l = 2, 3, \ldots$ Thus, the terms with $l \geq 2$ in (31) can be ignored.

We turn back now to Fig. 2. Let link 2 have weight function $g(t)$ and link 4, weight function $k(t)$. Then the spectral density of process $\underline{z}$ will be

$$S_z^{\bullet}(\omega,\ \varepsilon) = |G^{\bullet}(i\omega,\ \varepsilon)|^2 S_v^{\bullet}(\omega). \tag{32}$$

As a consequence of what has already been said about $S_x^{\bullet}(i\omega, \epsilon)$, we have that

$$S_x^{\bullet}(\omega,\ \varepsilon) \approx a_1 |G^{\bullet}(i\omega,\ \varepsilon)|^2 S_v^{\bullet}(\omega). \tag{33}$$

TABLE 1

m_z	σ_z	a_1	$a_2/2$	$a_3/6$	$a_4/24$

1.0	2.0	0.4950	0.0620	0.0465	0.03910

From this we find that the approximate spectral representation of the process x has the form

$$x(n\Delta t + \varepsilon\Delta t) = \frac{\Delta t}{2\pi} \int\limits_{-\pi/\Delta t}^{\pi/\Delta t} e^{i\omega n\Delta t} \sqrt{a_1} G^{*}(i\omega,\ \varepsilon)\, du(\omega), \tag{34}$$

where $u(\omega)$ is the spectral process of $v_0(n\Delta t)$.

Process x acts on the input of linear link 4. We find the spectral representation of process y at the circuit's output in the form of (26).

By taking into account that, in the given case, $Q^{*}(i\omega,\ \varepsilon)$ is $\sqrt{a_1}\ G^{*}(i\omega,\ \varepsilon)$, we obtain

$$P^{*}(\omega,\ \eta) = \frac{1}{\Delta t} \sum_{n=-\infty}^{\infty} \sqrt{a_1} K\left(i\omega + i\frac{2\pi n}{\Delta t}\right) G\left(i\omega + i\frac{2\pi n}{\Delta t}\right) e^{i\eta\Delta t\left(\omega + \frac{2\pi n}{\Delta t}\right)} \tag{35}$$

This expression is the frequency characteristic of the circuit in the case when the nonlinear element is replaced by an amplifier with gain equal to $\sqrt{a_1}$.

By using the representation of the nonlinear element in the form of a linear amplifier, we can easily calculate the probabilistic characteristics of the system with feedback. It is assumed for this that the process at the nonlinear element's input is normal. Such a method of calculating continuous systems is known as the method of statistical linearization, developed by L. E. Kazakov [13].

Thus, the statistical linearization method is also applicable to sampled-data systems. The computational methods for the discrete case are no different from those used in the continuous case, which are well-known. The coefficient $\sqrt{a_1}$ is computed for different types of nonlinear elements in [13].

CONCLUSIONS

In this paper we considered a number of questions dealing with the statistical computations of discontinuous control systems. We took as fundamental the spectral representation of stationary random processes with discrete arguments.

Starting from the relationship between the spectrum of a continuous process and that of the discrete process related to it, we found that under the same conditions the dispersion at the output will be larger in the sampled-data system than in the continuous system equivalent to it. This is a consequence of the fact that the sampled-data element transforms the high-frequency part of the input process spectrum into a low-frequency region.

The formulas obtained for the dispersion at the output of stationary systems permit the computations to be carried out in the cases when nonstationary processes act.

An investigation of the question of the action of a stationary process on a discrete system containing a nonlinear element led to the conclusion that the statistical linearization method is applicable to the discrete case, the computational methodology remaining the same as in the case of continuous systems.

ERROR ACCUMULATION IN DIGITAL COMPUTATIONS

V. A. Brik

(Moscow)

Translated from Avtomatika i Telemekhanika Vol. 21, No. 5, pp. 595-600, May, 1960
Original article submitted December 26, 1959

The paper describes a method, based on diffusion theory, of estimating the errors of computing devices used in automatic control systems, as well as special-purpose and general-purpose digital computers. An investigation is made of the errors of cyclical computational processes, in which the successively accumulated elementary errors can be considered as independent random variables with an approximately normal distribution density.

Digital computing devices which solve recursive difference equations [1] are used in automatic control systems. In the operation of these devices, the computations are implemented cyclically, wherein the results of the previous cycle, or cycles, are the input data for the following cycle. For this, it is desirable to have the results obtained after each cycle. Recursive computational processes with output of intermediate data also arise frequently in the solution of various problems on general-purpose or special-purpose computers, for example, in computing tables of some function or other by recursion formulas.

With each computational cycle there ordinarily arise errors which gradually accumulate. This accumulation can occur either quite regularly or randomly. If the successively arising errors are virtually statistically independent, then they may be estimated by the use of probabilistic methods [2, 3]. The possibility of using these methods can be established [3] after an analysis of the statistical properties of the table of successive errors.

In many cases, the process of error accumulation amounts to the addition, to some total error which determines the quality of the entire solution and which exists prior to the given cycle, of an error resulting from the given cycle.

If the error attributable to the given cycle is the result of the effect of several independent sources of error (for example, rounding errors after several multiplications), then the resulting error of the cycle may have a probability density close to normal. Ordinarily, the mean value of the error in a cycle is zero. The dispersion σ^2 of the cycle's error is computed from an analysis of the table of successive errors of the cycles.

If one is given some limit a > 0 which must not be exceeded by the absolute magnitude of the total error Δ_n then, if the conditions stated above are met (addition of the successive errors of the cycles, statistical independence of these errors), the process of error accumulation can be considered as the random walk (diffusion) of a point between two absorbing barriers (Fig. 1). The ordinal numbers of the successive cycles are laid out along the axis of abscissas on Fig. 1. The total error after the nth cycle is the sum of the individual cycle errors.

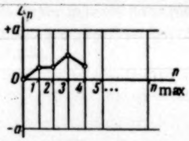

Fig. 1. Diffusion process with two absorbing barriers.

$$\Delta_n = \sum_{i=1}^{n} \delta_i.$$

The random walk begins at the point $\Delta_0 = 0$ (it is assumed that the initial data are given exactly). We shall assume that all the increments δ_i are independent random variables with identical normal distributions with dispersion σ^2 and zero mean value.

We now find the probability $P_0(n)$ that, in n cycles, the random walk will go beyond the barriers at least once.*

For a given n, the probability density of the random variable Δ_n has the form

$$f(x,\ n) = \frac{1}{\sqrt{n\sigma^2}\sqrt{2\pi}} \exp\left(-\frac{x^2}{2n\sigma^2}\right). \qquad (1)$$

Using the reflection method [4, 6], we can introduce a modified "distribution density"

$$f_1(x,\ n) = \sum_{s=-\infty}^{s=+\infty} (-1)^s \frac{1}{\sqrt{n\sigma^2}\sqrt{2\pi}} \exp\left\{-\frac{(x-2as)^2}{2n\sigma^2}\right\}, \qquad (2)$$

characterizing the probability distribution law of the complex event

$$f_1(x,\ n)\,dx = P\{x \leqslant \Delta_n \leqslant x + dx;\ |\Delta_i| < a\}\ (i = 1, 2, \ldots, n-1).$$

---

* For the case of continuous n, the problem, in a more general form, was solved by Bartlett [4, 5].

With this, consequently,

$$\int_{-a}^{a} f_1(x,\ n)\,dx = P\{|\Delta_n| < a;$$

$$|\Delta_i| < a\} \quad (i = 1,\ 2,\ \ldots,\ n-1).$$

$$\int_{-a}^{a} f_1(x,\ n)\,dx = P\{|\Delta_i| < a\} \qquad (i = 1,\ 2,\ \ldots,\ n).$$

The probability of interest to us, $P_0(n)$, equals

$$P_0(n) = 1 - \int_{-a}^{a} f_1(x,\ n)\,dx. \tag{3}$$

After some transformations, we can obtain from (2) and (3) that

$$P_0(n) = 4\sum_{s=0}^{\infty} F\left\{\frac{-a(2s+1)}{\sigma\sqrt{n}}\right\}(-1)^s =$$

$$= 4\left\{F\left(\frac{-a}{\sigma\sqrt{n}}\right) - F\left(\frac{-3a}{\sigma\sqrt{n}}\right) + F\left(\frac{-5a}{\sigma\sqrt{n}}\right) - \ldots\right\}, \tag{4}$$

where

$$F(u) = \int_{-\infty}^{u} \frac{1}{\sqrt{2\pi}} \exp\left(-\frac{z^2}{2}\right) dz.$$

$P_0(n)$, as a function of a/σ and n, computed by (4), is shown on Fig. 2.

The method of estimating the error consists in finding such a value of a that, for a given number of cycles n and a dispersion σ^2 of the maximum possible error D_n (D_n is the maximum of all the Δ_i, $i = 1, 2, \ldots, n$), $P_0(n)$ will equal some definite, sufficiently small, quantity α (for example, $\alpha = 10^{-2}$, 10^{-3} or 10^{-4}). Thus, α is the confidence level for which

$$-D_n < \Delta_i < D_n \quad (i = 1,\ 2,\ \ldots,\ n).$$

The dependence of D_n/σ on n for different α is shown in Fig. 3 on a semilogarithmic scale.

The graphs of Fig. 3 answer the question as to the practical limits of the errors Δ_i ($i = 1, 2, \ldots, n$) for a known dispersion σ^2 of the elementary errors (cycle errors). These graphs can be used for estimating the errors of any computing process in which there occurs accumulation (addition) of statistically independent successive errors with mean zero, dispersion σ^2, and a distribution close to a normal.

We now make an estimate of the error of computing the coordinates of successive equally spaced points on a

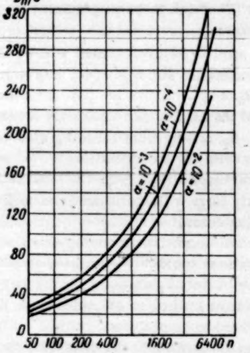

Fig. 3. Dependence of the maximum error D_n, divided by the mean-square deviation of the increment σ, on the number of cycles n and on the quantity α.

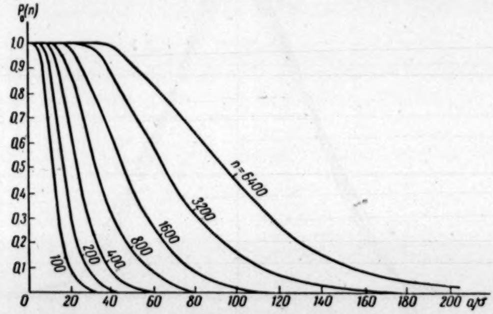

Fig. 2. The probability $P_0(n)$ of going beyond the barriers as a function of the number of cycles n and of the ratio of the distance to the barriers a to the mean-square deviation of the increment σ.

circle (with center at the origin) by means of the recursion formulas

$$x(n+1) = x(n)\cdot(1 - 2^{-2k-1}) \mp y(n)\cdot 2^{-k},$$

$$y(n+1) = y(n)\cdot(1 - 2^{-2k-1}) \pm x(n)\cdot 2^{-k},$$

which are obtained from the formulas

$$x(n+1) = x(n)\cos\omega \mp y(n)\sin\omega,$$

$$y(n+1) = y(n)\cos\omega \pm x(n)\sin\omega$$

after the substitutions

$$\cos\omega \approx 1 - 2^{-2k-1},\quad \sin\omega \approx 2^{-k}, \qquad (5)$$

where $\underline{k}$ is a positive integer and ω is a constant angular increment. This algorithm is used in a special-purpose computer [7] which prepares programs for automatic milling machines.

The error to be investigated will be the deviation of the current radius $R_i = \sqrt{x^2(i) + y^2(i)}$ from the initial radius $R_0 = \sqrt{x^2(0) + y^2(0)}$ over the entire circumference of the circle. We shall only investigate the errors $\Delta R_i = R_i - R_0$ arising from rounding after multiplication (in binary form) by the quantities 2^{-2k-1} and 2^{-k}. The methodical error arising from the substitution in (5), for sufficiently large $\underline{k}$ (larger than three to five), is small and may be neglected.

We shall denote the rounding errors arising from the multiplications $x(n)2^{-2k-1}$, $y(n)2^{-k}$, $y(n)2^{-2k-1}$, and $x(n)2^{-k}$ by $\xi_1(n)$, $\xi_2(n)$, $\xi_3(n)$, and $\xi_4(n)$, respectively, where an error leading to an increase of the radius will be considered to be positive.

It can be shown that the error of a cycle equals

$$\delta_i = R_i - R_{i-1} \approx [\xi_1(i-1) + \xi_2(i-1)]\cos\beta + [\xi_3(i-1) + \xi_4(i-1)]\sin\beta,$$

where

$$\beta = \operatorname{arctan}\frac{y(i)}{x(i)}.$$

We shall assume that the computer operates in fixed point, that $|x| < 1$, $|y| < 1$, and that the machine uses an N-bit word after the binary point. A statistical analysis of the successive errors ξ, carried out for the given problem, showed that for $R_0 > 2^{-N+4k+2}$, i.e., for sufficiently large N, all the quantities $\xi_1(n)$, $\xi_2(n)$, $\xi_3(n)$, $\xi_4(n)$ are statistically independent, and successive values do not depend on preceding ones. It turned out, with this, that they have a uniform distribution density p(z) (Fig. 4). The dispersion of such a distribution equals $2^{-2N}/12$, and the dispersion of the random variables $\delta_i = R_i - R_{i-1}$, the sum of the four independent random variables, equals

$$\sigma^2 = 2\frac{2^{-2N}}{12}\cos^2\beta + 2\frac{2^{-2N}}{12}\sin^2\beta = \frac{2^{-2N}}{6}.$$

The graphs of the distribution density p(z) of the quantity δ_i for various β, computed by a convolution integral, are shown on Fig. 5. Also constructed on the figure is the density curve for a normal distribution with the same dispersion. This curve differs slightly from the others, so that one can consider that all the δ_i are normally distributed with dispersion $2^{-2N}/6$.

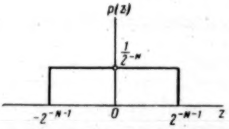

Fig. 4. Distribution density of the quantity ξ (n).

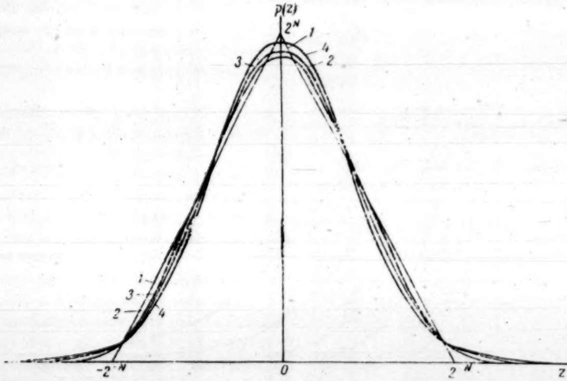

Fig. 5. Distribution density of the increment δ_i for various β: 1 is for $\beta = m\pi/2$; 2 is for $\beta = m\pi/2 \pm \pi/4$; 3 is for $\beta = m\pi/2 \pm \pi/8$, m = 0, 1, 2, 3; 4 is a normal distribution.

k	3	4	5	6	7	8	9	10
n	50	100	200	400	800	1600	3200	6400

The number of cycles n for the complete circle, equal approximately to $\pi 2^{k+1}$, changes by a factor of two when k changes by unity (cf., the table).

By using the graphs given on Fig. 3, one can determine the dependence of D_n on k. For example, for $k = 7$ and for a selected $\alpha = 10^{-3}$ the maximum error

$$|\Delta R_i|\,\max = \Big|\sum_{j=1}^{i} \delta_j\Big|_{\max} = D_n \;\; (i = 1, 2, \ldots, n)$$

equals approximately $(40)2^{-N}$. It is of interest to compare this value with the (theoretically) maximum possible error ΔR_n. Since the maximum value of $R_i - R_{i-1}$, for different β, varies from 2^{-N} to $\sqrt{2}\cdot 2^{-N}$ and, on the average, equals $(1.3)2^{-N}$, then the theoretically possible error ΔR_n equals $1.3n2^{-N} = (1040)2^{-N}$, which is 26 times the value obtained for D_n.

Instead of using graphs to determine D_n, one can use the well-known tables of the function $y = F(u)$. By substituting α instead of $P_0(n)$ and D_n instead of a in (4), and by discarding all except the first term, we get the equation

$$\alpha = 4F\left(\frac{D_n}{\sigma\sqrt{n}}\right).$$

Knowing α, σ, and n, we can easily determine D_n from the tables.

The simplification of (4) just given is admissible for $D_n/\sigma\sqrt{n}$, greater than 1 to 1.5 since, with this, the sum of the discarded terms, as a fraction of the first term, does not exceed 0.01 to 0.00005. For small $P_0(n)$ (or α), this condition is always met.

In about the same way, one can estimate the accumulated errors in those cases when the normal distribution of the independent variables δ_i has a nonzero mean.

EFFECT OF RATE FEEDBACK ON LOADED RELAY SERVOMECHANISM DYNAMICS

N. S. Gorskaya
(Moscow)

Translated from Avtomatika i Telemekhanika Vol. 21, No. 5, pp. 601-614, May, 1960
Original article submitted May 28, 1959

The effect of velocity feedback on the free oscillations of a loaded relay servomechanism is considered. The servomechanism's linear portion is described by a complete second-order equation. The investigation is carried out by the point method, using the theory of point transformations [1].

The dependence of the amplitude and time of the autooscillations' half periods on the system's parameters, including the velocity feedback coefficient, is determined.

1. Introduction and Posing of the Problem

The investigation of the dynamics of relay servomechanisms whose linear parts are described by complete second-order equations, has been carried out until now for the cases when the servomechanism's controlling element has a symmetric nonlinear characteristic. In [2-5] there were considered servomechanisms with Z-shaped or looped characteristics and, in [6], characteristics with loops and insensitive zones.

Few works have been published [7] in which consideration is given to unsymmetric looped characteristics of loaded-servomechanism controlling elements.

Some automatic control systems use electrical servomechanisms in which, by means of special relay circuits, there is implemented a charge in direction of the velocity by the switching of the supply voltage of an independently-excited motor from 24 to 48 v. To decrease the static error due to static friction, the servomechanisms are implemented in the form of autooscillatory systems. The autooscillations arise due to the unsymmetric characteristic of the controlling relay, which has one normally closed contact. In the servomechanism whose schematic is shown in Fig. 1, both direct and velocity (position and rate) feedback are employed.

2. Equations of Motion

As is clear from Fig. 1, the total voltage applied to the circuit is

$$\Delta U = U_{fb} - U_{fb} - U_{vf}, \qquad (1)$$

where U_{in} is the input signal voltage, U_{fb} is the (direct) feedback voltage and U_{vf} is the velocity feedback voltage (from the tachometer generator 4).

Controlling relay R_1, connected in the tube's anode circuit, has two working contacts $1R_1$ and $2R_1$. With no

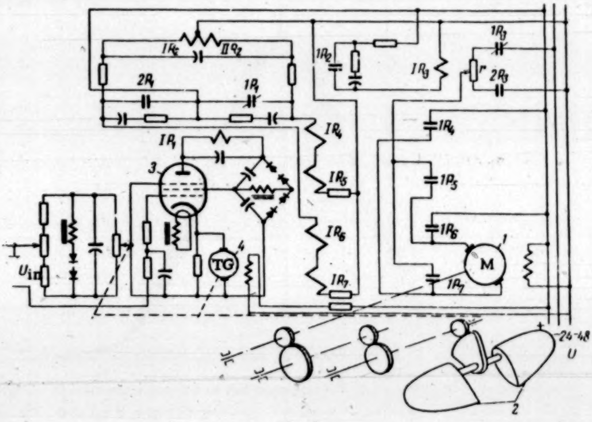

Fig. 1.

current in relay winding $1R_1$ (with negative grid bias), the relay closes contact 1R by means of a spring. With a positive grid bias, anode current will flow through the tube, causing relay R_1 to operate and closing contact $2R_1$. In this case, when contact $1R_1$ closes, current relays R_4 and R_5 and distributor relay R_2 are simultaneously in action. If contact $2R_1$ closes, then current relays R_6 and R_7 and distributor relay R_2 will be simultaneously in action. It is necessary to mention that, with zero signal on the input, relay R_1 operates with a frequency of 20 cps. With this, relay R_2 closes its working contact $1R_2$ with the doubled frequency 40 cps, since it is switched-in twice as frequently as the current relays. When relay R_2 operates, its armature touches contact $1R_2$ and switches in coil $1R_8$ of current relay R_8. Operation of current relays R_4 and R_5 leads to a rotation of motor 1 in one direction, while operation of relays R_6 and R_7 cause it to turn in the other direction. By its operation, relay R_8 switches the motor armature from the 24 v source to the 48 v source. When the winding of relay $1R_8$ is disconnected, its contact $1R_8$ closes the motor armature circuit on that side of resistor r which is connected to part of the 24 v storage battery.

When relay R_8 operates, its contact $2R_8$ closes the motor armature circuit to the other part of resistor r, which is connected to the full voltage of the 48 v storage battery. With no input signal, the motor will still be rotated by virtue of the absence of a neutral position for relay R_1. With zero input signal, the process of switching relay R_2 occurs so rapidly that the contact portion of relay R_8, due to its own inertia, cannot operate, and relay R_8 remains unconnected. With this, current relays R_4, R_5 or R_6,R_7 operate, feeding 24 v to the motor armature. In this case, steering organ 2, set into motion by the servomechanism, will oscillate with a frequency of 20 cps and an amplitude of about 0.5°. When a command is applied, the contact of relay $2R_1$ is closed. In this case, the duration of the closure is sufficient to allow relay R_2, and then relay R_3, to operate. In operating, relay R_3 applies 48 v to the motor armature. With this, the motor will execute the command with maximal speed and torque. Thanks to the presence in the circuit of the tachometer generator feedback, the operation of relay R_1 will be accelerated. With this, the motor will be switched to 24 volts upon reaching the position given by the input signal. This will preclude the arising of a lengthy oscillatory process.

We now consider the servomechanism's free oscillations, i.e., its motion for $U_{in} = 0$. The error equation of (1) can be given in the form

$$\Delta U = -K_\alpha \alpha - K_\Omega \Omega_1, \tag{2}$$

where α is the angle of rotation of the reducer's output axis, Ω_1 is the motor's angular rotational velocity, K_α and K_Ω are proportionality factors.

The speed of the reducer's output shaft is related to the motor velocity by the relationship $\Omega = \Omega_1/K_r = d\alpha/dt$, where K_r is the reduction coefficient.

The equation of the electronic amplifier can be given in the form

$$U_a = K_a \Delta U, \tag{3}$$

where U_a is the voltage at the amplifier's output and K_a is the gain.

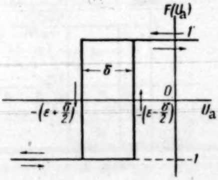
The equation of the relay block has the form

$$U = \Psi[U_a] = |U|\, F(U_a), \tag{4}$$

where U is the voltage applied to the motor circuit.

We take the motor's voltage supply to be constant and equal to 48 v, i.e., we do not take into account the action of the scheme for switching the supply voltage. Such an assumption significantly simplifies the solution of the problem without leading to any essential errors in the investigation, since it is based on the fact that switching of the supply voltage to 24 v occurs close to zero error, and turns out to be essential only for the autooscillatory mode. Consequently, in calculating the autooscillation parameters, it is necessary to consider the motor's supply voltage as equal to 24 v, while for the investigation of the system's transient motions one should take the supply voltage as equally 48 v.

The nonlinear function $F(U_a)$ is shown in Fig. 2, where $\left(\varepsilon + \frac{\delta}{2}\right)$ and $\left(\varepsilon - \frac{\delta}{2}\right)$ are the operate and release voltages, respectively, for the relays.



$F(U_a)$

$-(\varepsilon-\frac{\delta}{2})$
U_a
-1

Fig. 2.

The equation for the motor's electrical circuit, if one neglects the armature's inductance, looks as follows:

$$U = IR + C_e\Omega_1, \tag{5}$$

where I is the armature current, R is the active impedance of the armature winding, $E_l = C_e\,\Omega_1$ is the motor's counter-emf and C_e is the motor constant.

If we take the load torque M_L to be proportional to the angle of rotation of the reducer's output axis α, i.e., $M_L = K_L\alpha$, then the equation of motor motion can be given in the form

$$J_{re}\frac{d\Omega}{dt} = C_M I K_r - K_L\alpha, \tag{6}$$

where C_M is the motor constant and J_{re} is the moment of inertia, referred to the reducer's output axis. By eliminating from (2)-(6) all the variables except $U_1 = K_a K_\alpha \alpha$, we get

$$A\frac{d^2U_1}{dt^2} + B\frac{dU_1}{dt} + CU_1 = -F\left(U_1 + D\frac{dU_1}{dt}\right), \tag{7}$$

where

$$A = \frac{J_m R}{|U| C_M K_r K_\alpha K_a}, \quad B = \frac{C_e K_r}{|U| K_\alpha K_a},$$

$$C = \frac{R K_L}{|U| C_M K_r K_\alpha K_a}, \quad D = \frac{K_\Omega K_r}{K_a}.$$

We introduce the following dimensionless parameters:

$$t^* = \sqrt{\frac{C}{A}}\, t, \; x = CU_1, \; h = \frac{B}{2\sqrt{AC}},$$

$$k = D\sqrt{\frac{C}{A}}, \; \mu_\varepsilon = C\varepsilon, \; \Delta = C\delta. \tag{8}$$

Equation (7), written in dimensionless quantities, has the form

$$\frac{d^2x}{dt^{*2}} + 2h\frac{dx}{dt^*} + x = -\Phi\left(x + k\frac{dx}{dt^*}\right). \tag{9}$$

The function $\Phi(\sigma)$, where $\sigma = x + k\,dx/dt^*$, is shown on Fig. 3. This function is described by the equation

$$\Phi(\sigma) = \begin{cases} 1 \text{ for } \sigma \geqslant \mu_\varepsilon - \frac{\Delta}{2}, & \text{if } \Phi(\sigma_0) = 1, \\ -1 \text{ for } \sigma \leqslant \mu_\varepsilon + \frac{\Delta}{2}, & \text{if } \Phi(\sigma_0) = -1, \end{cases} \tag{10}$$

where σ_0 is the initial condition at time t = +0.

3. The Phase Plane

By setting $dx/dt^* = \dot{x} = y$, we write the equation of motion (9) in the form

$$\dot{x} = y, \quad \dot{y} + 2hy + x = -\Phi(x + ky). \tag{11}$$

We now consider the structure of the servomechanism's phase space. It follows, from the system of equations in (11), that the phase space of the system being investigated is a two-sheeted phase plane. On sheet I the system's motion is described by the differential equations

$$\dot{x} = y, \quad \dot{y} + 2hy + x = -1. \tag{12}$$

On sheet II,

$$\dot{x} = y, \quad \dot{y} + 2hy + x = 1. \tag{13}$$

From the system of equations (12) and (13), it follows that the system's equilibrium states are found at the points x = − 1, y = 0 and x = 1, y = 0, which are stable foci (if h < 1) on stable nodes (if h > 1). Since, in actual systems, $\left|\mu_\varepsilon \pm \frac{\Delta}{2}\right| < 1$ and $\mu_\varepsilon > \frac{\Delta}{2}$, then the representative point, moving along a sheet of the phase plane, always reaches the switching line, never falling on a point

of rest. For the purpose of system stabilization, the damping coefficient k is ordinarily chosen to be positive. The motion of the representative point along the two-shetted phase plane occurs in the following manner. While moving along sheet $I\ [\Phi(x+ky)=1]$ (Fig. 5), the representative point, during some interval of time, falls on the line $L\left(\sigma=\mu_\varepsilon+\frac{\Delta}{2}\right)$ from the line $L_1\left(\sigma=\mu_\varepsilon-\frac{\Delta}{2}\right)$.

The system's phase space is not symmetric, since its equilibrium states are found at points on the axis y = 0 which are unsymmetrically placed with respect to the point $x=\mu_\varepsilon$, $y=0$.

4. Point Transformation

The problem of seeking limiting cycles and of investigating the partitioning of the phase space leads to the study of the point transformation of line L into itself. This point transformation T is defined as $T=S^+S^-$ Transformation S^+ corresponds to a transition of the representative point, lying on line L, to a point lying on line L_1, and transformation S^- corresponds to a transition of the representative point lying on line L_1 to a point lying on line L. We shall find the analytic expressions for the transformations S^+ and S^-.

Sheet I of the Phase Plane $I\ [\Phi(\sigma)=-1]$

The case of small damping (h < 1). If, at time $t^*=0$, the representative point begins its motion from point (x_0, y_0) of line L (cf., Fig. 5) and, during the time interval $t^*=t_1$, arrives at point (x_1, y_1) of line L_1, then the analytic expression for transformation S^+, in the form of a correspondence function $u_1=u_1(v)$, in the case when h < 1, will have the form

$$u_1=\frac{\left(1+\mu_\varepsilon+\frac{\Delta}{2}\right)\cos w_1t_1-\left(1+\mu_\varepsilon-\frac{\Delta}{2}\right)e^{ht_1}}{\left(k-2h+\frac{1}{k}\right)\sin w_1t_1}w_1+$$

$$+\frac{\left(1+\mu_\varepsilon+\frac{\Delta}{2}\right)(h-k)}{k-2h+\frac{1}{k}}+\mu_\varepsilon+\frac{\Delta}{2}$$

$$v=\frac{-\left(1+\mu_\varepsilon-\frac{\Delta}{2}\right)\cos w_1t_1+\left(1+\mu_\varepsilon+\frac{\Delta}{2}\right)e^{-ht_1}}{\left(k-2h+\frac{1}{k}\right)\sin w_1t_1}w_1+ \tag{14}$$

$$+\frac{\left(1+\mu_\varepsilon-\frac{\Delta}{2}\right)(h-k)}{k-2h+\frac{1}{k}}+\mu_\varepsilon-\frac{\Delta}{2},$$

where $w_1^2=1-h^2$, $u_1=x_0$, $v=x_1$, and t_1 is a parameter. It follows from (14) that

$$\frac{dv}{du_1}=\frac{f_1(t_1)}{f_2(t_1)},$$

where

$$f_1(t_1)=w_1\left(1+\mu_\varepsilon-\frac{\Delta}{2}\right)-\left(1+\mu_\varepsilon+\frac{\Delta}{2}\right)$$

$$(w_1\cos w_1t_1+h\sin w_1t_1)\,e^{-ht_1},$$

$$f_2(t_1)=-w_1\left(1+\mu_\varepsilon+\frac{\Delta}{2}\right)+\left(1+\mu_\varepsilon-\frac{\Delta}{2}\right)$$

$$(w_1\cos w_1t_1-h\sin w_1t_1)\,e^{ht_1},$$

$$\frac{d^2v}{du_1^2}=\frac{(k-2h+1/k)\,f_3(t_1)\sin^3 w_1t_1}{f_2^3(t_1)}, \tag{15}$$

where

$$f_3(t_1)=-\frac{2h}{w_1}\left[(1+\mu_\varepsilon)^2-\frac{\Delta^2}{4}\right]\sin w_1t_1+$$

$$+\left(1+\mu_\varepsilon-\frac{\Delta}{2}\right)^2e^{ht_1}-\left(1+\mu_\varepsilon+\frac{\Delta}{2}\right)^2e^{-ht_1}.$$

If the initial conditions are changed on sheet I, i.e., if x_0 and y_0 are changed, the representative point will be translated along sheet I during different time intervals.

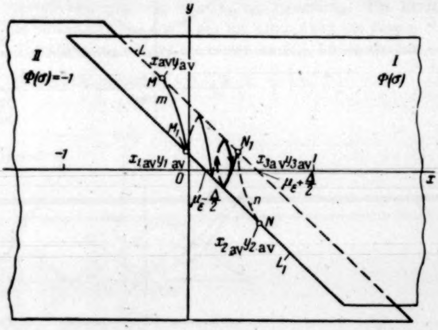

Fig. 6.

The transition time t_1 for the movement of the representative point from line L to line L_1 by a trajectory lying on sheet I and not going off on line L, i.e., the transition time along the "cylindrical" surface, lies in the interval $(0, t_{1s})$. The time T_{1s} is defined by the condition that trajectory m and line L be tangent at the point $M(x_{av}, y_{av})$ (cf., Fig. 6)

$$w_1\left(1+\mu_\varepsilon-\frac{\Delta}{2}\right)-\left(1+\mu_\varepsilon+\frac{\Delta}{2}\right)$$

$$(w_1\cos w_1t_{1s}+h\sin w_1t_{1s})\,e^{-ht_{1s}}=0. \tag{16}$$

The coordinates x_{av} and y_{av} of point M are also defined by the condition that trajectory m and line L be tangent:

$$x_{\text{av}} = -k\frac{\left(1+\mu_\varepsilon+\frac{\Delta}{2}\right)}{k-2h+\frac{1}{k}} + \mu_\varepsilon + \frac{\Delta}{2},\quad y_{\text{av}} = \frac{1+\mu_\varepsilon+\frac{\Delta}{2}}{k-2h+\frac{1}{k}}. \tag{17}$$

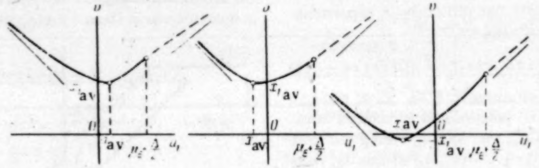
The transition time along a trajectory in sheet I and going off the L varies continuously from t_{1s} to π/w_1 as x_0 varies. An investigation of the function $v = v(u_1)$ for the case when $h < 1$ is given in Appendix I. The curve $v = v(u_1)$, given by the parametric equations (14) and (15), is defined for all t_1 from 0 to π/w_1. It is clear, from an analysis of the phase plane, that from the entire set of arms of the curve there should be retained only those arms which satisfy the following limits of coordinate variation:

$$u_1 \text{ from } \mu_\varepsilon + \frac{\Delta}{2} \text{ to } -\infty, \qquad v \text{ from } x_{1\,\text{av}} \text{ to } \infty.$$

The curves $v = v(u_1)$ for values of system parameters such that $h < 1\left|\mu_\varepsilon \pm \frac{\Delta}{2}\right| < 1$ are given in Fig. 7.

The case of large damping ($h > 1$). The transformation S^+ in the form of a correspondence function $u_1 = u_1(v)$, for the case when $h > 1$, has an analytic expression which may be obtained from (14) by replacing w_1, $\sin w_1t_1$ and $\cos w_1t_1$ by, respectively, w, $\sinh wt_1$ and $\cosh wt_1$, where $w^2 = h^2-1$. In the case when $h > 1$, the transition time along a trajectory in sheet I which goes off line L varies within the interval (t_{1s}, ∞). The time t_{1s}, in the case when $h > 1$, has an expression which may be obtained from (16) by replacing w_1, $\sin w_1t_1$ and $\cos w_1t_1$ by, respectively, $w \sinh wt_1$ and $\cosh wt_1$. For the case when $h > 1$, the coordinates x_{av} and y_{av} are expressed, as in the case for $h < 1$, by (17). An investigation of the function $v = v(u_1)$ for the case when $h > 1$ is given in Appendix I. The limits of variation of u_1 and v are the same as in the case when $h < 1$. The curves of $v = v(u_1)$ for values of the parameters $h > 1, \left|\mu_\varepsilon \pm \frac{\Delta}{2}\right| < 1$ are given in Fig. 8.

h close to zero



h close to unity

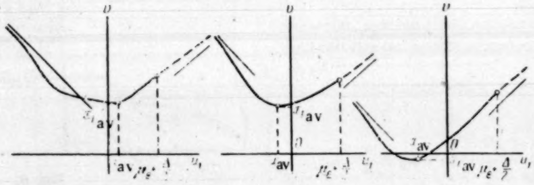


Fig. 7.

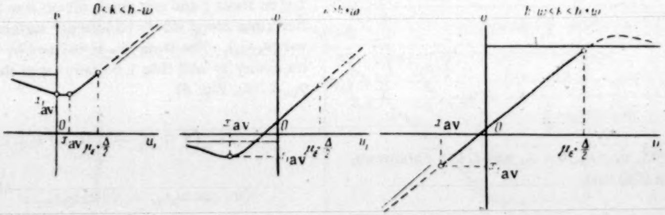

Fig. 8.

Sheet II of the Phase Plane [$\Phi(\sigma) = 1$]

The case of small damping (h < 1). If the representative point, at time $t^* = 0$, begins its motion from point (x_1, y_1) on line L_1 (Fig. 5) and, after a time interval $t^* = t_2$, arrives at the point (x_2, y_2) of line L, then the transformation S^- in the form of a correspondence function $u_2 = u_2(v)$ in the case h < 1 has an analytic expression which can be obtained from (14) by replacing v, u_1, t_1 and μ_ϵ by, respectively, $-u_2$, $-v$, t_2 and $-\mu_\epsilon$, where $u_2 = x_2$, $v = x_1$ and t_2 is a parameter.

The transition time t_2 for the movement of the representative point from line L_1 to line L along a trajectory in sheet II which does not leave line L_1 lies in the interval $(0, t_{25})$. The transition time by a trajectory in sheet II which leaves line L_1 varies continuously from t_{25} to π / w_1 as x_1 varies. The time t_{25}, defined by the condition that trajectory n and line L_1 be tangent at the point $N(x_{2av}, y_{2av})$, has an expression, in the case when h < 1, which can be obtained from (16) by replacing μ_ϵ and t_{15} by, respectively, $-\mu_\epsilon$ and t_{25}. The coordinates x_{2av} and y_{2av} in the case h < 1 and in the case h > 1 have expressions which can be obtained from (17) by replacing x_{av}, y_{av}, and μ_ϵ by, respectively, $-x_{2av}$, $-y_{2av}$ and $-\mu_\epsilon$.

Investigation of the correspondence function $u_2 = u_2(v)$ in the case h < 1 can be carried out in analogy with that of the function $v = v(u_1)$ in the case when h < 1, which is given in Appendix, I, by replacing v, u_1, μ_ϵ, t_1, t_{15} and t_{11} by, respectively, $-u_2$, $-v$, $-\mu_\epsilon$, t_2, t_{25} and t_{22}.

From an analysis of the phase plane (Fig. 5), it is clear that of the entire set of arms of the curve $u_2 = u_2(v)$, there should remain only those arms which satisfy the following limits of coordinate variation:

u_2 from x_{3av} to $-\infty$, v from x_{1av} to ∞.

Curves of $u_2 = u_2(v)$ for system parameter values $h < 1$, $\left|\mu_\epsilon \pm \frac{\Delta}{2}\right| < 1$ are shown on Fig. 9. Also shown on Fig. 9 are curves $u_1 = u_1(v)$ for system parameter values $h < 1$, $\left|\mu_\epsilon \pm \frac{\Delta}{2}\right| < 1$.

The case of large damping (h > 1). The transformation S^- in the form of a correspondence function $u_2 = u_2(v)$ in the case h > 1 has an analytic expression which can be obtained from (14) by replacing v, u_1, μ_ϵ, w_1, t_1, sin w_1t_1 and cos w_1t_1 by, respectively, $-u_2$, $-v$, $-\mu_\epsilon$, w, t_2, sinh wt_2 and cosh wt_2. In the case h > 1, the time t_{25} has an expression which can be obtained from (16) by replacing μ_ϵ, w_1, t_{15}, sin s_1t_{15} and cos w_1t_{15} by, respectively, $-\mu_\epsilon$, w, t_{25}, sinh wt_{25} and cosh wt_{25}

Investigation of the function $u_2 = u_2(v)$ in the case h > 1 can be carried out in analogy to the investigation, given in Appendix II, of the function $v = v(u_1)$ in the case h > 1 by replacing v, u_1, μ_ϵ, t_1, t_{15}, t_{13} and t_{14} by, respectively, $-u_2$, $-v$, $-\mu_\epsilon$, t_2, t_{25}, t_{23} and t_{24}. The limits of variation of u_2 and v are the same as in the case h < 1. The curves $u_2 = u_2(v)$ are shown on Fig. 10 for system parameter values $h > 1$, $\left|\mu_\epsilon \pm \frac{\Delta}{2}\right| < 1$.

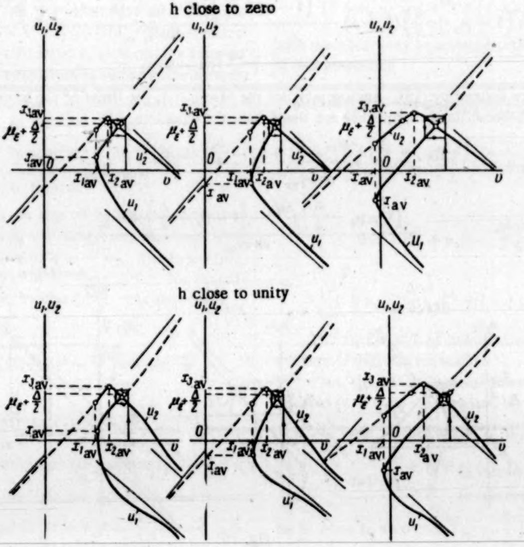

Fig. 9.

Figure 10 also shows curves of $u_1 = u_1(v)$ for system parameter values $h > 1$, $\left|\mu_\varepsilon \pm \frac{\Delta}{2}\right| < 1$.

System Autooscillations

It follows, from the diagrams of point transformation shown in Figs. 9 and 10 for the parameter values $h \neq 1$, $\left|\mu_\varepsilon \pm \frac{\Delta}{2}\right| < 1$, that for these system parameters, the curves of the correspondence function $u_1 = u_1(v)$ and $u_2 = u_2(v)$ must always have one point of intersection in the first quadrant. Consequently, there exists one stable limiting cycle, i.e., there are always autooscillations in the system.

These autooscillations can be established with the presence of a skipping mode (cf., Fig. 6). On the "cylindrical surface" between lines L and L_1, points MN_1NM_1 mark out the region in which a skipping mode occurs. From the conditions that the curves $u_1 = u_1(v)$ and $u_2 = u_2(v)$ intersect, in the case $h < 1$, we find the times t_{1a} and t_{2a} of the half periods of autooscillation in the case when $h < 1$. These conditions are written in the form

$$\begin{gathered}
\frac{\left(1+\mu_\varepsilon+\frac{\Delta}{2}\right)e^{-ht_{1a}}-\left(1+\mu_\varepsilon-\frac{\Delta}{2}\right)\cos w_1t_{1a}}{\sin w_1 t_a}\,w_1+2(h-k)= \\
=\frac{\left(1-\mu_\varepsilon-\frac{\Delta}{2}\right)e^{ht_{2a}}-\left(1-\mu_\varepsilon+\frac{\Delta}{2}\right)\cos w_1 t_{2a}}{\sin w_1 t_{2a}}\,w_1, \\
\frac{\left(1+\mu_\varepsilon+\frac{\Delta}{2}\right)\cos w_1 t_{1a}-\left(1+\mu_\varepsilon-\frac{\Delta}{2}\right)e^{ht_{1a}}}{\sin w_1 t_{1a}}\,w_1+2(h-k)= \\
=\frac{\left(1-\mu_\varepsilon-\frac{\Delta}{2}\right)\cos w_1 t_{2a}-\left(1-\mu_\varepsilon+\frac{\Delta}{2}\right)e^{-ht_{2a}}}{\sin w_1 t_{2a}}\,w_1
\end{gathered} \tag{18}$$

The amplitude of velocity autooscillation y is expressed, in the case when $h < 1$, by the equation $y_a = \frac{y_0 - y_1}{2}$ or

$$\begin{gathered}
y_a=\frac{1}{2k\left(k-2h+\frac{1}{k}\right)}\left[-\frac{\left(1+\mu_\varepsilon+\frac{\Delta}{2}\right)\cos w_1 t_{1a}-\left(1+\mu_\varepsilon-\frac{\Delta}{2}\right)e^{ht_{1a}}}{\sin w_1 t_{1a}}\,w_1-\right. \\
-\left(1+\mu_\varepsilon+\frac{\Delta}{2}\right)(h-k)-\frac{\left(1-\mu_\varepsilon+\frac{\Delta}{2}\right)\cos w_1 t_{2a}-\left(1-\mu_\varepsilon-\frac{\Delta}{2}\right)e^{ht_{2a}}}{\sin w_1 t_{2a}}\,w_1- \\
\left.-\left(1-\mu_\varepsilon+\frac{\Delta}{2}\right)(h-k)\right],
\end{gathered} \tag{19}$$

where t_{1a} and t_{2a} are defined by (18). Analogously, for the case $h > 1$, the times of the autooscillation half periods t_{1a} and t_{2a} and the autooscillation amplitude are found from the equations

$$\begin{gathered}
\frac{\left(1+\mu_\varepsilon+\frac{\Delta}{2}\right)e^{-ht_{1a}}-\left(1+\mu_\varepsilon-\frac{\Delta}{2}\right)\operatorname{ch} wt_{1a}}{\operatorname{sh} wt_{1a}}\,w+2(h-k)= \\
=\frac{\left(1-\mu_\varepsilon-\frac{\Delta}{2}\right)e^{ht_{2a}}-\left(1-\mu_\varepsilon+\frac{\Delta}{2}\right)\operatorname{ch} wt_{2a}}{\operatorname{sh} wt_{2a}}\,w,
\end{gathered} \tag{20}$$

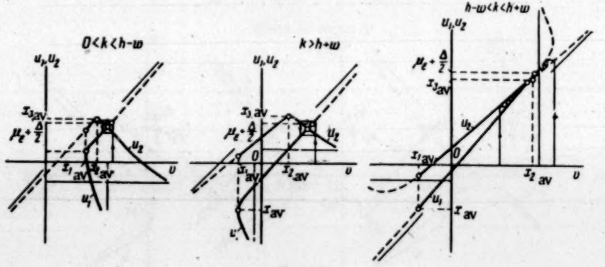

Fig. 10

$$\frac{\left(1+\mu_\varepsilon+\frac{\Delta}{2}\right)\operatorname{ch} wt_{1a}-\left(1+\mu_\varepsilon-\frac{\Delta}{2}\right)e^{ht_{1a}}}{\operatorname{sh} wt_{1a}}w+2(h-k)=$$

$$=\frac{\left(1-\mu_\varepsilon-\frac{\Delta}{2}\right)\operatorname{ch} wt_{2a}-\left(1-\mu_\varepsilon+\frac{\Delta}{2}\right)e^{-ht_{2a}}}{\operatorname{sh} wt_{2a}}w;$$

$$y_a=\frac{1}{2k\left(k-2h+\frac{1}{k}\right)}\left[-\frac{\left(1+\mu_\varepsilon+\frac{\Delta}{2}\right)\operatorname{ch} wt_{1a}-\left(1+\mu_\varepsilon-\frac{\Delta}{2}\right)e^{ht_{1a}}}{\operatorname{sh} wt_{1a}}w-\right.$$

$$-\left(1+\mu_\varepsilon+\frac{\Delta}{2}\right)(h-k)-\frac{\left(1-\mu_\varepsilon+\frac{\Delta}{2}\right)\operatorname{ch} wt_{2a}-\left(1-\mu_\varepsilon-\frac{\Delta}{2}\right)e^{ht_{2a}}}{\operatorname{sh} wt_{2a}}w- \qquad (21)$$

$$\left.-\left(1-\mu_\varepsilon+\frac{\Delta}{2}\right)(h-k)\right].$$

SUMMARY

With a looped relay characteristic of its controlling element, a loaded servomechanism whose linear portion is described by a complete second-order equation tends to an autooscillatory mode of operation for any parameter values satisfying the follow relationships:

$$h \neq 1, \quad \left|\mu_\varepsilon \pm \frac{\Delta}{2}\right| < 1, \quad k > 0.$$

The author wishes to thank N. A. Fufaev and A. S. Alekseev for their valuable advice and comments in their reading and correcting of the manuscript.

Appendix I

Investigation of the Function v = v(u₁) for the Case When h < 1

The function $v = v(u_1)$, for the case when $h < 1$, is defined by expression (14). We determine the signs of the derivatives dv/du_1 and d^2v/du_1^2 by (15). The derivative dv/du_1 is greater than zero when t_1 varies in the interval $(0, t_{1s})$ and is less than zero when t_1 varies in the interval $(t_{1s}, \pi/w_1)$ since

$$f_1(t_1)\begin{cases}<0 & \text{in interval } (0,\ t_{1s}),\\ >0 & \text{in interval } (t_{1s},\ \pi/w_1).\end{cases}$$

$$f_2(t_1)<0 \quad \text{in interval } (0,\ \pi/w_1).$$

We now determine the sign of the second derivative. The sine of the angle w_1t_1 will be greater than zero when t_1 varies in the interval from 0 to π/w_1. The expression $k-2h+1/k$ is greater than zero, since $h < 1$. We investigate the sign of the function $f_3(t_1)$ [5]. The derivative $f_3'(t_1)$ equals

$$f_3'(t_1)=h\left\{-2\left[(1+\mu_\varepsilon)^2-\frac{\Delta^2}{4}\right]\cos w_1t_1+\right.$$

$$\left.+\left(1+\mu_\varepsilon-\frac{\Delta}{2}\right)^2e^{ht_1}+\left(1+\mu_\varepsilon+\frac{\Delta}{2}\right)^2e^{-ht_1}\right\}.$$

Since, by the conditions of the problem $\left|\mu_\varepsilon \pm \frac{\Delta}{2}\right| < 1$ then, for $\cos w_1t_1 < 0$, the function $f_3'(t_1) > 0$, and for $\cos w_1t_1 < 0$, the expression $\left[(1+\mu_\varepsilon)^2-\frac{\Delta^2}{4}\right]\cos w_1t_1 > 0$ and in the undetermined inequality

$$2\left[(1+\mu_\varepsilon)^2-\frac{\Delta^2}{4}\right]\cos w_1t_1 \vee$$

$$\left(1+\mu_\varepsilon-\frac{\Delta}{2}\right)^2e^{ht_1}+\left(1+\mu_\varepsilon+\frac{\Delta}{2}\right)^2e^{-ht_1}$$

both members may be squared without changing the sign of the inequality

$$4\left[(1+\mu_\varepsilon)^2-\frac{\Delta^2}{4}\right]^2\cos^2 w_1t_1 \vee \left(1+\mu_\varepsilon-\frac{\Delta}{2}\right)^4e^{2ht_1}+$$

$$+2\left[(1+\mu_\varepsilon)^2-\frac{\Delta^2}{4}\right]^2+\left(1+\mu_\varepsilon+\frac{\Delta}{2}\right)^4e^{-2ht_1}$$

or

$$0<4\left[(1+\mu_\varepsilon)^2-\frac{\Delta^2}{4}\right]^2\sin^2 w_1t_1+$$

$$+\left[\left(1+\mu_\varepsilon-\frac{\Delta}{2}\right)^2e^{ht_1}+\left(1+\mu_\varepsilon+\frac{\Delta}{2}\right)^2e^{-ht_1}\right]^2.$$

This is, the sign of indetermined inequality $\vee$ is the sign of definite inequality <.

Thus, $f_3'(t_1)$ is greater than zero for all t_1. In the interval $(0, \pi/w_1)$ there exists, for h close to unity and $\left|\mu_\varepsilon \pm \frac{\Delta}{2}\right| < 1$, such a $t_1 = t_{11}$ that $f_3(t_{11}) = 0$ and

$$f_3(t_1)\begin{cases}<0 & \text{in interval } (0,\ t_{11}),\\ >0 & \text{in interval } (t_{11},\ \pi/w_1).\end{cases}$$

for h close to zero and $\left|\mu_\varepsilon \pm \frac{\Delta}{2}\right| < 1$, the function

$f_3(t_1)$ is less than zero in the interval $(0, \pi / w_1)$. Consequently, the second derivative d^2v/du_1^2 can take the following signs:

$$\frac{d^2v}{du_1^2}=\begin{cases} >0 \text{ at } (0, \pi/w_1) \text{ for } h, \sim 0 \ \left|\mu_\varepsilon \pm \frac{\Delta}{2}\right|<1, \\ \left.\begin{matrix} >0 \text{ at } (0, t_{11}) \\ <0 \text{ at } (t_{11}, \pi/w_1) \end{matrix}\right\} \text{ for } h, \sim 1 \ \left|\mu_\varepsilon \pm \frac{\Delta}{2}\right|<1. \end{cases}$$

For $t_1 \to 0$, the function $v \to \infty$ and $u_1 \to \infty$, but the derivative dv/du_1 tends to unity. For $t_1 \to 0$, the function $v = v(u_1)$ approximates to the asymptote

$$v = u_1 - \frac{\Delta}{k(k-2h+1/k)}.$$

For $t_1 \to \pi/w_1$, the functions $v \to \infty$ and $u_1 \to -\infty$, but the derivative tends to $-e^{-\pi h/w_1}$. The function $v = v(u_1)$, for $t_1 \to \pi/w_1$, tends to the asymptote

$$v = -e^{-\pi h/w_1} u_1 + \frac{(2h-k)(1+e^{-\pi h/w_1})}{k-2h+1/k} + \frac{\left(\mu_\varepsilon + \frac{\Delta}{2}\right)e^{-\pi h/w_1} + \mu_\varepsilon - \frac{\Delta}{4}}{k(k-2h+1/k)}.$$

Appendix II

Investigation of the Function $v = v(u_1)$ for the Case When $h > 1$

The function $v = v(u_1)$ and its derivatives dv/du_1 and d^2v/du_1^2 are defined by expressions which may be obtained from (14) and (15) by replacing w_1, $\sin w_1t_1$ and $\cos w_1t_1$ by w, $\sinh wt_1$ and $\cosh wt_1$, respectively.

We determine the sign of the derivative dv/du_1. The function $f_1(t_1)$ is less than zero for $0 < t_1 < t_{1s}$ and greater than zero for $t_{1s} < t_1 < \infty$, since $f_1(0) < 0$ and, for $t_1 = t_{1s}$, the function $f_1(t_{1s}) = 0$ and $f_1'(t_{1s}) > 0$. The function $f_2(t_1)$ is less than zero in the interval $0 < t_1 < \infty$, since $f_2(0)$ and $f_2'(t_1) = -(1 + \mu_\varepsilon - \Delta/2)e^{ht_1} \cosh wt_1 < 0$. Consequently, the derivative dv/du_1 is greater than zero in the interval $0 < t_1 < t_{1s}$ and less than zero in the interval $t_{1s} < t_1 < \infty$.

We determine the sign of the derivative d^2v/du_1^2. For $t_1 > 0$, the function $\sinh wt_1$ is greater than zero. The function $f_3(t_1)$, for t_1 equal to zero, is negative. For t_1 equal to t_{1s}, the function $f_3(t_1)$, equal to

$$\frac{(-\operatorname{ch}^2 wt_{1s}+1)\left[(1+\mu_\varepsilon)^2-\frac{\Delta^2}{4}\right]}{w \operatorname{ch} wt_{1s} + h \operatorname{sh} w t_{1s}},$$

is also less than zero and, for $t_1 = \infty$, equals infinity. Moreover, the derivative $f_3'(t_1)$, for $t_1 = 0$, equal $hw\Delta^2$ and is positive. Further, the derivative $f_3'(t_1)$ equals zero for $t_1 = t_{13}$ and $t_1 = t_{14}$, whereby

$$\left(1+\mu_\varepsilon+\frac{\Delta}{2}\right)e^{wt_{13}} = \left(1+\mu_\varepsilon-\frac{\Delta}{2}\right)e^{ht_{13}}$$

and

$$\left(1+\mu_\varepsilon+\frac{\Delta}{2}\right)e^{-wt_{14}} = \left(1+\mu_\varepsilon-\frac{\Delta}{2}\right)e^{ht_{14}},$$

where $t_{14} < t_{13}$. Since the function $f_3(t_1)$ for $t_1 = t_{14}$ equals $\left[(1+\mu_\varepsilon)^2-\frac{\Delta^2}{4}\right](h+w)e^{-wt_{14}}[1-e^{2wt_{14}}]$, and is less than zero, then $f_3(t_1)$ changes sign only once for some $t_{15} > t_{1s}$. In the case when $h > 1$, the expression $\left(k-2h+\frac{1}{k}\right)$ is positive for $0 < k < h - \sqrt{h^2-1}$ or $k > h + \sqrt{h^2-1}$, and is negative for

$$h-\sqrt{h^2-1} < k < h+\sqrt{h^2+1}.$$

It thus follows from the analysis made that the derivative d^2v/du_1^2 may assume the following signs:

$$\begin{aligned} >0 \text{ for } &\begin{cases} 0<k<h-w \quad \text{or} \quad k>h+w & \text{for } 0<t_1<t_{13}, \quad t_{1s}<t_1<t_{15}, \\ h-w<k<h+w & \text{for } t_{15}<t_1<\infty; \end{cases} \\ <0 \text{ for } &\begin{cases} 0<k<h-w \quad \text{or} \quad k>h+w & \text{for } t_{15}<t_1<\infty, \\ h-w<k<h+w & \text{for } 0<t_1<t_{1s} \quad t_{1s}<t_1<t_{15}. \end{cases} \end{aligned}$$

For $t_1 \to 0$, the functions $v \to \infty$ and $u_1 \to \infty$, for $0 < k < h-w$ or $k > h+w$, and $v \to -\infty$ and $u_1 \to -\infty$ for $h-w < k < h+w$. The derivative dv/du_1 tends to unity for $t_1 \to 0$. For $t_1 \to 0$, the function $v = v(u_1)$ approximates to the asymptote $v = u_1 - \Delta/k(k-2h+1/k)$. For $t_1 \to \infty$, the function u_1 tends to ∞ for $h-w < k < h+w$ and to $-\infty$ for $0 < k < h-w$ or $k > h+w$, and the function

$$v \to \frac{-k-\left(\mu_\varepsilon-\frac{\Delta}{2}\right)(h+w)+(h-w)+\left(\mu_\varepsilon-\frac{\Delta}{2}\right)\frac{1}{k}}{k-2h+1/k}.$$

For $t_1 \to \infty$, the function $v = v(u_1)$ approximates to the asymptote

$$v = \frac{-k-\left(\mu_\varepsilon-\frac{\Delta}{2}\right)(h+w)+(h-w)+\left(\mu_\varepsilon-\frac{\Delta}{2}\right)\frac{1}{k}}{k-2h+1/k}$$

ON BINARY SIGNAL CORRECTOR SCHEMES

V. M. Ostianu
(Moscow)

Translated from Avtomatika i Telemekhanika Vol. 21, No. 5, pp. 615-623, May, 1960
Original article submitted January 8, 1959

Brief descriptions are given of the methods of constructing and correcting signal systems which were developed by M. A. Gavrilov [1, 2, 3], R. R. Varshamov [4, 5], and R. W. Hamming [6]. The structural formulas of the corrector scheme for each of the correction methods described are found. Corrector schemes are contrived.

One of the methods of providing for correct transmission of discrete signals entails the use of a corrector, which may be connected anywhere in the transmission channel.

We shall assume that the correctors are built of diodes and relay-contact elements.

Every discrete signal can be presented in the form of sequences of zeroes and ones. The number of binary digits (bits) in a signal is called its length. There are 2^n different signals of length n. In this set, one defines the concept of the distance between any pair of codes α and β as the number of noncoincident bits in them, i.e.,

$$\rho(\alpha, \beta) = \sum_{i=1}^{n} \alpha_i - \beta_i |,$$

where $\alpha = (\alpha_1, \alpha_2, \ldots, \alpha_n)$ and $\beta = (\beta_1, \beta_2, \ldots, \beta_n)$.

It is well known [6, 3] that, in a system capable of correcting d errors (i.e., d simultaneous inverted bits), the distance between any two codes in the system must be not less than 2d + 1.

Various methods of constructing such signal systems and implementing error correction are known [4-7]. Here, we shall consider only three of them.

Gavrilov's method of signal correction. Let a set N of working signals be so constructed that any two elements of N are separated by a distance not less than D = 2d + 1. There is established such a correspondence between the signals in N and the set M of all 2^n signals that each signal α in N corresponds to the same signal α in M and that all signals $\alpha' \in M$, whose distance from $\alpha \in M$ is not greater than d correspond to the same signal $\alpha \in N$. Then, instead of correcting the signal α', one can require that each α' be executed as the signal α which corresponds to it

This is a convenient method in that it can be realized for correcting any number of errors d that is desired.

Hamming's method for signal construction and correction. This method is applicable for the correction of single errors only. The construction of the set N is carried out according to definite rules, and signal correction (i.e., error detection) reduces to the verification that these rules are satisfied.

Let it be required to construct a set N of working signals which contains not more than k signals. There is then a number l which satisfies the inequality $k \leq 2$. Then, from the relationship

$$2^t - t - 1 \geqslant l \geqslant 2^{t-1} - (t-1) - 1$$

t is determined, and the signal length is found to be $n = l + t$. t bits of the signal (specifically, reading from left to right, the first, second fourth, eight, sixteenth, etc., i.e., the bits in positions $2^0 = 1$, $2^1 = 2$, $2^2 = 4, \ldots, 2^{t-1}$) are called the check bits, while the remaining l bits are the information bits. The information bit positions are filled by all the possible combinations of zeroes and ones. The check bit positions are filled in accordance with the following rules.

In bit position $2^0 = 1$ there is placed a bit which will give a sum of zero modulo two to the bits in positions $2q + 1$ $(q = 0, 1, \ldots)$.

In bit position $2^1 = 2$ there is placed a bit which will give a sum of zero modulo two to the bits in positions $4q + 2$ and $4q + 3$ $(q = 0, 1, \ldots)$.

In bit position $2^2 = 4$ there is placed a bit which will give a sum of zero modulo two to the bits in positions $8q + 4$, $8q + 5$, $8q + 6$, and $8q + 7$ $(q = 0, 1, \ldots)$.

In general, in bit position 2^i there is placed a bit which will give a sum of zero modulo two to the bits in positions $2^{i+1}q + 2^i$, $2^{i+1}q + 2^i + 1, \ldots, 2^{i+1}q + 2^{i+1} - 1$ $(q = 0, 1, \ldots)$.

We now give an example of the construction of the set N by Hamming's method. Let k = 4, then $l = 2$, t = 3, and n = 5. The signals of set N are given in Table 1.

It is easily verified that the distance between any two signals is not less than 3.

Error-checking is executed by verifying the rules for the construction of set N. All three verifications are made; if the results of the verifications are denoted by the letters ξ, ζ and η, respectively, then the bit position in error in the signal is given by the binary number $\xi \zeta \eta$ (if one takes 1 = 100. . .0, 2 = 010. . .0, 4 = 00100. . . 0). For example,

TABLE 1

Bit position	1	2	3	4	5
Position weight	2^0	2^1	2^2	2^3	2^4
α_1	0	0	0	0	0
α_2	1	0	0	1	1
α_3	1	1	1	0	0
α_4	0	1	1	1	1

if the signal sent were α_3 = (11100) and the signal received were α_3' = (11101), then $\xi = 1$, $\zeta = 0$ and $\eta = 1$. The bit position of the error is given by the number $\xi\zeta\eta$, equal, in this case, to 101 = 5.

Varshatov's method for signal construction and correction. The set N of working signals is so constructed that its elements form an additive group with respect to the operation of bit-by-bit addition modulo two, i.e., with respect to the operation defined by the relationship

$$a \dotplus b = (a_1 \dotplus b_1, a_2 \dotplus b_2, \ldots, a_n \dotplus b_n),$$

where a = $(a_1, a_2, \ldots, a_n)$, b = $(b_1, b_2, \ldots, b_n)$ and the sign "$\dotplus$" is to be understood as addition modulo two.

Varshamov [4, 5] developed a methodology for constructing such sets N for any given code distance D. We limit ourselves here to just a brief description of this methodology.

Let it be required to construct a set N of signals containing not less than k elements. We determine the least integer l satisfying the relationship $k \leq 2^l$. We then find the least integer t satisfying the relationship

$$1 + C^1_{n-1} + C^2_{n-1} + \ldots + C^{D-2}_{n-1} < 2^t.$$

Then, $n = l + t$.

The first l bits in the signal are the information bits, the remaining t bits being the check bits.

The construction is executed as follows. One first constructs a unit matrix of l rows and l columns, to which one appends a second matrix of l rows and t columns. With this, the rows of this latter matrix must satisfy the following conditions: the number of ones in each row is not less than D-1; the number of ones in each sum (modulo two) of any two rows is not less than D-2 and, in general, the number of ones in each sum (modulo two) of any i rows is not less than D-i, where i assumes the values i = = 1, 2, . . . , D-1..

The set of l signals thus constructed is called a basis. The entire set of working signals is comprised of the set of basis signals plus all the possible sums (modulo two) of any 2,3,. . . , l basis signals (including the sum of any signal with itself, i.e., the null signal).

Example. Let k = 4 and D = 3, so that l = 2. We now determine t. For D = 3, we get

$$2^t - t - 1 \geqslant l$$

From this, t = 3 and, consequently, n = 5. We construct the unit matrix and append to it a matrix of two rows and three columns, in each row of which there is not less than two ones, the sum of these two rows containing not less than one "1"

10 011
01 111

The set N is made up of the two basis signals, their sum (modulo two) and the null signal. It is given in Table 2 (and coincides with the signals given in Table 1).

TABLE 2

α_1	00 000
α_2	10 011
α_3	11 100
α_4	01 111

R. R. Varshamov developed [5] a method for correcting d errors if the system of working signals has a code distance of D = 2d + 1. We limit ourselves here to a description of the method for correcting unitary errors, i.e., the case when D = 3.

Let there be received some signal α.

If follows, from the method of constructing the set N, that the information bits of all elements of N exhaust all the 2^l different sequences of binary numbers. Therefore, for each received signal there can be found, among the elements of set N, one element whose information bits coincide with the information bits of signal α. We denote this signal by β. We compare their check bits. It can happen that their check bits coincide exactly, i.e., $\alpha \equiv \beta$, and this means that the transmitted signal was received without distortion (error).

As was shown by the author of the method, if a unitary error changes one of the check bits of the transmitted signal, then the check bits of signal α will differ by one bit from the corresponding bits of signal β, where the bit position of the error is the bit position of the noncoinciding bit. If the unitary error changed one of the information bits of the transmitted signal, then the check bits of signal α will differ from the same bits of signal β by more than one bit, i.e., $\alpha \dotplus \beta = \gamma$.

With this, the information bits of γ will all be zero, and there will be more than one "one" among the check bits. To determine the bit position of the error, one seeks, among the signals of set N, a signal with the same check bits as γ (as was shown in [6], if the transmitted signal underwent no more than one distortion, then such a signal must of necessity be found). We denote it by δ. γ and δ differ by just one bit. The position of the latter gives the position of the error in signal α.

We give an example. Let the signal α_2 = (10011) be transmitted. We assume that the signal α = (10010) is received, i.e., that an error distorted the last check bit. From the table we find the unique signal α_2 with the same information bits as in α. Their check bits differ in one place (bit position). The position of the differing bits is the fifth one; consequently, the error distorted the fifth bit, which was in fact the case.

We now assume that the same signal α_2 was transmitted, but that the error distorted its second bit, i.e., $\alpha = (11011)$. From Table 2 we find the unique signal $\sigma_3 = (11100)$ with the same information bits as α. Their check bits differ in three positions. We then compute the sum $\alpha \dotplus \beta = \gamma = (00111)$.

In Table 2 there is a signal δ whose check bits would be the sequence 111. Obviously, $\delta = \alpha_4$. By comparing the information bits of γ and δ, we convince ourselves that the second bits do not coincide, i.e., that the error distorted the second bit, which was in fact the case.

With some modifications, this method can be extended to correct any number of simultaneous errors.

Synthesis of the correctors. We now determine the structure of the corrector for each method of correction implementation.

If each bit of a signal is simulated by the contact of some relay, then the signal itself will be simulated by the constituent units.

The corrector schemes are relay devices at whose inputs are applied distorted or correct signals from the constructed system of working signals and at whose outputs appear only correct signals (the distorted signals will have been corrected by the corrector). It is very important in this connection that the number of (simultaneous) errors in the signals be matched by the code distances.

It is obvious that such devices must be nonsequential. With identical systems of working signals, identical sets of constituents are applied to the correctors' input, and the circuits, in which one and the same set of elements operate, can be made identical. Therefore, the correctors' schemes can also be made identical, despite the fact that the sequences of operations to be executed by them are different. Obviously, this assertion is valid for any n and d.

We illustrate its validity by the example wherein n = 5 and d = 1.

Corrector for the Gavrilov method. We write the states of relays X_1, X_2, X_3, X_4, and X_5, corresponding to the signals of Table 2:

$$\begin{aligned}
&\alpha_1 - \bar{x}_1\bar{x}_2\bar{x}_3\bar{x}_4\bar{x}_5,\\
&\alpha_2 - x_1\bar{x}_2\bar{x}_3x_4x_5,\\
&\alpha_3 - x_1x_2x_3\bar{x}_4\bar{x}_5,\\
&\alpha_4 - \bar{x}_1x_2x_3x_4x_5.
\end{aligned}$$

We write all the signals at unit distance from α_1, α_2, α_3, and α_4, denoting them, respectively, by

$$\alpha_1^{\mathrm{I}}, \alpha_1^{\mathrm{II}}, \alpha_1^{\mathrm{III}}, \alpha_1^{\mathrm{IV}}, \alpha_1^{\mathrm{V}}, \alpha_2^{\mathrm{I}}, \alpha_2^{\mathrm{II}}, \ldots, \alpha_4^{\mathrm{V}}:$$

$$\begin{array}{llll}
\alpha_1^{\mathrm{I}} - \bar{x}_1\bar{x}_2\bar{x}_3\bar{x}_4\bar{x}_5; & \alpha_2^{\mathrm{I}} - \bar{x}_1\bar{x}_2\bar{x}_3x_4x_5; & \alpha_3^{\mathrm{I}} - \bar{x}_1x_2x_3\bar{x}_4\bar{x}_5; & \alpha_4^{\mathrm{I}} - \bar{x}_1x_2x_3x_4\bar{x}_5;\\
\alpha_1^{\mathrm{II}} - \bar{x}_1x_2\bar{x}_3\bar{x}_4\bar{x}_5; & \alpha_2^{\mathrm{II}} - x_1x_2\bar{x}_3x_4x_5; & \alpha_3^{\mathrm{II}} - x_1\bar{x}_2x_3\bar{x}_4\bar{x}_5; & \alpha_4^{\mathrm{II}} - \bar{x}_1x_2x_3\bar{x}_4x_5;\\
\alpha_1^{\mathrm{III}} - \bar{x}_1\bar{x}_2x_3\bar{x}_4\bar{x}_5; & \alpha_2^{\mathrm{III}} - x_1\bar{x}_2x_3x_4x_5; & \alpha_3^{\mathrm{III}} - x_1x_2\bar{x}_3\bar{x}_4\bar{x}_5; & \alpha_4^{\mathrm{III}} - \bar{x}_1x_2\bar{x}_3x_4x_5;\\
\alpha_1^{\mathrm{IV}} - \bar{x}_1\bar{x}_2\bar{x}_3x_4\bar{x}_5; & \alpha_2^{\mathrm{IV}} - x_1\bar{x}_2\bar{x}_3\bar{x}_4x_5; & \alpha_3^{\mathrm{IV}} - x_1x_2x_3x_4\bar{x}_5; & \alpha_4^{\mathrm{IV}} - \bar{x}_1\bar{x}_2x_3x_4x_5;\\
\alpha_1^{\mathrm{V}} - \bar{x}_1\bar{x}_2\bar{x}_3\bar{x}_4x_5; & \alpha_2^{\mathrm{V}} - x_1\bar{x}_2\bar{x}_3x_4\bar{x}_5; & \alpha_3^{\mathrm{V}} - x_1x_2x_3\bar{x}_4x_5; & \alpha_4^{\mathrm{V}} - x_1x_2x_3x_4x_5.
\end{array}$$

We shall denote the corrector's outputs by Y_i (the state of the i th output coincides with the undistorted state of the i th input).

Output Y_1 must be high (must carry voltage) if the second (α_2) or third (α_3) signal was transmitted or if any of the signals at unit distance from α_2 or α_3^{I} was applied to the corrector input.

We denote by c_2 the sum of the constituents corresponding to α_2 and α_2^{I}, α_2^{II}, α_2^{III}, α_2^{IV}, α_2^{V}, and, by c_3, the sum of the constituents corresponding to α_3, α_3^{I}, α_3^{II}, α_3^{III}, α_3^{IV}, and α_3^{V}.

$$\begin{aligned}
c_2 &= \bar{x}_1\bar{x}_2\bar{x}_3x_4x_5 + x_1x_2\bar{x}_3x_4x_5 + x_1\bar{x}_2x_3x_4x_5 +\\
&+ x_1\bar{x}_2\bar{x}_3\bar{x}_4x_5 + x_1\bar{x}_2\bar{x}_3x_4\bar{x}_5 + x_1\bar{x}_2\bar{x}_3x_4x_5, +\\
+ c_3 &= \bar{x}_1x_2x_3\bar{x}_4\bar{x}_5 + x_1\bar{x}_2x_3\bar{x}_4\bar{x}_5 + x_1x_2\bar{x}_3\bar{x}_4\bar{x}_5 +\\
&+ x_1x_2x_3x_4\bar{x}_5 + x_1x_2x_3\bar{x}_4x_5 + x_1x_2x_3\bar{x}_4\bar{x}_5, \qquad (1)
\end{aligned}$$

which gives us

$$F_{(Y_1)} = c_2 + c_3. \qquad (2)$$

By introducing the analogous notation for c_4

$$\begin{aligned}
c_4 = {} & \bar{x}_1x_2x_3x_4x_5 + x_1x_2x_3x_4x_5 +\\
& + \bar{x}_1\bar{x}_2x_3x_4x_5 + \bar{x}_1x_2\bar{x}_3x_4x_5 +\\
& + \bar{x}_1x_2x_3\bar{x}_4x_5 + \bar{x}_1x_2x_3x_4\bar{x}_5 \qquad (1')
\end{aligned}$$

and by reasoning the same as in the derivation of $F_{(Y_1)}$, we get

$$\begin{aligned}
F_{(Y_2)} &= c_3 + c_4,\\
F_{(Y_3)} &= c_3 + c_1,\\
F_{(Y_4)} &= c_2 + c_4,\\
F_{(Y_5)} &= c_2 + c_4.
\end{aligned} \qquad (2')$$

Corrector for the Hamming method. The corrector must execute three verifications. Let the result of each of these be recorded by the auxiliary relays Z_1, Z_2, and Z_3. Then

$$\begin{aligned}
F_{(Z_1)}' = x_1 \oplus x_3 \oplus x_5 = {} & x_1x_3x_5\\
& + \bar{x}_1\bar{x}_3x_5 + x_1\bar{x}_3\bar{x}_5 + \bar{x}_1x_3\bar{x}_5,
\end{aligned}$$

$$F_{(Z_2)} = x_2 \otimes x_3 = x_2\bar{x}_3 + \bar{x}_2 x_3,$$
$$F_{(Z_3)} = x_4 \oplus x_5 = x_4\bar{x}_5 + \bar{x}_4 x_5. \qquad (3)$$

The circuit comprised of $\bar{z}_1\bar{z}_2\bar{z}_3$ indicates an absence of errors, the circuit $z_1z_2z_3$ indicates that an error occurred in the second bit, $\bar{z}_1z_2z_3$ indicated that an error occurred in the third bit, etc. On the basis of such arguments, we can arrive at the functional schematic shown on Fig. 1. Such a scheme was developed in practice and was described in [8]* but, due to the presence of feedback in it (from relay Z_1 to relay X_j), its operation is unstable. To eliminate the instability of circuit operation, one can transform it in the following way: at the circuit's outputs we supply the states of the input elements and the corresponding corrections to them, obtained by means of the auxiliary relay. Then, the action functions for the input circuits are written as follows:

$$\begin{aligned}
F_{(Y_1)} &= x_1(\bar{z}_1\bar{z}_2\bar{z}_3 + \bar{z}_1z_2\bar{z}_3 + \bar{z}_1\bar{z}_2z_3 + z_1z_2\bar{z}_3 + z_1\bar{z}_2z_3) + \bar{x}_1z_1\bar{z}_2\bar{z}_3,\\
F_{(Y_2)} &= x_2(\bar{z}_1\bar{z}_2\bar{z}_3 + z_1\bar{z}_2\bar{z}_3 + \bar{z}_1\bar{z}_2z_3 + z_1z_2\bar{z}_3 + z_1\bar{z}_2z_3) + \bar{x}_2\bar{z}_1z_2\bar{z}_3,\\
F_{(Y_3)} &= x_3(\bar{z}_1\bar{z}_2\bar{z}_3 + z_1\bar{z}_2\bar{z}_3 + \bar{z}_1z_2\bar{z}_3 + \bar{z}_1\bar{z}_2z_3 + z_1\bar{z}_2z_3) + \bar{x}_3z_1z_2\bar{z}_3,\\
F_{(Y_4)} &= x_4(\bar{z}_1\bar{z}_2\bar{z}_3 + z_1\bar{z}_2\bar{z}_3 + \bar{z}_1z_2\bar{z}_3 + z_1z_2\bar{z}_3 + z_1\bar{z}_2z_3) + \bar{x}_4\bar{z}_1\bar{z}_2z_3,\\
F_{(Y_5)} &= x_5(\bar{z}_1\bar{z}_2\bar{z}_3 + z_1\bar{z}_2\bar{z}_3 + \bar{z}_1z_2\bar{z}_3 + \bar{z}_1\bar{z}_2z_3 + z_1z_2\bar{z}_3) + \bar{x}_5z_1z_2z_3.
\end{aligned} \qquad (4)$$

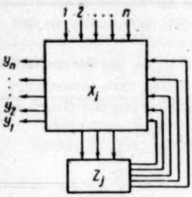

Fig. 1.

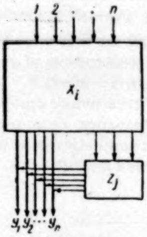

Fig. 2.

The functional schematic of such a corrector is shown on Fig. 2.

If the corrector is constructed in accordance with the structural formulas (3) and (4), then the corrector will contain three auxiliary relays, in addition to the five basic ones, and will be a two-cycle circuit.

Since we established that, in principle, the corrector is a nonsequential device, we carry out a number of transformations of structural formulas (4), specifically: we replace the letter z_1 in them by the corresponding circuit paths of contacts x_j from (3). As a result of such substitutions, using the notation of (1), (1'), we obtain structural formulas (2), (2').

Corrector for the Varshamov method. The noncoinciding check bits in the received signal α and the signal from N with the same information bits as in α will be simulated by relays Z_1, Z_2, and Z_3. Relay Z_1, consequently, must be switched on if, when signal α is applied, one of the following four conditions holds: relays X_1 and X_2 do not operate and relay X_3 does operate; relays X_1 and X_3 do operate and relay X_2 does not; relays X_1 and X_2 do operate and relay X_3 does not; relays X_1 and X_3 do not operate and relay X_2 does, i.e.,

$$F_{(Z_1)} = \bar{x}_1\bar{x}_2x_3 + x_1\bar{x}_2x_3 + x_1x_2\bar{x}_3 + \bar{x}_1x\,\bar{x}\,. \qquad (5)$$

By analogous reasoning, we can obtain the action functions for relays Z_2 and Z_3:

$$F_{(Z_2)} = \bar{x}_1\bar{x}_2x_4 + x_1\bar{x}_2\bar{x}_4 + x_1x_2x_4 + \bar{x}_1x_2\bar{x}_4,$$
$$F_{(Z_3)} = \bar{x}_1\bar{x}_2x_5 + x_1\bar{x}_2\bar{x}_5 + x_1x_2x_5 + \bar{x}_1x_2\bar{x}_5. \qquad (5')$$

If only some one relay Z is activated, then the error occurred in the check bits where, if relay Z_1 is activated, then the first check bit should be corrected, i.e., Y_3 must have voltage on it if relay X_3 is switched off, and conversely, and all the other outputs must be under voltage if the corresponding X relays are switched in. If only relay Z_2 is activated, then the output Y_4 is in the privileged position and , if the single relay Z_3 is activated, then this position will be held only by the output Y_5.

It is easily remarked that an error in the first information bit of any signal will lead to a noncorrespondence in the second and third check bits, i.e., relays Z_2 and Z_3 must be activated simultaneously. It is also easily verified that an error in the second information bit of any signal leads to a noncorrespondence of all three check bits, i.e., relays Z_1, Z_2, and Z_3 must be activated simultaneously. And, finally, if there are no errors in the signal, then there will be no noncorrespondences in the check bits, i.e., all the Z relays will be inactivated.

---

* In the circuit drawings certain annoying misprints occurred: in circuit (a) $\bar{x}_1$ should appear instead of x_1, and x_1 should appear instead of $\bar{x}_1$.

All that has been said so far can be written in the form of the following table:

If	$z_1\bar{z}_2\bar{z}_3$	then	$Y_1=x_1$	$Y_2=x_2$	$Y_3=\bar{x}_3$	$Y_4=x_4$	$Y_5=x_5$
If	$\bar{z}_1z_2\bar{z}_3$	then	$Y_1=x_1$	$Y_2=x_2$	$Y_3=x_3$	$Y_4=\bar{x}_4$	$Y_5=x_5$
If	$\bar{z}_1\bar{z}_2z_3$	then	$Y_1=x_1$	$Y_2=x_2$	$Y_3=x_3$	$Y_4=x_4$	$Y_5=\bar{x}_5$
If	$\bar{z}_1z_2z_3$	then	$Y_1=\bar{x}_1$	$Y_2=x_2$	$Y_3=x_3$	$Y_4=x_4$	$Y_5=x_5$
If	$z_1z_2z_3$	then	$Y_1=x_1$	$Y_2=\bar{x}_2$	$Y_3=x_3$	$Y_4=x_4$	$Y_5=x_5$
If	$\bar{z}_1\bar{z}_2\bar{z}_3$	then	$Y_1=x_1$	$Y_2=x_2$	$Y_3=x_3$	$Y_4=x_4$	$Y_5=x_5$

One can conclude from the table that

$$\begin{aligned}
F_{(Y_1)} &= x_1(z_1\bar{z}_2\bar{z}_3+\bar{z}_1z_2\bar{z}_3+\bar{z}_1\bar{z}_2z_3+z_1z_2z_3+\bar{z}_1\bar{z}_2\bar{z}_3)+\bar{x}_1\bar{z}_1z_2z_3,\\
F_{(Y_2)} &= x_2(z_1\bar{z}_2\bar{z}_3+\bar{z}_1z_2\bar{z}_3+\bar{z}_1\bar{z}_2z_3+\bar{z}_1z_2z_3+\bar{z}_1\bar{z}_2\bar{z}_3)+\bar{x}_2z_1z_2z_3,\\
F_{(Y_3)} &= x_3(\bar{z}_1z_2\bar{z}_3+\bar{z}_1\bar{z}_2z_3+\bar{z}_1z_2z_3+z_1z_2z_3+\bar{z}_1\bar{z}_2\bar{z}_3)+\bar{x}_3z_1\bar{z}_2\bar{z}_3,\\
F_{(Y_4)} &= x_4(z_1\bar{z}_2\bar{z}_3+\bar{z}_1\bar{z}_2z_3+\bar{z}_1z_2z_3+z_1z_2z_3+\bar{z}_1\bar{z}_2\bar{z}_3)+\bar{x}_4\bar{z}_1z_2\bar{z}_3,\\
F_{(Y_5)} &= x_5(z_1\bar{z}_2\bar{z}_3+\bar{z}_1z_2\bar{z}_3+\bar{z}_1z_2z_3+z_1z_2z_3+\bar{z}_1\bar{z}_2\bar{z}_3)+\bar{x}_5\bar{z}_1\bar{z}_2z_3.
\end{aligned} \qquad (6)$$

The functional schematic of such a corrector coincides with the one given on Fig. 2.

By eliminating contacts of the Z_i relays on the basis of (5) and (5'), and by using the notation of (1) and (1'), we also arrive at (2) and (2').

The synthesis of the corrector circuit can be executed in the following way. We construct the (1,3)-terminal network which realizes the conductances c_2, c_3, and c_4. Then, by means of diode networks, we realize the function of $F_{(Y_1)}$, $F_{(Y_2)}$, $F_{(Y_3)}$, $F_{(Y_4)}$, and $F_{(Y_5)}$.

The corresponding circuit is shown on Fig. 3.

In the general case, to synthesis a scheme for any n, it is convenient to construct a (1,p)-terminal network† with a diode network instead of a (1,n) -terminal network if, in the system of working signals, there are many in which the sign "1" arises in the same bit positions.

With this, the number of diodes R does not exceed Q:

$$Q = 2[2^p - (p+1)], \qquad (7)$$

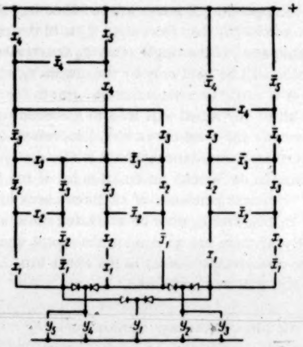

Fig. 3.

whereby R = Q if one of the n functions $F_{(Y_1)}$, $F_{(Y_2)}$, . . ., $F_{(Y_n)}$, for example, $F_{(Y_l)}$, is the sum of the aforementioned p functions, i.e.,

$$F_{(Y_l)} = c_1 + c_2 + \ldots + c_p, \qquad (8)$$

and all the remaining functions are all the possible logical consequences of applying (8). (Obviously, in this case, $n-1 = 2^p-2$).‡

To convince ourselves of this, we use the method of mathematical induction, first noting that, to construct each new output from two existing ones, two diodes are required (Fig. 4).

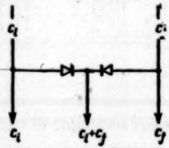

Fig. 4.

We first consider the case $n + 1 = 2^p$. We convince ourselves of the correctness of formula (7) for $p = 2(n=3)$. In this case

$$F_{(Y_1)} = c_1 + c_2, \quad F_{(Y_2)} = c_1, \quad F_{(Y_3)} = c_2$$

and

$$Q = 2[2^2 - (2+1)] = 2(4-3) = 2,$$

which is in accord with the actual facts (Fig. 4).

We now assume that (7) is valid for some p > 2, and we prove its validity for p + 1.

---

† Here, p is the number of different Boolean functions c_1, c_2, . . . , c_p entering into the expressions $F_{(Y_i)}$ (i = 1, 2, . . . , n), each of which is the sum of the constituent units corresponding to some working signal and all of its distorted variants.

‡ We exclude from the number of all the consequences the two trivial ones: 0, and the function $F_{(Y_l)}$ itself.

Let there be given p + 1 outputs, and let it be necessary to obtain from them all possible outputs by interconnecting the primordial p + 1. We assume that, from p outputs, we have already obtained all their possible outputs (their number will be $C_p^1 + C_p^2 + C_p^3 + \ldots + C_p^p$) and that we have used $2[2^p-(p+1)]$ diodes for this. We shall connect the (p+1)'th output with each of these outputs, using two diode elements for each of these connections. With this, we shall use

$$2\,[C_p^1 + C_p^2 + C_p^3 + \ldots + C_p^p] = 2^p\,(2^p - 1)$$

diodes.

Consequently, we shall use a total of

$$2\,(2^p - 1) + 2\,[2^p - (p+1)] = 2\,(2^{p+1} - [(p+1)+1])$$

diodes, q.e.d.

If $n + 1 < 2^p$, then the number of connections and the number of diode elements used will be smaller.

It should be mentioned that the assumption that the correctors be realized by relay contact circuits is not an essential one. In [9] there was presented a method of synthesizing correctors from contactless elements by structural formulas of the form of (2) and (2').

10-CHANNEL AUTOMATIC ELECTRONIC-RELAY OPTIMIZER

A. B. Shubin
(Moscow)

Translated from Avtomatika i Telemekhanika Vol. 21, No. 5, pp. 624-632, May, 1960
Original article submitted January 5, 1959

A description is given of a 10-channel automatic electronic-relay optimizer. The operational part of the optimizer consists of electronic operational amplifiers, while the controlling portion is comprised of relays and stepping switches.

The optimizer is designed to operate with electronic analog computers and is used to obtain solutions to complicated variational problems, and problems of finding extrema. An example of problem solution by means of the optimizer is given.

Certain problems in finding extrema cannot be solved analytically, either because analytic expressions of the functions are not known, or because these expressions are too complicated. This is particularly the case for the problems related to the finding of extrema of functions of many variables. In actual systems, or in systems simulated on analog computers, one can, by giving increments to the individual variables, easily determine partial derivatives and, consequently, gradients of a function. By moving either in the direction of the gradient or in a directly opposite direction, one can find a maximum or a minimum of a function. The processes of automatically determining partial derivatives and of moving in the direction of the gradient can be implemented by means of the so-called automatic optimization systems. If, from the conditions of the problem, certain boundaries are imposed on the variables then, as was shown in [1], the determination of an extremum lying on a boundary is possible in this case.

The theoretical considerations bearing on the automatic search process were presented in [1, 2]. A complete electronic variant of an optimizer was described in [3].

Below there is given a description of an electronic-relay instrument which executes automatic search for extrema. For brevity, we shall henceforth call this instrument an optimizer. Participants in the design and adjustment of the optimizer were I. N. Bocharov, A. V. Kalinina, R. I. Stakhovskii, and the author of the present paper.

The optimizer permits one to find the extremum of a function of many variables (up to 10) with the presence of limitations (boundaries).

The function whose extremum is to be sought, as well as the function which is bounded, are applied to the optimizer in the form of dc voltages whose range of variation is ±100 v. The optimizer can operate with objects which continuously output the value of the function whose extremum is being sought, as well as with objects which output the function value only at certain moments of time (for example, after solution on an electronic analog computer).

The optimizer can be divided into two parts: the operational part and the controlling part. The basic computing portions of the automatic optimizer are the electronic analog blocks. The output voltages $x_1, x_2, \ldots, x_{10}$ are formed on dc integrators; the range of variation of the output voltages is ± 100 v. The size of the trial step, applied for the determination of the partial derivatives, is regulated within the limits of 0 to 15 v. The choices just cited are related to the circumstance that the optimizer is basically designed to operate with electronic analog computers and, with such choices for the computing (operational) part, matching of the optimizer with analog computers is executed with extreme simplicity. The accuracy of the operations effected by the computer and the optimizer is of the same order of magnitude in all cases. The accuracy with which the extremum is determined depends on the character of the problem to be solved. For a test object, which was the sum of the moduli of the ten variables $Q = k\sum_{i=1}^{10} |x_i|$, the maximum relative error in determining Q_{extr} was 1%.

The optimizer's controlling portion analyzes the data applied to the optimizer and analyzes the state of the optimizer itself and, as a function of the information obtained, carries out some switching or other. Relays and stepping switches are the basic elements of the controlling portion. Adequate operation of such a controlling block is possible for frequencies of the synchronizing pulses up to 5 cps, i.e., it requires about 0.2 sec to apply the trial increments and to remember (store) the partial derivatives. Such a speed of operation is completely sufficient for operation with ordinary electronic computers which are also relay-controlled.

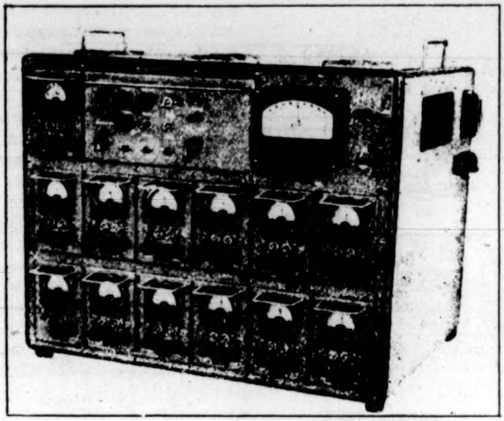

Fig. 1.

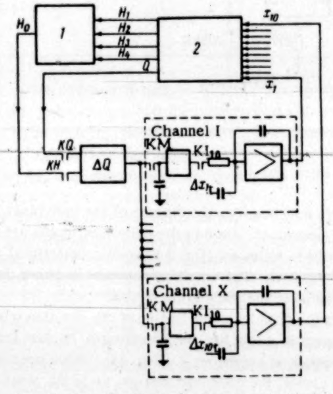

Fig. 2. 1 is the block for forming limitations, 2 is the object.

An exterior view of the optimizer is shown on Fig. 1. The optimizer design incorporates, in one chassis, the controlling block, the limitations block, the ΔQ block, the test block and 10 channel blocks. The front panel of the optimizer is comprised of the front panels of the individual blocks, on which are provided the necessary devices for manual control and testing of the instrument. The dimensions of the optimizer, without the power supply, are 650 × 500 × 450 cm.

Operational Portion

Figure 2 shows the functional schematic of the optimizer's operational portion. The theory of operation amounts to the following: the quantity Q, whose extremum is sought, is applied to the ΔQ block. This block remembers the function and determines its variation. We assume, that, in the ΔQ block, there has been remembered the value of the function for some values of $x_1, x_2, \ldots, x_{10}$; if we now give a trial increment Δx_{1t} to the first variable then, at the output of the ΔQ block we obtain the increment of the function $\Delta Q_1 \approx (\partial Q/\partial x_1)\Delta x_{1t}$, i.e., a quantity which is proportional to the partial derivative of the function with respect to the first variable. Simultaneously with the application of the trial increment, contact KM_1 closes, and storage of the quantities $\pm(\partial Q/\partial x_1)\Delta x_{1t}$ occurs in the memory link of channel 1.

After this, a trial increment is applied to the second variable, etc., up to the tenth variable. At the end of the cycle, there have been stored in the channels' memory links the quantities which are proportional to the partial derivatives, or components of the function's gradient. Upon simultaneous closure, at time t_s, of contacts KI_1, KI_2, . . . , KI_{10}, the integrators receive the increments

$$\Delta x_{1r} = \pm \frac{\partial Q}{\partial x_1} \Delta x_{1t} k t_s \,,$$

$$\Delta x_{2r} = \pm \frac{\partial Q}{\partial x_2} \Delta x_2 \, k t_s \qquad \text{etc.}$$

The trial increments Δx_t and the integration constants k are identical in all the channels, so that the operating variations of the variables (the working steps) are proportional to the components of the gradient. After a working step, one can repeat the determination of the gradient and carry out a new working step along the new gradient; in this case, the search is carried out by the gradient method. After the working step one can determine the sign of the function's change and, if this change

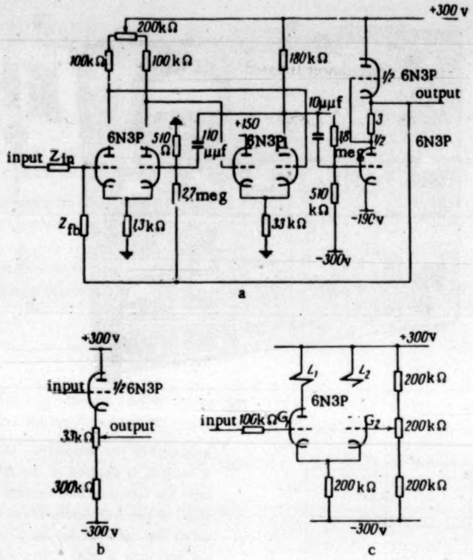

Fig. 3.

occurred in the proper direction, then the working step along the previous gradient may be repeated until such time as the increment changes sign, i.e., until such time as a partial extremum in the direction of the previous gradient is reached. This method of search is called the method of steepest descent. There are a number of switches on the controlling block whose positions correspond to the various search methods.

If limitations are imposed on the system's coordinates i.e., if some function $H_0(x_1, x_2, \ldots, x_{10})$ must not exceed a given value, then the search for an extremum is executed in the following manner. Optimization of the function Q proceeds until the function H_0 goes beyond the limits of the admissible region; with this, there is automatically switched to the input of the ΔQ block, not the function Q whose extremum is sought, but the bounded function H_0. In this case, $x_1, x_2, \ldots, x_{10}$ are so changed that they move out of the region of limitation. After the region of limitation has been left, the process of finding an extremum of function Q is continued. If an extremum is found either on the boundary or inside the region of limitation, there then occurs an oscillation about the boundary and, in the process of these oscillations, the optimizer finds the true extremum or a conditional extremum on the boundary.

We now consider the circuits of the individual blocks of the optimizer. Used in the optimizer blocks are standard cathode followers (Fig. 3 b) and dc operational amplifiers (Fig. 3 a). The amplifiers operate in either the amplification or the integration modes.

In the ΔQ block, the storing of the function whose extremum is sought and the obtaining of its next increment occur on condenser C_1 (Fig. 4a). When contact R_m is closed, the condenser charges up to the potential Q_0 while, when the contact is opened and Q varies, the following voltage is formed at the output of the cathode followers:

$$\Delta Q = (Q - Q_0)\, k_{tc},$$

where k_{tc} is the cathode follower's transfer coefficient.

The function increment obtained from the cathode follower is amplified and applied to the channels' memory links. There are inverters at the input of the ΔQ block which are switched in to the input Q by toggle switch T_{QI} and to input H_0 by toggle switch T_{HI}. This makes it possible to change the signs of the partial derivatives $(\partial Q/\partial x_i)\Delta x_{it}$ and $(\partial H_0/\partial x_i)\Delta x_{it}$, and thereby to carry out either minimization or maximization.

Figure 4b gives the functional schematic for one channel. Storage of the partial derivative occurs on condenser C_2 upon operation of storage relay R_m, i.e., upon closure of contact KM. In order that the charge on the condenser not be decreased when connected in to the integrator's input, the voltage is taken off from it by means of the cathode follower. The cathode follower is based on tube 6 N 3P which has low grid current; the change in the condenser's charge due to grid current does not exceed 0.1 v/ min. To eliminate potential leakage from condensers C_2 and C_3 (and also from condenser C_1 in the ΔQ block) as well as a fatigue effect, polystyrene MPGT condensers of 1 μf capacity are used in the optimizer.

The output voltages $x_1, x_2, \ldots, x_{10}$ are supplied from the dc amplifier-integrators. The amplifier has high gain, uses tube 6N3P in its first stage, and the operating mode of its first stage is chosen so as to minimize grid current. Integrating capacitor C_3 is connected in the amplifier's feedback path.

Application of the trial step is implemented by means of condenser C_4. Upon closure of contact RR at the integrator input, a step voltage U_{ts} is applied via the condenser. As is known, the integrator is an amplifier under these conditions, so that the following increment appears at the integrator output.

$$\Delta x_t = U_{ts}\,\frac{C_4}{C_3}.$$

Upon opening of contact RR there is a voltage step of the opposite sign, and the increment Δx_t is tapped off.

The working changes of the output voltages $x_1, x_2, \ldots, x_{10}$ (the working steps) occur upon operation of step relay R_s, i.e., upon closure of contact KI. With this, the integrator input, via a resistor of 1 meg, is connected to the output of the cathode follower, the voltage on which is proportional to the partial derivative with respect to these variables. Thus, the output voltages receive increments proportional to the partial derivatives.

The initial conditions on the integrators are established by connecting toggle switch T_2 to the channel block. With this, the capacitance of the feedback path is shunted by a resistance and, at the integrator's input, a voltage from a divider is applied.

The circuit for forming the limitation H_0 is given in Fig. 4c. The circuit includes an amplifier with four inputs. There is a vacuum-tube diode at each input. Thus, the circuit gives the sum of only the positive voltages H_i which is just the bounded function H_0. The function to be limited is applied to the limitation indication circuit in the indicator block.

The circuit for indicating limitiations (similar to the circuit used for indicating partial minima and indicating the final solution) is shown on Fig. 3c. The circuit works as follows. In the differential stage's anode circuit there are connected the windings of the polarized relay RP-4. The windings are connected toward each other. On one of the grids, G_2, the constant voltage U_0 is applied, while on the second grid, G_1, the voltage U to be compared is applied. If $U > U_0$, then the current in winding L_1 is greater than that in winding L_2, and the polarized relay is found in one of its positions. For $U < U_0$, the relay is transferred to its other position. Such a circuit allows one to fix the transition of a voltage through any threshold level with an accuracy of about 0.5 v; the hysteresis of the circuit is less than 0.1 v.

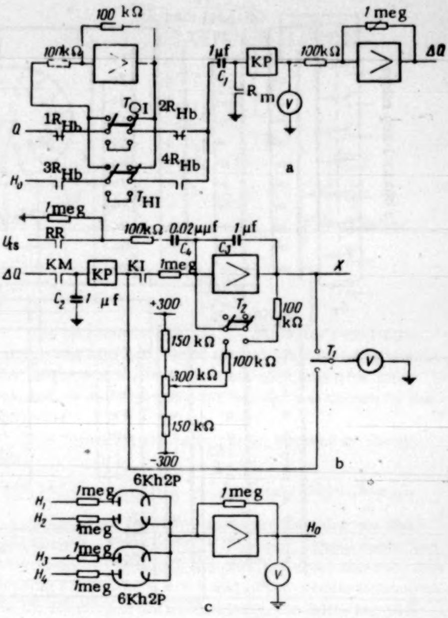

Fig. 4.

Controlling Block

The controlling block is comprised of a stepping switches, relays and switches of various types of operation (Fig. 5).

The first stepping switch SSI executes successive switching in of the memory relays of the channels and, by the Gauss-Seidel method, also executes the individual switching of the channels' step relays. Simultaneously with the switching of the channels' memory relays, the trial increments for the variables are supplied. Thus, as SSI moves along commutator segments 2-11, the gradient is determined for the function whose extremum is being sought. When on the first commutator segment, SSI applies voltage to SSII, causing execution of the operations of working-step implementation and determination of the change in the function during the working steps. With the Gauss-Seidel method, these operations are possible on seg-

ments 2-11, while commutator segment of stepping switch SSI is passed over by shunt running.

Various relays implement the following basic functions:

1. Start relay R_b, when the start button is pushed, switches in cycle relay R_c.

2. Cycle relay R_c operates upon the reception of a sync pulse from the synchronization block, and transfers SSI or SSII to the following commutator segment, i.e., implements transfer from one operation to the following one. For the optimization of continuous objects, the relay is transferred to the autooscillatory mode by toggle switch S_5.

3. Relay R_s, for shortening the variables cycle, switches SSI to shunt running in order to pass rapidly over the commutator segments which correspond to unused channels.

4. Step relays R_p and R_{p2} provide the required delay to the working step. This delay is determined by condenser C_2 and resistor R_s.

5. The minimum relay R_M operates when a partial (relative) minimum is reached. After the storage operation, relay R_M, by its own contact $2R_M$, switches SSI to gradient determination. The operation of gradient determination must also be executed when the instrument is started and upon input or output of limitations. In the first case, relay R_M is switched on by a normally open contact of the start button and, in the second case, by a special contact $6R_{Hb}$ of limitation blocking (holding) relay R_{Hb}. This contact is closed only in the periods when the relay is transferring from one state to another.

6. Holding relay R_h operates after the termination of a working step. At this moment there is implemented the analysis of the increment of the function whose extrumum is being sought, contact $3R_h$ is closed and the minimum relay is switched to the circuit for minimum indication.

Contact $1R_h$ releases relay R_{Hb}, and contact $2R_h$ switches the limitation holding relay to the limitation indication circuit. After release of R_h, the state of relay R_{Hb} depends on the state of relay R_H at the moment of holding, and remains unchanged until the following operation of relay R_h.

For the optimization of functions obtained after a solution on an analog computer, it is necessary that the holding relay operate at the moment when there is a value of the function to be optimized available at the computer. For this, 2-holding is used.

For an extremum search using the Gauss-Seidel method, the memory relays in the channels are connected-in via the commutator segments of SSI and contact $3R_{ws}$

of the working step relay. To switch this relay in, there is auxiliary relay R_x. Relay R_x operates simultaneously with SSI. Thus, when SSI transfers to the following segment, i.e., when the optimization cycle for the previous variable terminates, relay R_X is found in the operated state. Since contact $4R_x$ is closed, then simultaneously with the operation of R_p working step relay R_{ws} operates and, by its contact $3R_{ws}$, it connects in the memory relay in the corresponding channel; the operation of partial derivative determination then ensues. Contact $5R_{ws}$ cuts out the channel working step relay. Simultaneously relay R_{ws}, by contact $4R_{ws}$, cuts out relay R_x. At the time of the following working step, contact $4R_x$ will be open, relay R_{ws} will not operate, so that a working step will be executed, etc. With the Gauss-Seidel method, the channels' working step relays are opened by switch S_3, and the working step is executed for one of the channels.

The switches have the following basic functions: T_1 applies voltage to the circuit; the closed position of switch S_2 corresponds to search by the gradient method, i.e., after each working step the determination of a new gradient is made; S_3 switches of optimizer from operation by the gradient method to operation by the Gauss-Seidel method; S_4 switches in 2-holding (secondary holding) for discrete objects; S_5 connects the cycle relay to a source of external pulses; S_6 reduces the number of variables for optimization.

Solution of a Problem by Means of the Automatic Optimizer

In addition to the solution of problems without limitations, such as the automatic approximation of a given curve [3], the optimizer permits the solution of complicated problems with limitations.

The problem arose of finding the optimal control program for a motor-generator system such that, during a given time τ, the motor would make the maximum number of rotations from the moment of starting to the moment of stopping, while observing the limitations imposed on the system's internal coordinates.

As the first step, it was assumed that the motor's excitation current remains constant. An approximate linearized system of equations for the object has the form:

$$T_1 \frac{dE_g}{dt} + E_g = kU_1,$$

$$E_g - c\Omega I_{em} = I_a R_a, \quad \frac{dX}{dt} = \xi_0 \Omega.$$

Here, U_1 is the voltage applied to the generator's excitation winding, E_g is the generator's emf, I_a is the motor's armature current, I_{em} is the motor's excitation current, Ω is the angular velocity of the motor shaft, X is the angle of rotation of the output shaft, connected by a reducer to the motor shaft, R_a is the resistor of the circuit of the motor armature and the generator armature.

The circuit set up on the analog computer to simulate the given differential equations is shown on Fig. 6a.

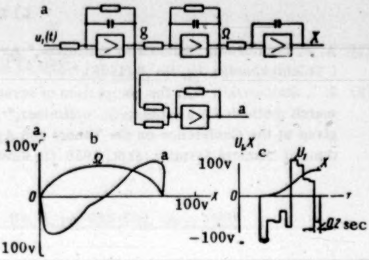

Fig. 6.

The program for varying the generator's excitation voltage was supplied from a special synchronizing block. The program was divided into ten identical time intervals and, in each interval, the voltage was chosen by the optimizer.

The following limitations were imposed on the system:

$$|U_1| \leqslant U_{1\,\max} \quad |I_a| \leqslant I_{a\,\max} \quad |\Omega| \leqslant \Omega_{\max}.$$

In the given problem, it was required that the final conditions $\Omega_{end} = 0$ and $E_g = 0$ be met. These conditions derive from the posing of the problem, since the complete stopping of the motor at the end of the process is required. For the meeting of these conditions, the following additional limitations were imposed:

$$\Omega_{end} \leqslant 0 \text{ and } E_{g\,end} \leqslant 0.$$

After starting of the system from null initial conditions, the optimizer automatically found the optimal program. In the majority of cases, the maximum X lay at the point of intersection of the boundaries of limitation:

$$\Omega_{end} \leqslant 0 \quad E_{g\,end} \leqslant 0, \quad I_a \leqslant I_{a\,\max}.$$

The optimal processes found by the optimizer are shown on Fig. 6, b and c.

CONCLUSIONS

The automatic multichannel optimizer is an instrument allowing one to solve variational problems and problems of finding extrema of functions of many variables.

The given optimizer was designed basically to operate with electronic analog computers with relay control. However, the principles on which the instrument is based can be used for creating optimizers to operate with actual objects. It is possible to have optimization of actual objects carried out in two time scales, i.e., rapid finding of extrema on an analog computer and a subsequent transfer of the results to the actual object.

RELIABILITY CHARACTERISTICS OF RESISTORS AND CONDENSERS

B. S. Sotskov and S. E. Rostkovskaya
(Moscow)

Translated from Avtomatika i Telemekhanika Vol. 21, No. 5, pp. 633-638, May, 1960
Original article submitted August 7, 1959

Methods are considered for the presentation of reliability characteristics of resistors and condensers as functions of ambient air temperature and power dissipation or applied voltage.

The reliability of constant carbon resistors, among the most widely used elements of different systems, depends on the physicochemical processes occurring both within the conducting layer and on its surface. Therefore, the reliability of resistor operation is determined, to a large degree, by the choice of materials, the design, and the technology of manufacture. In addition, the reliability of resistor operation also depends on the correctness of the selection of its operating regimen and on external conditions.

In designing circuits containing resistors and condensers, one must know how to determine their reliability under given conditions of use, which may be characterized by the ambient temperature θ_X, dissipated power P_X, voltage U_X and length of serviceable life T. For this end, it is convenient to introduce characteristics which give the connections between reliability and the parameters which define the conditions of use. The consideration of these connections comprises the subject matter of the present paper.

1. By considering the breakdowns of resistors to be random events, we have that the number of operational failures during time interval dt will be the larger, the greater is the number N of resistors, i.e.,

$$-dN = cNdt. \tag{1}$$

It follows from this that

$$\ln N = -ct + \ln k \quad \text{or} \quad N = ke^{-ct}.$$

Since $N = N_0 = k$ for $t = 0$, then

$$N = N_0 e^{-ct} \quad \text{or} \quad \frac{N}{N_0} = p = e^{-ct}.$$

Here, N is the number of existing elements (resistors) at time t: $N/N_0 = p$ is the reliability of action of the set of N_0 elements at time t; $c = 1/\tau$ is the reliability factor (the relative speed of breakdown).

Experimental data substantiate the foregoing dependence of element reliability on time for the fundamental portion of the characteristic $p = N/N_0 = f(t)$ (segment AB on Fig. 1). Deviations occur only in the initial period, when the unconditioned elements go out of order, and after point B when, due to accelerated aging and to other irreversible changes, the element breakdown rate begins to accelerate.

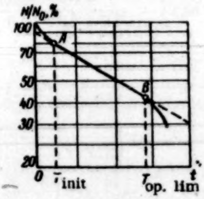

Fig. 1

Point B determines the length of serviceable life T for the given conditions of operation.

We now consider the dependence of the coefficient c on the resistor's heating temperature θ_X.

The velocity of change of material during the reaction process is defined by the equation

$$-\frac{dn}{dt} = \alpha n,$$

where n is the quantity of material at the moment of time under consideration and α is the constant velocity of the reaction.

From the equation given it follows that

$$\frac{dn}{n} = -\alpha\, dt,$$

i.e.,

$$\ln n = -\int_0^T \alpha\, dt,$$

or, for α = const,

$$\ln \frac{n}{n_0} = -\alpha T.$$

The dependence of the constant reaction speed on temperature is determined, according to Arrhenius, by the formula

$$\alpha = A_k \exp\left(-\frac{B}{273° + \theta_x}\right),$$

where A_k and B are constants and $(273 + \theta_X)$ degrees is

the absolute temperature.

Consequently,

$$\ln\frac{n}{n_0} = -A_k \exp\left(-\frac{B}{273^\circ + \theta_x}\right)T.$$

We find from the last expression that

$$T = \left[\frac{1}{A_k}\ln\frac{n_0}{n}\right]\exp\left(\frac{B}{273^\circ + \theta_x}\right)$$

or

$$T = T_\infty \exp\left(\frac{B}{273^\circ + \theta_x}\right).$$

If $\theta_x \lesseqgtr 273^\circ\,\mathrm{C}$, then

$$\frac{T}{T_0} = \frac{T}{T_\infty}\,\frac{\exp\left(\frac{B}{273^\circ + \theta_x}\right)}{\exp\left(\frac{B}{273^\circ + \theta_0}\right)} =$$

$$= \exp\left(-\frac{B\,(\theta_x - \theta_0)}{(273^\circ + \theta_x)\,(273^\circ + \theta_0)}.\right)$$

If $\theta_x \ll 273^\circ\,\mathrm{C}$, then

$$T = T_\infty \exp\left(\frac{B}{273^\circ + \theta_x}\right) =$$

$$= T_\infty \exp\left(\frac{B}{273^\circ\left(1 + \frac{\theta_x}{273^\circ}\right)}\right) \approx$$

$$\approx T_\infty \exp\frac{B}{273^\circ}\exp\left(-\frac{B}{273^2}\theta\right) =$$

$$= T_a \exp\left(-\beta\theta_x\right),$$

or

$$T = T_0 \exp\left[-\beta\left(\theta_x - \theta_0\right)\right],$$

$$T_a = T_\infty \exp\frac{B}{273^\circ}.$$

$$\beta = \frac{B}{273^2},\ T_0 = T_a \exp\left(-\beta\theta_0\right).$$

By denoting by s_0 the amount of material in one resistor, we get that $n = s_0N$ and, consequently $-s_0dN/dt = s_0N\alpha$ or $-dN/dt = N\alpha$.

By comparing the last equation with Eq. (1), we get that $\alpha = c$. We denote by c_0 the value of $\underline{c}$ which corresponds to θ_0; we then find that

$$\frac{c}{c_0} = \frac{A_k \exp\left(-\frac{B}{273^\circ + \theta_x}\right)}{A_k \exp\left(-\frac{B}{273^\circ + \theta_0}\right)} =$$

$$= \exp\left(\frac{B\,(\theta_x - \theta_0)}{(273^\circ + \theta_x)\,(273^\circ + \theta_0)}\right) \tag{2}$$

The value of the temperature θ_x is determined as the sum

$$\theta_x = \theta_{0x} + R_tP_x, \tag{3}$$

where θ_{0x} is the ambient temperature, R_t is the thermal impedance for heat transfer from the surface to the ambient medium and P_x is the power dissipated in the electrical impedance.

By substituting from (3) to (2), and by denoting by c_N the value of $\underline{c}$ for the nominal load P_N and the admissible temperature $\theta_{0x} = \theta_{0N}$, we get

$$\frac{c}{c_N} = \exp\frac{B\left[\theta_{0x} - \theta_{cN} + R_tP\ \left(\frac{P_x}{P_N} - 1\right)\right]}{(273^\circ + \theta_{0x} + R_tP_x)\,(273^\circ + \theta_{0N} + R_tP_N)}.$$

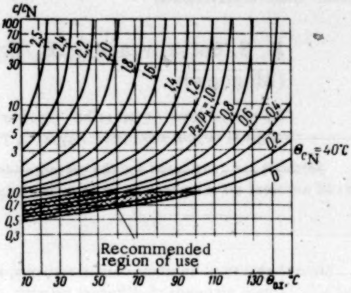

Fig. 2

Figure 2 shows the function c/c_N for one type of resistor. This function is also the characteristic $c/c_N = f(\theta_{0x}, P_x)$ for the resistor.

The quantities B, R_t and c_N are obtained by processing experimental data. The value θ_{0N} corresponds to the maximum permissible temperature for the nominal load $P_x = P_N$.

It should be kept in mind that the values of B, R_t, and c_N vary somewhat as functions of the type and the nominal resistance. However, for determining resistor reliability in the process of designing a scheme, it suffices to estimate the average value of reliability for a given type of resistor. Such averaged values of c_N and B are given in the following table.

If the limiting admissible value for the resistor temperature is $\theta_{x\,\max}$, then the magnitude of the admissible power dissipation equals $P_x = (\theta_{x\,\max} - \theta_{0x})/R_t$.

Figure 3 shows the function $P_x = f(\theta_x)$.

The value of $\theta_{0x} = \theta_{\mathrm{nom}} = \theta_{xN}$ is chosen from the condition limiting the relative variation of the resistance $\Delta R/R = f(\theta_x)$ for $\theta_{0x} = \theta_{xN}$, and should be a value which is achievable technologically or which is determined from the given conditions of use.

The method of choosing the value of $P_{\mathrm{nom}} = P_N$ consists of this: that knowing the length of useful life T_0 and the temperature θ_0 corresponding to it, we give a value to the admissible service life T. Then, based on the foregoing, we obtain

$$P_N = \frac{1}{R_t}\left[\frac{B}{\frac{B}{273^\circ + \theta_0} + \ln\frac{T}{T_0}} - (273^\circ + \theta_{0x})\right].$$

With the condition that the value of $\underline{c}$ remain invariant, the limiting value $\theta_{0x} = \theta_{x\,\max}$ is determined if we set $P_x = 0$, i.e.,

$$\theta_{x\,\max} = \theta_{0x} = \frac{B}{\frac{B}{273^\circ + \theta_0} + \ln\frac{T}{T_0}} - 273^\circ.$$

Type of resistor	Nominal power in W	Admissible limiting temperature θ_{max}, in °C	Limiting ambient temperature θ (for $P = P_N$), in °C	Thermal impedance R_t, in °C/w	c_k (mean value), hr^{-1}	β

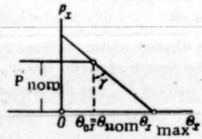

Fig. 3

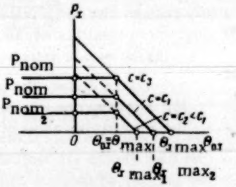

Fig. 4

Conversely, by giving various values: $c = c_1$, $c = c_2$, c c_3, . . . , we obtain various magnitudes of $\theta_{x\ max}$. This makes it possible to define P_N for a given θ_N = const (Fig. 4). The graph of Fig. 4 is another form of the same characteristic $c/c_0 = f(\theta_{0x}, P_x)$ which relates the change of reliability to the change of temperature of the ambient medium and to the change of power dissipation P_x.

The value of the thermal impedance can be found from the formula

$$R_t = \frac{1}{\mu S + 2\lambda S_0 / l_0},$$

where μ is the total heat transfer coefficient, S is the cooling surface, λ is the thermal conductivity of the current leads and S_0 and l_0 are their cross section and length. The expression for the heat transfer coefficient is written in the form

$$\mu = \mu_1 + b\frac{(273^\circ + \theta_x)^4 - (273^\circ + \theta_{0x})^4}{\theta_x - \theta_{0x}},$$

where μ_1 is the heat transfer coefficient due to gas heat conduction and convection. It should be kept in mind that the value of μ_1 varies with changes in p_{h_x}, the pressure of the air surrounding the resistor, by the law

$$\mu_{1h_x} = \mu_{1h_0}\sqrt{\frac{p_{h_x}}{p_{h_0}}},$$

where p_{h_0} is air pressure at sea level. The magnitude of μ_1 also depends on the temperature difference $\theta_x - \theta_{x_0} = \Delta\theta$. The relationship can be expressed approximately by the formula

$$\mu_1 = \mu_{10}(\Delta\theta)^m,$$

where μ_{10} corresponds to the temperature difference $\Delta\theta = 1$°C.

Thus, the value of the nominal power is determined from the expression

$$P'_N = (\theta_{x_{max}} - \theta_N)\left\{S\left[\mu_{10}(\Delta\theta)^m\sqrt{\frac{p_{h_x}}{p_{h_0}}} + b\frac{(273^\circ + \theta_{x\ max})^4 - (273^\circ + \theta\ )^4}{\theta_{x_{max}} - \theta_N}\right] + 2\lambda\frac{S_0}{l_0}\right\}.$$

It follows from this expression that the value of the nominal power must vary somewhat as a function of the air pressure and the value of $\theta_N = \theta_{x\,max} - \theta_N$. It will also depend on the mounting, since l_0 and μ_{10} also vary with this.

The foregoing table gave the values of R_t and c_N for a number of standard resistors, and also gave the permissible temperature of the ambient medium, the value of which changes for resistors of different power ratings.

2. In the case of condensers, it is necessary in estimating the reliability of the finished articles, to take into account both the effect of temperature and the effect of voltage.

The useful life of paper condensers, determined by the aging of the insulation, as a function of the temperature θ_x, is expressed by the formula

$$T_{x0} = T_0 \exp\left[-\beta_n(\theta_x - \theta_0)\right], \tag{4}$$

where β_n is a coefficient which depends on the form of the insulation.

On the other hand, for dielectric aging in the presence of an electric field, we have the empirical relationship

$$\varepsilon = AT^{-n} = \frac{A}{T^n}, \tag{5}$$

where ε is the electric field strength, T is the length of useful life and A is a constant.

By taking into account that $U = \epsilon d$ we get that $U = AdT^{-n}$, where d is the thickness of the dielectric. For condensers with paper insulation, $n \approx 0.2$.

For two different voltages U_x and U_{x0} we have that

$$\left(\frac{U_x}{U_{x0}}\right)^{1/n} = \frac{T_{x0}}{T_x}.$$

In order to take into account the influence both of U_x and of θ_x, we write the ratio T_{x0}/T_x in the form

$$\frac{T_{x0}}{T_x} = \frac{T_0}{T_x}\frac{T_{x0}}{T_0}.$$

Then,

$$\left(\frac{U_x}{U_{x0}}\right)^{1/n} = \frac{T_0}{T_x}\exp\left[-\beta_n(\theta_x - \theta_0)\right],$$

i.e.,

$$\ln\frac{U_x}{U_{x0}} = -n\ln\frac{T_x}{T_0} - n\beta_n(\theta_x - \theta_0). \qquad (6)$$

If the number of condensers remaining in service for $U_x = \text{const}$ and $\theta_x = \text{const}$ is defined by the relationship

$$p = \frac{N}{N_0} = \exp\left(-c_k T_x\right)$$

or

$$\ln p = \ln\frac{N}{N_0} = -c_k T_x,$$

then, by giving some value of p, one can easily determine the value of length of useful life which corresponds to it:

$$T_x = -\frac{\ln p}{c_k}. \qquad (7)$$

By substituting the value of T_x in (6), we get

$$\ln\frac{U_x}{U_{x0}} = -n\ln\left[-\frac{\ln p}{c_k T_0}\right] - n\beta_n(\theta_x - \theta_0). \qquad (8)$$

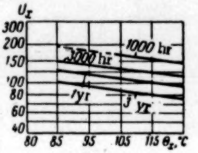

Fig. 5

Figure 5 gives the given characteristic, defined by (6), allowing one to relate the length of useful life T_x to the admissible values of the voltage U_x and the temperature θ_x.

ON THE DESIGN OF MAGNETIC AMPLIFIERS SINGLE-PHASE AND THREE-PHASE SEMICONDUCTOR RECTIFIERS ON AN ACTIVE LOAD ANDOPERATING WITH A COUNTER-EMF

A. G. Zdrok
(Moscow)

Translated from Avtomatika i Telemekhanika Vol. 21, No. 5, pp. 639-651, May, 1960
Original article submitted January 7, 1960

Methods are presented for the transfiguration of single-phase and three-phase rectifier bridges to equivalent loads, and graphicoanalytic methods are considered for determining the characteristics of saturated reactor magnetic amplifiers operating on active loads and counter-emf's.

Circuits for automatic current stabilizers in charging devices are given, and anexample of determining a magnetic amplifier's basic parameters is considered.

Semiconductor rectifiers, in conjunction with magnetic amplifiers, allow the construction of compact automatic control devices. Such devices are widely used for controlling the speed of a motor's rotation by varying the voltage applied to the armature, for charging storage batteries, etc. [1-4]. Setups with magnetic amplifiers and semiconductor rectifiers are increasingly superceding electronic and ionic tubes with grid control.

The currents and voltages at the input and output of rectifier circuits are different, in the majority of cases. The relationships between them vary with changes in the circuit's operating mode (sinusoidal) voltage or sinusoidal current at the rectifier input, etc.) and also with changes in the form of the load (active load, inductive load, counter-emf, etc.). It is usually quite difficult to find the relationships between the input and output currents and voltages, as well as to design the magnetic amplifiers operating in such circuits.

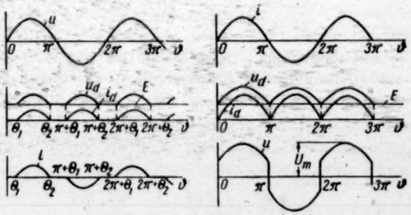
In this paper we present graphicoanalytic methods for determining the characteristics of saturated reactor magnetic amplifiers which operate with single-phase and three-phase semiconductor rectifiers, these methods being based on the transfiguration of the rectifier scheme to a load which is equivalent to it. All other rectifier schemes can be dealt with similarly to the schemes to be considered here.

Magnetic Amplifier Operation with Single-Phase Rectifier Bridge

With operation of a magnetic amplifier on an active load, supplied with rectified current, the instantaneous, average and effective currents at the input and output of the rectifier bridge are all equal to one another, as are the corresponding values of voltage. These relationships are considered for the case of ideal rectifiers, for the absolute magnitudes of the instantaneous values and the average values over a half-period. If the voltage at the rectifier inputs is sinusoidal, then the relationship between the voltage's average value and effective value, as well as the relationship between the analogous current quantities, are constant and equal to 0.9. Therefore, the design of such a circuit engenders no difficulty.

Significant difficulty is engendered in the design of a circuit for rectifier operation on a counter-emf since, in this case, the relationships between the mean and effective values of current and voltage differ from each other, and do not remain constant under variations of the circuit's mode of operation (for example, for sinusoidal voltage and sinusoidal current on the rectifier inputs).

Figure 1 shows the variation of voltages and currents for the operation of a single-phase rectifier bridge on a counter emf for the modes of sinusoidal voltage (Fig. 1a) and sinusoidal current (Fig. 1b) on the rectifier inputs. Here, u and i are the instantaneous values of voltage and current on the rectifier inputs, u_d is the instantaneous value of voltage at the rectifier bridge's output and E is the value of the counter-emf.



a b

Fig. 1.

In the mode of sinusoidal voltage on the rectifier inputs, the angles θ_1 and θ_2 are defined by the following relationships [1]:

$$\sin \theta_1 = \frac{E}{U_m}, \quad \theta_2 = \pi - \theta_1, \tag{1}$$

where U_m is the amplitude of the voltage applied to the rectifier bridge.

We denote by β_i the ratio of the mean value of rectified current I_d to the effective value of current I at the input of the rectifier bridge, i.e.,

$$\beta_i = \frac{I_d}{I}, \tag{2}$$

and, by β_u, the analogous relationship for voltage, i.e.,

$$\beta_u = \frac{U_d}{U}. \tag{3}$$

With a sinusoidal voltage at the input of a single-phase rectifier bridge, the coefficients β_i and β_u have the following values [1]:

$$\beta_i = 0.9, \quad \beta_u = 0.9 \text{ for } \frac{E}{U_m} = 0, \tag{4a}$$

$$\beta_i = 1.41, \quad \beta_u = 1 \quad \text{for} \quad \frac{E}{U_m} \approx 1. \tag{4b}$$

In order to obtain the analogous values of β_u for the mode of sinusoidal current at the rectifier inputs, we make use of the curves of current and voltage (Fig. 1b). The variation in the voltage u at the rectifier inputs can, with this, be presented by the following relationship:

$$u = E + (U_m - E) \sin \vartheta,$$

$$0 \leqslant \vartheta \leqslant n\pi \quad (n = 1, 3, 5, \ldots). \tag{5}$$

Since $|u| = |u_d|$, then the expression for the rectified voltage will have the same form as in (5), with the sole difference that n = 1, 2, 3, . . .

According to (5), the mean value of the voltage at the rectifier output will equal

$$U_d = E + \frac{1}{\pi}\int_0^{\pi} (U_m - E) \sin \vartheta =$$

$$= E + \frac{2}{\pi}(U_m - E). \tag{6}$$

The effective value of the voltage at the rectifier input is

$$U = \sqrt{E^2 + \frac{(U_m - E)^2}{2}}. \tag{7}$$

By substituting (6) and (7) in (3) we obtain, after some transformations, the expression for the coefficient β_u for the mode of sinusoidal current at the rectifier inputs:

$$\beta_u = \frac{\frac{E}{U_m} + \frac{2}{\pi}\left(1 - \frac{E}{U_m}\right)}{\sqrt{\left(\frac{E}{U_m}\right)^2 + \frac{\left(1 - \frac{E}{U_m}\right)^2}{2}}}. \tag{8}$$

For a sinusoidal current at the input of a single-phase rectifier bridge, the coefficients β_u and β_i have the following values:

$$\beta_u = 0{,}9 \quad \text{for} \quad \frac{E}{U_m} = 0, \tag{9a}$$

$$\beta_u = 1 \quad \text{for} \quad \frac{E}{U_m} = 1, \tag{9b}$$

$$\beta_i = 9 \quad \left(0 \leqslant \frac{E}{U_m} \leqslant 1\right). \tag{9c}$$

Due to the inconstancy of the coefficients β_u and β_i for a variable ratio of E/U_m, and also for sinusoidal current and sinusoidal voltage at the rectifier inputs, it is much more convenient, in designing the circuit, to use the replacement circuit with an equivalent active load r_e instead of the rectifier bridge.

For operation on a counter emf we have

$$U_d = E + I_d r, \tag{10}$$

where r is the active impedance in series with the counter-emf E (if the rectifier output is connected to the armature circuit of a motor or to a storage battery, then r is the active impedance of the armature winding or the battery's internal impedance).

The rectified voltage U_d can also be expressed in terms of the resistance r_d':

$$U_d = I_d r_d', \tag{11a}$$

where, in accordance with (10)

$$r_d' = \frac{E}{I_d} + r. \tag{11b}$$

The power applied to the rectifier bridge equals

$$P = UI. \tag{12}$$

By substituting (2) and (3) in (12), and taking (11a) into account, we get

$$P = I_d^2 \frac{r_d'}{\beta_u \beta_i}. \tag{13}$$

We introduce the concept of the equivalent load impedance r_e, and express the power P in terms of it

$$P = I^2 r_e, \tag{14}$$

where $r_e = U/I$.

By substituting (2) in (14), we get

$$P = I_d^2 \frac{r_e}{\beta_i^2}. \tag{15}$$

By equating (13) and (15), we obtain the definitive expression for the equivalent impedance r_e in the form

$$r_e = \frac{\beta_i}{\beta_u} r_d'. \tag{16}$$

Figure 2 shows the circuit for a single-phase rectifier bridge operating on a counter-emf (a) and its equivalent circuit with active impedance r_e(b). Such a transfiguration of rectifiers with counter-emf to an equivalent active impedance significantly simplifies the circuit design if a

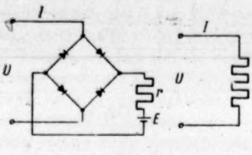


Fig. 2.

magnetic amplifier is connected in series with this impedance. For example, if one ignores the losses in the steel of the magnetic amplifier's cores, then the following equation will be valid for the fundamental harmonics of the voltages and currents (in order to simplify the notation, the subscripts for the fundamental harmonics have been suppressed in this and the following equations):

$$U_L^2 + I^2(r_e + r_{ma})^2 = U^2, \tag{17}$$

where U_L is the fundamental harmonic of the effective value of the inductive component of the voltage across the terminals of the magnetic amplifier's working winding $w_\sim$, U is the fundamental harmonic of the effective value of the source voltage, r_{ma} is the resistance of working winding $w_\sim$ of the magnetic amplifier.

By expressing the voltage and current in terms of the magnetic induction and magnetic field strength we obtain after some uncomplicated transformations,

$$\frac{B_m^2}{B_{m0}^2} + \frac{H^2}{H_0^2} = 1, \tag{18}$$

where

$$B_m = \frac{U_L}{4.44 f w_\sim S}, \quad B_{m0} = \frac{U}{4.44 f w_\sim S};$$

$$H = \frac{w_\sim I}{l}, \quad H_0 = \frac{w_\sim I_{\max}}{l} = \frac{w_\sim U}{l(r_e + r_{ma})}. \tag{19}$$

Here, l and S are the average length and cross-section of the magnetic amplifier's magnetic circuit and I_{max} is the maximum current, corresponding to $U_L = 0$.

Equation (18) is the equation of an ellipse with its center at the origin and with semiaxes B_{m0} and H_0. By joining such an ellipse with the characteristics $B_m = f(H, H_=)$, we easily obtain the magnetic amplifier characteristics we are seeking. A graphicoanalytic method of obtaining magnetic amplifier characteristics is explained in more detail in [5].

The magnitude of the resistance r_e which enters into the expression for the magnetic field strength H_0 depends on the ratio of the coefficients B_I/B_u. For example, for a sinusoidal voltage, according to (4a) and (4b), we have: for $E/U_m = 0$, $r_e = r'_d$; for $E/U_m \approx 1$, $r_e = 1.41r'_d$. For sinusoidal current, according to (9a), (9b), and (9c), we have: for $E/U_m = 0$, $r_e = r'_d$; for $E/U_m = 1$, $r_e = 0.9r'_d$.

Thus, in determining the characteristics of a magnetic amplifier by conjoining the magnetic characteristics $B_m = f(H, H_=)$ with the equation of an ellipse, (18), three limiting cases can be found (Fig. 3): $E/U_m = 0$, i.e., there is a purely active load ($r_e = r'_d = r_l$, where r_l is the load resistance); $E/U_m \approx 1$, i.e., the load is a counter-emf. Here there can be either $r_e = 0.9r'_d$ or $r_e = 1.41r'_d$.

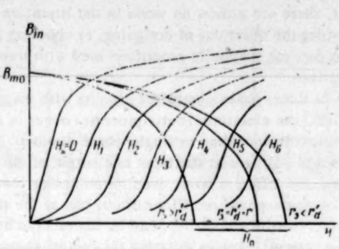

Fig. 3. Working trajectories of a magnetic amplifier with a counter-emf.

In charging storage batteries, principally starter batteries, there is a significantly large voltage drop from their emf, caused by internal impedances, so that E U_m ≈ ≈ 1. In schemes for controlling the rotational speed of motor armatures, there can be, as a function of its magnitude, $0 \leq E/U_m \leq 1$.

If the voltage drop across a magnetic amplifier is greater than the voltage drop across the input (the magnetic amplifier is operating on the upper portion of the magnetic characteristics) (Fig. 3), then $r_e < r'_d$.

The method just presented for obtaining the desired characteristic is convenient in those cases when the supply voltage and the load parameters are invariant.

When the load parameters vary, it is convenient to give different values to the resistance r_e and the current I, and to compute the value of H corresponding to them from (19), and the value of B_m from the formula

$$B_m = \frac{\sqrt{U^2 - I^2(r_e + r_{ma})^2}}{4.44 f w_\sim S}. \tag{20}$$

By conjoining the thus obtained function $B_m = f(H)$ with the characteristics $B_m = f(H, H_=)$, we can find the magnetic amplifier characteristics being sought.

In many cases, the magnetic amplifier operates with H = const. Such modes of amplifier operation occur, for example, in charging starter storage batteries, in controlling the rotational velocity of a motor armature with constant torque, etc.

In order to obtain the characteristic of a saturated reactor magnetic amplifier, providing a constancy of charging current, it is necessary to know the law of variation of the voltage across the terminals of the storage battery as a function of the charging time for I = const, i.e., it is necessary to have the function $U_d = f(t)$ or $E = f(t)$ and the internal resistance r.

Magnetic Amplifier Operation with Three-Phase Rectifier Bridge

Three-phase rectifier schemes are widely used in technology, chiefly in power rectification stands. However, there are almost no works in the literature which consider the questions of designing, or choosing the parameters for, the magnetic amplifiers used with three-phase rectifiers.

In three-phase controlled circuits with magnetic amplifiers, the electromagnetic processes occur in a more complex manner than in single-phase circuits. The currents and voltages at the input and output of the rectifier bridge are different here, even for an active load.

A three-phase rectifier circuit, just as the single-phase circuits considered earlier, can be represented by an equivalent circuit. For calculating the circuit elements, it is convenient to represent a three-phase rectifier circuit by a Y-network. With this, the transfiguration must be so effected that, in the equivalent Y-network, the same linear voltages and currents occur as in the rectifier circuit, while the same power as before acts on the load.

With an active load, the power of one phase of the equivalent Y-network, P_p, equals

$$P_p = U_p I \tag{21a}$$

or

$$P_p = I^2 r_p , \tag{21b}$$

where r_p is the phase resistance of the equivalent Y-network.

In a circuit with an active load, the rectified voltage ordinarily equals

$$U_d = I_d r_d , \tag{22}$$

where r_d is the active load impedance.

By setting $U = U_p$ in (3), and by substituting (2), (3), and (22) in (21a) and (21b), we get

$$P_p = I_d^2 \frac{r}{\beta_u \beta_i} \tag{23a}$$

$$P_p = I_d^2 \frac{r_p}{\beta_i^2} . \tag{23b}$$

Equating (23a) and (23b), we obtain, finally,

$$r_p = \frac{\beta_i}{\beta_u} r_d . \tag{24}$$

Expression (24) is the condition for the transfiguration of a three-phase rectifier circuit to an equivalent Y-network with the resistance of each phase equal to r_p. This expression is analogous to Expression (16) for single-phase rectifier circuits.

Figure 4 shows the three-phase rectifier bridge circuit with an active load (a) and the equivalent Y-network corresponding to this circuit (b). An analogous Y-network is also equivalent to a three-phase circuit with zero output. The difference is solely in the magnitude of phase resistance r_p, determined by the coefficients β_i and β_u.

The values of the coefficients β_i and β_u for a three-phase rectifier bridge circuit operating on an active load are given in Table 1.

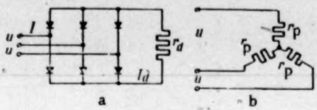

Fig. 4.

TABLE 1

Mode of rectifier operation	β_i	β_u
Sinusoidal voltage on rectifier input	1.227	2.12
Sinusoidal current on rectifier input	1.35	2.34

For other forms of load (counter-emf and active-inductive load), the coefficients β_i and β_u are given in [1, 6, 7].

Figure 5 shows the circuit of a three-phase rectifier with a magnetic amplifier and an active load (a) and the equivalent Y-network (b) (for the purposes of simplification, the functional dependence of the magnetic amplifier's induction on current is not shown in Fig. 5b).

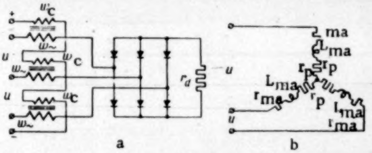

Fig. 5.

The following equation is valid for the fundamental harmonics of voltage and current for each phase of the equivalent Y-network [with the same assumptions as for (17)]:

$$U_L^2 + I^2 (r_p + r_{ma})^2 = U_p^2 . \tag{25}$$

In designing three-phase circuits, one frequently has to do with linear voltage sources. By taking this into account, and by expressing the voltage and current in terms of magnetic induction and magnetic field strength, according to (19), after some uncomplicated transformations, we obtain

$$\frac{3B_m^2}{B_{m0}^2} + \frac{3H^2}{H_0^2} = 1. \tag{26}$$

For the substituting of (19) in (25), it is assumed that U is the linear source voltage and that $r_e = r_p$.

As with (18), (26) is the equation of an ellipse which, when joined to the characteristics $B_m = f(H, H_=)$, allows one to obtain easily the desired magnetic amplifier characteristics.

The coefficients β_I and β_u are different for the modes of sinusoidal current and sinusoidal voltage on the rectifier input. However, the ratios of the coefficients, β_I/β_u for each of these modes are almost identical, being equal to 0.579 for the mode of sinusoidal voltage, and to 0.577 for the mode of sinusoidal current.

Sinusoidal voltage at the rectifier input occurs only for $B_m = 0$. But, $B_m \neq 0$ always for magnetic amplifier operation. Therefore, in computing the magnetic amplifier characteristics $H = f(H_=)$, the ratio $r_p = 0.577 r_d$ should be used.

If it is required to determine the load characteristics $H_d = f(H_=)$, then it is necessary to multiply the ordinates of the curves $H = f(H_=)$ by the coefficient β_I.

For variations of the load parameters or of the line voltage U, it is convenient to compute the magnetic induction B_m by the formula

$$B_m = \frac{\sqrt{U^2 - 3I^2(r_p + r_{ma})^2}}{\sqrt{3} \cdot 4.44 f w_{\sim} S}. \qquad (27)$$

For operation of the rectifier on a counter-emf, the equivalent Y-network in accordance with (11a), will have a form analogous to that shown in Fig. 4. The only difference will be that, in this case,

$$r_p = \frac{\beta_I}{\beta_u} r_d'. \qquad (28)$$

For operation of a three-phase rectifier on a counter-emf, the same ratio is retained between the fundamental harmonic of the input voltage and the dc component of the output voltage as for a purely active impedance, i.e., for charging storage batteries with rectified current, the coefficients β_u given in Table 1 are valid. Also retained is the ratio between the fundamental harmonic of input current and the dc component of the output current [1]. As for an active load, we consider that $r_p = 0.577 r_d'$, and r_d' is defined by (22), where $r_d = r_d'$.

Schemes for Devices for the Automatic Stabilization of Charging Current

Charging of many types of storage batteries is carried out with dc which is invariant in magnitude. In many case, the invariance in current magnitude is necessary in the charging process in order that the battery charge can be gauged. For example, the charge on acid storage batteries is determined by the density of electrolyte and voltage across the terminals, both invariant over several hours, for one and the same charging current. The charge of alkaline batteries is determined by the magnitude of the capacitance obtained by them (with an invariant charging current, the charge is here determined actually by the batteries' charging time).

In charging devices with saturated-core magnetic amplifiers, it is not difficult to implement automatic stabilization of the charging current (shown in Figs. 6 and 7).

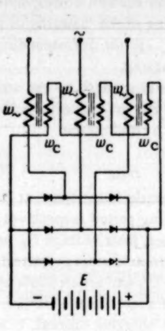

Fig. 7.

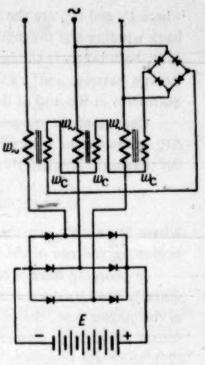

Fig. 6.

As a function of the quality of the steel and of the operational mode of the magnetic amplifier, the control winding w_c, in order to obtain a stabilized charging current, can be connected either to the terminals of the storage battery to be charged, to provide positive voltage feedback (Fig. 6), or to a source of invariable voltage, to provide constant bias (Fig. 7).

To explain the choice of one scheme or another for magnetic amplifier control, Fig. 8 shows the characteristics $B_m = f(H, H_=)$.

In the process of charging storage batteries, their voltages is changed from U_d' to U_d'' by the amount

$$\Delta U_d = U_d'' - U_d'. \qquad (29)$$

This change of voltage, in the circuit with positive feedback (cf., Fig. 6), gives rise to an increase in the magnetic amplifier's magnetizing current and, consequently, the magnetic field strength due to the current in the positive feedback winding is increased by an amount $\Delta H_= \equiv \Delta U_d$. The quantity $\Delta H_=$ is defined by the formula

$$\Delta H_= = H_='' - H_=' = \frac{\Delta U_d}{\varepsilon} \frac{w_c}{l} = (I_='' - I_=') \frac{w_c}{l}, \qquad (30)$$

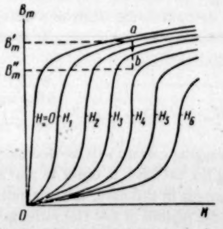

Fig. 8. Working trajectories of a magnetic amplifier used in charging devices.

where $I'_=$ and $H'_=$ are the magnetizing current of the feedback winding and magnetic field strength corresponding to it, both taken at the beginning of the charging of the storage battery, and $''_=$ and $H''_=$ are the corresponding quantities at the end of the charging.

Change of the magnetic field strength by the amount $\Delta H_=$ gives rise to a decrease in the magnetic induction in the magnetic amplifier's cores by an amount

$$\Delta B_m = B'_m - B''_m, \qquad (31)$$

Where B'_m and B''_m are the magentic inductions at the beginning and end of the charging period respectively.

In charging storage batteries, their voltage U_d ordinarily changes considerably (in acid storage batteries of the starter type, the voltage U''_d can reach 135% of its initial value U'_d). However, in accordance with (20) or (27), to obtain constancy of the charging current, it is necessary to decrease insignificantly the magnetic induction in the magnetic amplifier's cores. Therefore, the magnetic amplifier must operate in the saturated region of the characteristic $B_m = f(H, H_=)$ so that, with an increase in voltage U_d, the relative growth in the magnetic field strength $\Delta H_=$, induced by the positive feedback current, will be larger than the relative decrease in magnetic induction ΔB_m. In Fig. 8, the working trajectories of the magnetic amplifier are shown by the dashed lines between points a and b.

To obtain a charging current which is invariant in magnitude, it is necessary to choose such a mode of magnetic amplifier operation in which, for a variation in magnetizing magnetic field strength defined by (30), the magnetic induction must be changed by the amount ΔB_m, computed in accordance with (20) or (27) and (31). This mode of magnetic amplifier operation, providing automatic stabilization of the charging current, we express by the equation

$$(H''_= - H'_=)_{H=\text{const}} = \frac{\Delta U_d}{r_c}\frac{w_c}{l}, \qquad (32a)$$

where $(H''_= - H'_=)_{H=\text{const}}$ are the limits of variation of the magnetizing strength on the family of characteristics $B_m = f(H, H_=)$ for variation of the magnetic induction, computed from (20) or (27), from B'_m to B''_m.

The right member of (32a) is the increment of magnetic field strength as the result of a change in voltage of the storage battery in accordance with (29).

If

$$(H''_= - H'_=)_{H=\text{const}} > \frac{\Delta U_d}{r_c}\frac{u_c}{l}, \qquad (32b)$$

then the charging current will be decreased in the process of charging the battery. In order to provide a constant charging current in this case, the magnetic amplifier must operate in the regions of low field strength H or high field strength $H_=$, i.e., the trajectory must be shifted either to the left, or down, or down and to the left simultaneously.

$$(H''_= - H'_=)_{H=\text{const}} < \frac{\Delta U_d}{r_c}\frac{w_c}{l}, \qquad (32c)$$

then the charging current will be increased in the process of charging the battery. In order to provide here a constant charging current, the magnetic amplifier must operate in the regions of large field strength H and low field strength $H_=$, i.e., the trajectory must be shifted either to the right, or up, or up and to the right simultaneously.

Charging devices in which stabilization of charging current was provided by the choice of the proper mode of magnetic amplifier operation were considered in [3, 4].

To decrease the dimensions and weight of the power magnetic amplifiers used in charging devices, it is ordinarily recommended that one use cold-rolled steel such as, for example, É320, É330, É370. These brands of steel differ from transformer steel, not only by their large values of magnetic saturation induction, but also by the steepness of the slope of the characteristics, particularly in the case when toroidal cores prepared from strips are used [8].

If the characteristics $B_m = f(H, H_=)$ of the magnetic amplifiers used are almost vertical in their unsaturated portions then, to provide constancy of charging current, it suffices to provide a constant bias using, for this, small-size germanium diodes of type DG-Ts (Fig. 7). Connecting a battery in the bias circuit can permit the elimination of the effect of oscillations in the supply voltage U on the magnitude of the charging current. Since the magnetic induction B_m changes within narrow limits during the battery charging process, then this method allows the implementation of a completely satisfactory stabilization of charging current.

Example of the Determination of the Basic Parameters of a Saturated Reactor Magnetic Amplifier

We earlier considered methods for determining the characteristics of magnetic amplifiers operating on a counter emf. We now show that, by means of the relationships already provided, we can also compute the basic parameters of a planned magnetic amplifier.

We consider the sequence of the determinations of the basic parameters of a magnetic amplifier intended for the charging of 14 starter storage batteries of type 6STÉN-140M by a current of invariable magnitude, equal to 10 amperes.

In Table 2 (the upper two rows) there are given the charging characteristics of one element of a 6STÉN-140M storage battery, 50% discharged, for charging by a 10 amp current.

The rectified voltage will equal

$$U_d = mnU_{el},$$

where m is the number of storage batteries to be charged (m = 14) and n is the number of elements in one battery (n = 6).

To determine whether or not it is possible to charge the given quantity of storage batteries, one must com-

TABLE 2

Circuit parameters	Time, in hours						
	0	1	2	4	6	8	10
Charging current I_d amperes	10	10	10	10	10	10	10
Voltage on a storage battery element, volts	2.1	2.17	2.2	2.23	2.34	2.59	2.59
Rectified voltage, volts	176.4	182	185	187	196.4	217.5	217.5
Equivalent phase resistance r_p, ohms	10.18	10.5	10.68	10.8	11.33	12.54	12.54
$B_m = f(t)$	. . .	. . .	. . .	. . .	. . .	. . .	. . .

pute $U_{d\ max}$. For this, it is necessary to know the maximum possible voltage on one element, $U_{el\ max}$. For starter batteries, ordinarily $U_{el\ max} \leq 2.7$ v. Then, $U_{d\ max} = 226.8$ v.

According to (3) and the data of Table 1, in the example under consideration, if the voltage drop in the rectifier is neglected, the rectified voltage can equal

$$U_d = \beta_u U_p = (2.12 - 2.34) \frac{220}{\sqrt{3}} = 269 - 297 \text{ v.}$$

With the given relationships of the possible rectified voltage and the maximum possible voltage on the storage batteries, we decide that charging will occur with an approximately sinusoidal voltage on the rectifier bridge's input. But since $B_m \neq 0$ with this, then the equivalent phase resistance will be defined by the relationship

$$r_p = 0.577 \frac{U_d}{10}.$$

The results of computing r_p are given in Table 2.

The current I on the rectifier input, according to (2), will equal 8.15 amp.

In (27), which relates the given parameters with the magnetic amplifier's parameters, there are still four unknown quantities: B_m, $w_\sim$, S and r_{ma}. The active impedance of winding $w_\sim$ is very small and, for a preliminary estimate of the parameters, it may be neglected.

When positive voltage feedback is used, constancy of charging current can be attained only when the magnetic amplifier operates on the saturated portion of characteristics $B_m = f(H, H_=)$. Therefore, the magnitude of B_m can be given for a well-known brand of steel. By being given the magnitude of S as well, we can compute the number of turns of winding $w_\sim$.

In order that the initially chosen values of $w_\sim$ and S correspond closely to the actual magnitudes, we can use the following assumptions.

For the initial and final moments of storage battery charging, the following relationships are valid:

$$U^2 = U'^2_L + I^2 r'^2_p, \qquad U'_L = 4.44 f w_\sim S B'_m \cdot 10^{-8},$$

$$U^2 = U''^2_L + I^2 r''^2_p, \qquad U''_L = 4.44 f w_\sim S B''_m \cdot 10^{-8},$$

$$H' = H'' = H = \frac{I w_\sim}{l}.$$

The quantities with one prime (') relate to the beginning of the charging period of the storage battery, while those with two primes relate to the period's end. The resistances r_{ma} are ignored here, since we are making only a preliminary choice of parameters.

By transforming these equations, we obtain a function for the determination of the volume of steel

$$V = \frac{I^2 \sqrt{r''^2_p - r'^2_p}}{4.44 f H \cdot 10^{-8} \sqrt{B'^2_m - B''^2_m}}.$$

Due to the increase of voltage on the storage batteries to provide I = const, the magnetic induction B_m must be decreased. This decrease in induction is ordinarily insignificant in the charging of starter storage batteries. By taking this into account, and by selecting the magnetic induction B_m, one can compute the value of the square root $\sqrt{B'^2_m - B''^2_m}$.

By being given the magnitude of the magnetic field strength H for the selected type of steel, we can approximately determine the core volume.

If the invariance of the charging current is to be provided by biasing, then the chosen magnitude of H must correspond to the vertical segments of the steel's magnetic characteristics.

The expression given for the volume of steel can facilitate to a significant degree the determination of the magnetic amplifier parameters if one uses, for example, standard three-leg laminas [9]. From the known volume V one can choose the type of lamina and, from this, one can select l and S. From the known value of S, one can approximately determine the number of turns of winding $w_\sim$ by the formula

$$w_\sim = \frac{I \sqrt{r''^2_p - r'^2_p}}{4.44 f S \cdot 10^{-8} \sqrt{B'^2_m - B''^2_m}}.$$

From the number of turns found for winding $w_\sim$, one can approximately gauge the resistance r_{ma}, for which it is necessary to be given the current density and to compute the mean length of the turns.

In thus computing approximately the basic parameters of the magnetic amplifier, it is necessary to determine the law of variation of variation of magnetic induction $B_m = f(t)$ in accordance with (27) and to conjoin the function thus obtained for H = const with the characteristics $B_m = f(H, H_{=})$. The results of the computation of $B_m = f(t)$ can be found in Table 2.

The choice of the required mode of magnetic amplifier operation to provide I_d = const was presented in a previous section.

Limitations on the size of this paper prevent us from giving here the entire design of the magnetic amplifier.

CONCLUSIONS

The transfiguration suggested of one-phase and three-phase rectifier bridges to equivalent loads permits the use of the simplest, most graphic and sufficiently accurate graphicoanalytic method of designing saturated reactor magnetic amplifiers.

In this paper we have shown the simplest methods of stabilizing charging current, which are attained by the proper choice of operating mode of the magnetic amplifier.

ON THE SIMULATION OF LINEAR SYSTEMS WITH n STATIONARY RANDOM INPUT PROCESSES WITHOUT THE USE OF RANDOM FUNCTION GENERATORS

Ya. Shilkhanek

(Pardubice, Czechoslovakia)

Translated from Avtomatika i Telemekhanika Vol. 21, No. 5, pp. 652-654, May, 1960
Original article submitted January 12, 1960

A method is described for determining the mean value of the square of the output quantity of a linear system with n stationary random input processes by means of a simulating device without the use of random function generators. This method is a generalization to systems with n inputs of the method described in [2].

In solving various problems in the domain of regulation and automatic control, one frequently has to deal with the problem of determining the average value of the square of the output quantity of a system with n stationary random processes at the system's inputs. We shall assume that the input processes are stationary and ergodic, and that their spectral densities (proper and mutual) are rational fractional functions of the complex frequency s.

Posing of the Problem

We denote by y(t) the output quantity of the linear system under consideration. The mean value of the square of y(t) is defined by the relationship

$$\overline{y^2} = \lim_{t\to\infty} \frac{1}{t} \int_0^t [y(\tau)]^2 d\tau. \tag{1}$$

A generator of n stationary random processes with given proper and mutual spectral densities was described in [1]. On the basis of this generator we can construct a block schematic for determining the mean value of the square of the system's output quantity (Fig. 1). On this block schematic, $Q_1, Q_2, \ldots, Q_n$ are the noncorrelated generators of white noise, Sh are shaping filters, S_n is the given linear system with n inputs, Sq is a squaring device, I is an integrator, $x_1(t), x_2(t), \ldots, x_n(t)$ are the random input processes of system S_n, and y(t) is the system's output process.

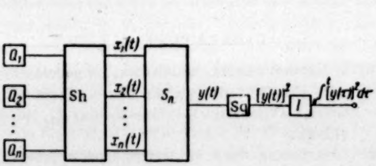

Fig. 1.

For sufficiently large t, one can determine the mean value of the square of y(t) from the integrator's output quantity in accordance with (1). With this, it is necessary to use n generators of noncorrelated white noise. These generators must be quite accurate and stable.

A method was described in [2], applicable to linear systems with one stationary random input process, for determining the mean value of the square of the output quantity by means of a simulating device, eliminating the necessity of using white noise generators. This method is based on the possibility of generating an input random process with a known spectral density by means of a white noise generator and a linear shaping filter Sh (the determination of whose transfer function is described in [1, 2,]).

We denote by W(t) the impulsive response of the series-connected shaping filter Sh and the given linear system S_1. Based on known relationships, we obtain

$$\overline{y^2} = \int_0^\infty [W(\tau)]^2 d\tau. \tag{2}$$

The block schematic shown on Fig. 2 follows from this. In this case, the input of the shaping filter has applied to it, not white noise, but a unit pulse function (a Dirac function). With increasing t, the integrator's output quantity tends to the quantity $\overline{y^2}$.

The superiority of this method is primarily that the white noise generator is excluded from the solving block schematic. The linear system is acted upon by a precisely defined function of time, which increases the accuracy of the determination of the quantity $\overline{y^2}$. Below we give a generalization of this method for a linear system S_n with n stationary random process at the system's inputs.

Fig. 2.

Solution of the Problem

The correlation function of the output quantity of a linear system with n stationary random processes at the inputs is defined [2] by the relationship.

$$\varphi_{yy}(\tau) = \sum_{m=1}^{n} \sum_{k=1}^{n} \int_{0}^{\infty} -$$

$$- \left[W_m(\tau_1) \int_{0}^{\infty} W_k(\tau_2)\, \varphi_{mk}(\tau - \tau_2 + \tau_1)\, d\tau_2 \right] d\tau_1, \tag{3}$$

where $\varphi_{mk}(\tau)$ is the mutual correlation (cross-correlation) function of the mth and kth random processes at the input, $W_i(\tau)$ is the system's impulsive response to the ith input and $\varphi_{yy}(\tau)$ is the correlation function of the system's output quantity.

We use (3) to determine the magnitude of $\overline{y^2}$. Since the series connection of the shaping filters Sh and the system S_n is a linear system with n inputs then, in our case, $W_i(\tau)$ will be the impulsive response to the ith input of shaping filters Sh at the output of the system S_n. The function $\varphi_{mk}(\tau)$ (the correlation functions of the random processes at the inputs of shaping filters Sh) are defined by the equations

$$\begin{aligned} \varphi_{mk}(\tau) &= \delta(\tau) \quad \text{for} \quad m = k, \\ \varphi_{mk}(\tau) &= 0 \quad \text{for} \quad m \neq k. \end{aligned} \tag{4}$$

By substituting (4) in (3), for $\tau = 0$, we obtain the quantity $\overline{y^2}$ in the form

$$\overline{y^2} = \varphi_{yy}(0) = \sum_{i=1}^{n} \int_{0}^{\infty} [W_i(\tau)]^2\, d\tau. \tag{5}$$

We denote by $\overline{y_i^2}$

$$\overline{y_i^2} = \int_{0}^{\infty} [W_i(\tau)]^2\, d\tau, \tag{6}$$

i.e., the mean value of the square of the output quantity y when the inputs of the shaping filters are acted upon by only one white noise generator Q_i.

Then, from (5), we get

$$\overline{y^2} = \sum_{i=1}^{n} \overline{y_i^2}. \tag{7}$$

Consequently, each value of $\overline{y_i^2}$ [cf., (6)] can be determined by the method described in [2].

Thus, the mean value of the square $\overline{y^2}$ of the output quantity of linear system S_n with n stationary random input processes can be obtained at the output of the block schematic shown on Fig. 3. At the inputs of shaping filters Sh there act, at the individual moments of time T_i, unit pulse functions $\delta(t - T_i)$. The moments T_i (i = 1, 2, . . . , n) must be so determined that, at these moments, the entire system is found in a virtual resting state. The integrator I sums the values of $\overline{y^2}$ step by step in accordance with (7), such that, for $t > \max\{T_1, T_2, \ldots, T_n\}$, its output quantity tends to the value $\overline{y^2}$.

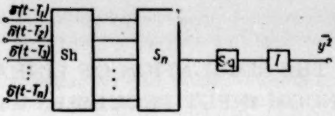

Fig. 3.

It is well known, from the methods of solving problems on simulating devices (analog computers), that the unit pulse functions can be replaced by the introduction of the proper initial conditions.

CONCLUSIONS

In the solution of various practical problems, it is necessary to determine the mean value of the square of the output quality of a linear system S_n at the n inputs of which there act n stationary random processes with known spectral densities in the form of rational-fractional functions of the complex frequency s. This problem can be solved by using the block schematic shown in Fig. 1.

For a system S_1 with one stationary random process at the input, a method is described in [2] which eliminates the use of a random process generator. In the present paper, this method was generalized to an arbitrary linear system S_n with n inputs, acted upon by n stationary random processes with known proper and mutual spectral densities.

The block schematic for the analog computer computations consists, in addition to the given linear system, of shaping filters (their transfer functions are determined by the very simple methods described in [1]) a squaring device and an integrator (Fig. 3). At the inputs of the shaping filters appear, not white noise, but unit pulse functions. With this, the mean value of the square $\overline{y^2}$ is obtained at the integrator's output.

The advantage of this method of computing the quantity $\overline{y^2}$ is, above all, that random function generators are eliminated. Since the entire system is acted upon, not by random processes, but by accurately defined functions of time [the pulse functions $\delta(\tau)$], one can expect a greater accuracy in determining the desired quantity $\overline{y^2}$.

INFORMATION

BUREAU OF THE PRESIDIUM OF THE ACADEMY OF SCIENCES OF THE USSR

Decision of Feb. 12, 1960, Number 134, Moscow

On the Decision of the Conference on the Theory of Invariance and its Application to Automatic Devices of October 20, 1958 (Kiev)

After hearing the communication of the chairman A. A. Dorodnitsyn, of the commission of the Presidium of the AN SSSR on the decision of the Conference on the Theory of Invariance and its Application to Automatic Devices, of Oct. 20, 1958 (in Kiev), the Bureau of the Presidium of the Academy of Science of the USSR has decided:

1. To endorse the conclusions of the commission of the Presidium of the AN SSSR on the decision of the Conference on the Theory of Invariance and its Application to Automatic Devices, of Oct. 20, 1958 (in Kiev) the Appendix).

2. To publish the conclusions of the commission in the journal Avtomatika i Telemekhanika (Automation and Remote Control).

Vice-President of the
Academy of Science, USSR
Academician A. V. Topchiev

Chief Scientific Secretary
Presidium of the Academy of
Science, USSR
Corresponding Member AN SSSR
E. K. Fedorov

APPENDIX TO THE DECISION OF THE BUREAU OF THE PRESIDIUM AN SSSR OF FEBRUARY 12, 1960, Number 134

Conclusions of the Commission in Connection with the Discussion on the Theory of Invariance

The commission, consisting of Academician A. A. Dorodnitsyn, Academician AN Ukrainian SSR A. Yu. Ishlinskii and Corresponding Member AN SSSR B. N. Petrov, designated on October 28, 1958 by the vice president of the AN SSSR, Academician A. V. Topchiev, in considering the decisions of the Kiev Conference on the Theory of Invariance and Its Application to Automatic Devices (Oct. 20, 1958), the decisions of the Presidium of the Academy of Science of the USSR of April 1, 1941, Section 5, the conclusions of the commission of the Presidium of the Academy of Science of the USSR for discussion and judging the work of Professor G. V. Shchipanov, "Autocontrolled systems with several degrees of freedom," the work of Prof. G. V. Shchipanov itself, and certain materials in the discussion of the work of G. V. Shchipanov, established the following.

In the journal Avtomatika i Telemekhanika (Automation and Remote Control) No. 1 (1939) there was published the paper of Prof. G.V. Shchipanov, "Autocontrolled systems with several degrees of freedom". This paper gave rise to wide discussion, the materials of which were published in a number of journals.

By decision of the Presidium of the Academy of Science of the USSR, taken on March 4, 1940, a commission was created to discuss and judge the work of Prof. G. V. Shchipanov, "Autocontrolled systems with several degrees of freedom ," this commission consisting of Vice-President of the AN SSSR Academician O. Yu. Shmidt, Academician S. A. Chaplygin, S. L. Sobolev, N. E. Kochin, and Corresponding Member AN SSSR N. G. Bruevich.

The commission's conclusions were discussed at the April 1, 1941 session of the Presidium of the AN SSSR, at which time the decision was taken to take the commision's conclusions under consideration, to publish them, and to consider the work of the commision as finished.

The commission's conclusions contained the dissenting opinions of Academicians V. S. Kulebakin and N. N. Luzin which considered necessary further research into the conclusions of Section 2, in which the estimate of the work of G. V. Shchipanov was contained.

In the following years, a number of works were published which, in some degree or other, treated the questions of compensation or invariance (the works of Academician

N. N. Luzin, Academician V. S. Kulebakin, A. G. Ivakhnenko , B. N. Petrov, G. M. Ulanov, and others).

On October 16-20, 1958, in Kiev, there was held the Conference on the Theory of Invariance and Its Application to Automatic Devices, convened by the Engineering Section of the AN Ukr SSR, the Kiev City Seminar and the Electrical Engineering Institute of the Ukr SSR, in which scientific workers from Moscow, Leningrad, Kiev and other cities of the Soviet Union participated.

At the Kiev Conference, a decision (resolution) was taken, noting the necessity of developing methods of disturbance compensation and the principle of invariance, in which it was stated, in Section 7:

"7. In view of the fact that the decision of the Presidium of the Academy of Science of the USSR on April 1, 1941 concerning the assertions of the conclusions of the special commission on the work of G. V. Shchipanov delayed development of the theory and practice of constructing automatic systems using compensation of disturbing stimuli and various invariance principles and does not make possible the proper and necessary progress in this important area of automation today, we ask the Presidium of the Academy of Science of the USSR to reconsider its decision as concerns the erroneous conclusions of the aforementioned commission."

As a result of the consideration of all the material cited above, we can draw the following conclusions:

1. The conclusions of the aforementioned commission to discuss and judge the work of Prof. G. V. Shchipanov, taken into consideration and published by the Presidium of the Academy of Science of the USSR, must be considered correct as concerns the first point and the first paragraph of the second point, in which it is stated that:

"1. The commission considers that questions of control theory have undoubtedly tremendous importance in the matter of the development of our national economy and the strengthening of the defense of our country, and must be worked out in the Institute for Automation and Remote Control of the Academy of Science of the USSR.

2. The work of Prof. G. V. Shchipanov under consideration, "Autocontrolled systems with several degrees of freedom," contains a whole series of incorrect and unfounded assertions."

Indeed, G. V. Shchipanov's work did contain incorrect and unfounded assertions. Among these assertions were the author's conclusions that, if the compensation condition held, then an ideal and universal controller was obtained; that the construction of regulators which did not satisfy the theorems presented in the paper must be considered as unsuitable; that with the compensation condition met, and for zero initial conditions, a free component appears, etc.

As is clear from the test and diagrams of G. V. Shchipanov's paper, he considered controllers based on the principle of deviation without additional direct or indirect stimuli proportional to the disturbance f(t) acting on the object of control, and he attempted to use, for the synthesis of such controllers, the condition of complete compensation while, in this case, it is impossible to use the condition of complete compensation.

2. However, the commission's conclusion (second paragraph of the second point) that the basic error in Prof. G. V. Shchipanov's paper is the "compensation condition", which leads mathematically to absurd conclusions and which does not correspond at all to actually realizable controllers, contains itself an erroneous conclusion, in that it is far too general a statement.

The basic error of G. V. Shchipanov consisted, not in the formulation of this condition, as was asserted in the commission's conclusions (on the contrary, this was his fundamental result!), but in the application of the compensation condition to the design of a class of control systems which does not permit its use.

As was shown by subsequent investigations, including those in Proceedings of the Kiev Conference on Invariance Theory, "the compensation condition" or the "invariance condition" can be used for designing a number of types of automatic control systems, for example, combined systems, with stimulus by deviation and by disturbance, interconnected automatic control systems for several quantities, and also several types of dynamic systems which do not come under the heading of automatic control systems, for example, bridge systems, complex electric networks, gyroscopic devices, etc.

Thus, the "compensation condition", or the "invariance condition" formulated by Prof. G. V. Shchipanov was a new design relationship which can be successfully used for designing a definite class of dynamic systems.

3. The aforementioned inaccuracy in the formulation of the commission's conclusions, and the absence of constructive criticisms in them, led, in some cases, to incorrect judgments on works in automatic control, even when the compensation condition was used correctly in them, which could not render possible development in this direction. Therefore, the commission considers it advantageous to publish, in one of the technical journals an expanded paper devoted to the prospective applications of the invariance principle, and which would cite the cases when it is advantageous to use this principle and when its use is inadmissible.

At the same time, the commission considers it necessary to note the imperfect editing of the decision of the Kiev Conference on the Theory of Invariance and its Application to Automatic Devices, from which one might gather the impression that the works of G. V. Shchipanov did not contain errors.

THE APPROACHING FIRST CONGRESS OF THE INTERNATIONAL FEDERATION OF AUTOMATIC CONTROL

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 6, pp. 657-658, June, 1960

In June of this year, the First Congress of the International Federation of Automatic Control (IFAC) will convene in Moscow. The coming Congress is a great event in world science in the area of automatic control, one recognized as exerting an influence on the development of automation in all countries.

Automation, one of the most important phenomena of our time, puts into practice the most daring dreams of many generations of mankind. Automation opens up new horizons for various branches of industry; the theory of automatic control approaches many scientific disciplines, with the raising of many problems regarding control, and modifies in principle many notions in science and technology which prevailed 10 to 15 years ago.

In recent years scientists have been faced with the most complex scientific problems of automatic control. It is difficult to overestimate the significance of these problems. Success in working them out will create the basis of rapid growth of technical progress.

It is clear that if the scientists and engineers of all countries will work in close accord on the problems of automatic control, the necessary results will be obtained very much sooner and at less expense. Such international collaboration in the field of research on automatic control is natural and necessary. Collaboration in automation is a demand of our times. Our country has made its choice; we are for the uniting of the efforts of the scientists and engineers of different countries, we are for collaboration, for close contacts of Soviet and foreign specialists in automation.

Even in 1956, Soviet scientists, along with those of other countries, were taking the initiative in this field by founding the International Federation of Automatic Control (IFAC). The formation and establishment of the IFAC has resulted in a condition of creative scientific and commercial collaboration.

The Executive Council of the IFAC, with Dr. G. Chesnut (USA) as its chairman, which was elected in September, 1957, at the First General Assembly in Paris, performed a great and very useful work. It set down the life principle of the new international scientific organization.

The Second General Assembly of IFAC was held in Chicago in September, 1959. It approved the new, improved rules and regulations, endorsed the draft of organization of the First Congress prepared by the Soviet National Committee, and heard a series of special reports.

The General Assembly elected the new staff of the Executive Council and a new President, Professor A. M. Letov, representative of the National Committee on Automative Control of the USSR.

The activity of the Federation proceeds in a condition of close scientific and commercial collaboration. To strengthen the exchange of scientific information between the national organizations of the IFAC at the present time, scientific-technical committees have been formed on theory, the technical resources of automation, on applications, terminology, education, and bibliography.

An important aspect of the activity of the IFAC is the conducting of international congresses on automation. The preparation and organization of the First Congress of the IFAC, entrusted to the National Committee of the Soviet Union, developed with the active participation of almost all the national organizations of the IFAC. In the total preparatory work a new contribution is made to the international collaboration of scientists. Reports totalling 285 were submitted for scientific consideration; they can be classified into three groups.

The reports of the first group were concerned with current problems of the theory of continuous and discrete systems of automatic control, the theory of structures and the construction of signals, stochastic, and special mathematic problems. Much attention was allotted to the theory of optimal and self-adjusting systems. A description of experimental methods of research was given in a series of reports.

Reports of the second group were concerned with the theory and experience in constructing elements of control systems, programming and computing equipment, control machines and systems of automatic control. There were reports explaining special problems in the construction of logical and digital elements and their use in digital machines.

The third group of reports tell of the experience of automation in various branches of industry — machine building, metallurgy, chemistry, energetics, petroleum production, and so on. Much attention is given to problems in the application of digital computing technique for the control of complex technological processes.

It is expected that in June of this year a considerable number of eminent specialists in the field of automation from various countries will meet in Moscow. They will be able to exchange current ideas, scientific engineering problems and the methods of solving them. This will significantly expand the scientific and business contacts of Soviet specialists with their foreign colleagues.

For more comprehensive discussion of the reports presented to the Congress, the texts of the reports were sent beforehand to the participants, which should promote at the Congress a broad scientific discussion of the most important problems of automation. This discussion may evoke independent scientific interest. It will give the participants in the Congress the possibility of profoundly discussing with the authors of reports and other specialists the problems which interest them. Discussion is a manifestation of the creative form of contacts within the framework of the IFAC which enables exposing "white spots in the field of the theory of automatic control, posing new scientific problems, defining the limits of application of the various methods of solving theoretical or applied problems. Soviet scientists and engineers whose work has won universal recognition are preparing with great interest for the Congress and for discussion at the Congress of actual problems of automatic control.

Soviet specialists working in the field of automation will receive in their own country a considerable number of foreign colleagues. They are doing everything they can to assure that this reception will be friendly and mutually advantageous.

The development of scientific contacts between scientists and engineers of different countries which will result from the Congress will undoubtedly have an important value for the further strengthening of peace and friendship between nations.

A MESSAGE FROM THE PRESIDENT OF THE IFAC

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 6, pp. 659-660, June, 1960

The occasion of the First Congress of the International Federation of Automatic Control (IFAC) is a primary event in the life of specialists in automation throughout the world.

It is expected that a very large number of eminent specialists from 30 countries will gather in Moscow in the summer of 1960 and will be able to discuss current ideas, scientific and engineering problems arising in automatics, and the methods of solving them. The principal importance of this event is that the coming Congress, like the earlier assemblies of IFAC, will demonstrate the potential possibilities of science and the acceptability for all of the form of organization of the IFAC, in which the need for cooperation, for a living exchange of scientific ideas and scientific results, is vitally important and inescapable.

The first Congress of the IFAC is a serious event of international significance, destined to exert a notable influence on the development of automation throughout the world; this explains the enormous interest in the Congress on the part of scientists, engineers, and business circles of the various countries.

The first task of IFAC is to conduct this Congress on the highest scientific and engineering level.

The Congress is being conducted with the motto: to theory – practical applicability; to technical resources – maximum reliability; to applications – the greatest effectiveness. It expresses the clear thought of the central administration regarding the creative activity of scientists and engineers throughout the world who have in mind enriching the world with products of material security. The conditions necessary for conducting the Congress have been created.

More than 280 scientific papers are to be discussed. The more active the discussion of the reports, the better IFAC will fulfill its first task. The Organizing Committee of the Congress is enlisting about 100 scientists and engineers from different countries in the posts of section chairmen of the session. They should not only know the reports well and comment on the addresses, but also foresee the possible development of discussion as regards both various aspects of the reports, and the long-range development and application of the ideas they contain.

Discussion at the Congress will be a development of the highest form of scientific contacts within the framework of the IFAC, for which we are striving so much. The IFAC has developed excellent prospects, for future scientific contacts, and in other directions.

The Executive Council of IFAC has formed scientific-technical committees which are beginning work in the following areas:

1. Theory
2. Technical resources
3. Applications of automation
4. Terminology and designations
5. Education
6. Bibliography

The basic task of the committees is to effect the international exchange of scientific information in the field of automation among the member countries of the IFAC.

Scientific connections of the IFAC with other, related international federations are also being developed.

At the present time the IFAC includes the most eminent organizations in the area of automation from 23 countries: Austria, Belgium, Great Britain, the Hungarian People's Republic, Denmark, India, Israel, Italy, the Chinese People's Republic, the Netherlands, Norway, the Polish People's Republic, the Rumanian People's Republic, the USSR, the USA, Turkey, France, Finland, Czechoslovakia, Sweden, Switzerland, Yugoslavia, and Japan.

It is expected that a number of new countries will join the IFAC in the near future.

It is a pleasure for me to mention here that a spirit of excellent, close scientific and business collaboration prevails in our international society, and that this has been shown above all by the fact that in all questions that have arisen in the IFAC, a complete and general agreement has always been reached.

All our meetings which have been held in Germany, France, Switzerland, Italy, and America have taken place with the warm hospitality of the national organizations of the IFAC and their active participation.

The spirit of collaboration in the IFAC is expressed likewise by the fact that a reciprocal exchange of books is developing among the various national organizations of the IFAC, and likewise the visitation of scientific institutions and automated enterprises. Such an exchange of visits and books is of great mutual benefit.

It is to be hoped that the spirit ot collaboration will grow and be strengthened even more during the First Congress of the IFAC.

The National Committee of the Soviet Union has developed a broad program of action in preparation for the Congress, the realization of which is a contribution of the utmost importance to the strengthening and growth of the IFAC.

The spirit of collaboration in the IFAC will serve the strengthening of peace throughout the world.

A. Letov, President of the IFAC

ANALYTICAL CONTROLLER DESIGN. III

A. M. Letov

Moscow

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 6, pp. 661-665, June, 1960

A solution is given of the variational problem of an optimally controlled system when account is taken of servomotor speed limitations.

1. Servomotor. Speed Limitations

In the present paper we shall study the case of analytical controller design when limitations ou servomotor speed are taken into account, a problem which was touched on slightly in [1, 2]. Let us pose the problem. We consider a closed autocontrolled system in which the disturbed motion is given by the equations

$$g_k = \dot{\eta}_k - \left(\sum_\alpha b_{k\alpha}\eta_\alpha + m_k\xi\right) = 0 \quad (k = 1, \ldots, n), \quad \dot{\xi} = f(\sigma) \tag{1.1}$$

Here, the η_k are the coordinates, and the $b_{k\alpha}$ are constant parameters of the object of control, while ξ is the coordinate, and the m_k are parameters of the controlling organ. The function $f(\sigma)$ is the subject of our search.

By basing ourselves on well-known attempts [3]*, we shall assume that $f(\sigma)$ lies in functions of class A', for which the following relationships hold:

$$\sigma f(\sigma) > 0, \quad \sigma \neq 0, \quad \left(\frac{df}{d\sigma}\right)_{\sigma=0} > 0. \tag{1.2}$$

The argument of the function, $\sigma = \sigma(\eta_1, \ldots, \eta_n, \xi)$ is also to be determined.

As the criterion of optimality, we consider the functional

$$I[f(\sigma)] = \int_0^\sigma (V + \dot{\xi}^2)\, dt, \tag{1.3}$$

where V is a positive-definite function of the form

$$V = \sum_k a_k\eta_k^2 + c\xi^2. \tag{1.4}$$

We consider the natural boundary conditions:

$$\begin{gathered}\eta_1(0) = \eta_{10}, \ldots, \ \eta_n(0) = \eta_{n0}, \ \xi(0) = \xi_0, \\ \eta_1(\infty) = \ldots = \eta_n(\infty) = \xi(\infty) = 0.\end{gathered} \tag{1.5}$$

We shall search for those continuous functions ξ, $\eta_1, \ldots, \eta_n$ of class C_1 which, while satisfying (1.1) and boundary conditions (1.5), minimize the functional in (1.3). Equations (1.1) are defined in the open region $N(\xi, \eta_1, \ldots, \eta_n)$, so that the problem just formulated is an ordinary Lagrange variational problem, the procedures for whose solution are well known.

To obtain the equations of the variational problem, we set

$$H = V + f^2(\sigma) + \lambda[\xi - f(\sigma)] + \sum \lambda_k g_k. \tag{1.6}$$

We then write the partial derivatives of the function H:

$$\begin{aligned}&\frac{\partial H}{\partial\dot{\eta}_k} = \lambda_k, \quad &&\frac{\partial H}{\partial\eta_k} = 2a_k\eta_k - \sum_\alpha \lambda_\alpha b_{\alpha k},\\ &\frac{\partial H}{\partial\dot{\xi}} = \lambda, \quad &&\frac{\partial H}{\partial\xi} = 2c\xi - \sum_\alpha m_\alpha\lambda_\alpha,\\ &\frac{\partial H}{\partial\dot{\sigma}} = 0, \quad &&\frac{\partial H}{\partial\sigma} = [2f(\sigma) - \lambda]\frac{\partial f}{\partial\sigma}.\end{aligned}$$

The equations sought have the form

$$\begin{gathered}\dot{\eta}_k = \sum_\alpha b_{k\alpha}\eta_\alpha + m_k\xi, \quad \dot{\xi} = f(\sigma),\\ \dot{\lambda}_k = -\sum_\alpha b_{\alpha k}\lambda_\alpha + 2a_k\eta_k \\ \dot{\lambda} = 2c\xi - \sum_k \lambda_k m_k,\\ 0 = [2f(\sigma) - \lambda]\frac{\partial f}{\partial\sigma} \qquad (k = 1, \ldots, n).\end{gathered} \tag{1.7}$$

2. Solution Abutting the Optimal Curve's Left End

We shall study the solution of the problem for the two cases presented by the last equation of (1.7).

We consider the first case:

$$\frac{\partial f}{\partial\sigma} = 0. \tag{2.1}$$

---

* In autocontrol systems such as (1.1), the function σ describes the control law, and depends on $\eta_1, \ldots, \eta_n, \xi$.

If we are considering class A' functions, then there exists a positive number σ_* such that, from (2.1), we find

$$f(\sigma) = \pm \bar{f}, \quad |\sigma| \geqslant \sigma_*. \tag{2.2}$$

Thus, the controller equation is defined everywhere for $|\sigma| \geq \sigma_*$, although the number σ_* itself is still unknown.

Let

$$\Delta(\rho) = |b_{k\alpha} - \rho\delta_{k\alpha}| \tag{2.3}$$

be the determinant system (1.1) for $m_k = 0$. Then Solution (2.2) of system (1.1) is written in the following form:

$$\begin{gathered} \eta_k = \sum_{s=1}^{n} \Delta_k(\rho_s) C_s e^{\rho_s t} + M_k + N_k t, \\ \xi = \bar{C} \pm \bar{f}t, \\ \lambda_k = \sum_{s=1}^{n} \bar{\Delta}(-\rho_s) \bar{D}_s e^{-\rho_s t} + \varphi_k(t), \\ \lambda = \bar{D} + \psi(t) \end{gathered} \tag{2.4}$$

Here, ρ_k are simple roots of the equation $\Delta(\rho) = 0$, while $-\rho_k$ are simple roots of the equation

$$\bar{\Delta}(\rho) = |-b_{\alpha k} - \rho\delta_{\alpha k}| = 0; \tag{2.5}$$

$M_k + N_k t$, $\varphi_k(t)$, $\psi(t)$ are the corresponding particular solutions arising from the appearance of the line integral for the function ξ; Δ_k are the minors of the determinant in (2.3) and $\bar{\Delta}_k$ are the minors of the determinant in (2.5) corresponding to the elements with ordinal number k in the first row; $\bar{C}_1, \ldots, \bar{C}_n, \bar{C}, \bar{D}, \bar{D}_1, \ldots, \bar{D}_n$ are the $2n + 2$ arbitrary constants. We call the function defined by (2.4) a solution abutting the left (initial) end of the optimal curve ($t = 0$).

This solution will be necessary only for the verification that the boundary conditions hold.

3. Solution Abutting the Optimal Curve's Right End

We now consider the second case presented by the last of Eqs. (1.7)

$$2f(\sigma) = \lambda \tag{3.1}$$

System (1.7) becomes linear with constant coefficients:

$$\begin{gathered} \dot{\eta}_k = \sum_\alpha b_{k\alpha}\eta_\alpha + m_k\xi, \\ 2\ddot{\xi} = 2c\xi - \sum_k m_k\lambda_k, \\ \dot{\lambda}_k = -\sum_\alpha b_{\alpha k}\lambda_\alpha + 2a_k\eta_k \qquad (k = 1, \ldots, n) \end{gathered} \tag{3.2}$$

Let

$$\nabla(\mu) = \left|\begin{array}{l} b_{11} - \mu, \ldots \quad b_{1n}, \; . \; m_1 \ldots\ldots, 0 \ldots\ldots, 0 \\ \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ b_{n1}, \ldots\ldots, b_{nn} - \mu m_n, \quad \ldots 0 \ldots\ldots, \bar{0} \\ 0, \ldots\ldots, 0, \ldots, 2c, -2\mu^2, -m_1, \ldots, -m_n \\ 2a_1, \ldots\ldots, 0, \; . \; 0, \ldots\ldots -b_{11} - \mu, \; ., -b_{n1} \\ \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ 0, \ldots\ldots, 2a_n, \; . \; 0, \ldots\ldots -b_{1n}, \ldots, -b_{nn} - \mu \end{array}\right| \tag{3.3}$$

be the determinant of the system. It is easily proven that, if $\mu_1, \ldots, \mu_n$ are simple roots of the equation $\nabla(\mu) = 0$, then $-\mu_1, \ldots, -\mu_n$ will also be simple roots of this equation. For the proof of this assertion, it suffices to execute the following operations:

1) write the determinant $\nabla(-\mu)$,

2) transpose the middle row downwards,

3) transpose the first n rows downwards,

4) in the determinant thus formed, transpose the middle column to the right, making it the last column,

5) transpose the first n columns to the right.

As the result of these operations, we obtain the determinant

$$\nabla(-\mu) = \left|\begin{array}{l} -b_{11} + \mu, \ldots, -b_{n1}, \quad 0, \quad 2a_1, \ldots, \quad 0 \\ \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ -b_{1n}, \ldots, \quad -b_{nn} + \mu, \quad 0, \quad 0, \ldots, \quad 2a_n \\ -m_1, \ldots\ldots, -m_n, \quad 2c - 2\mu^2, \; 0, \ldots, \quad 0 \\ 0, \ldots, \quad 0, \quad m_1, \; b_{11} + \mu, \ldots, \; b_{1n} \\ \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ 0, \ldots, \quad 0, \quad m_n, \; b_{n1}, \ldots, \; b_{nn} + \mu \end{array}\right|$$

Now, in order to convince ourselves of the validity of our assertion, it suffices to:

a) take out the minus signs in the first n columns and make them rows;

b) multiply the last n rows by -1 and make them columns.

If, with such transpositions, the column numbers become row numbers and conversely, we obtain, after their termination, the following identity:

$$\nabla(\mu) = \nabla(-\mu). \tag{3.4}$$

To complete the argument, we recall the possibility of so numbering the roots that the following condition holds:

$$\operatorname{Re}\mu_k \leqslant 0 \quad (k = 1, \dots n+1). \tag{3.5}$$

Then, taking the conditions at infinity into account, we write the solution of Eqs. (3.2) in the following form:

$$\begin{aligned}\eta_k &= \sum_{s=1}^{n+1} \Delta_k(\mu_s) c_s e^{\mu_s t},\\ \xi &= \sum_{s=1}^{n+1} \Delta_{n+1}(\mu_s) c_s e^{\mu_s t},\\ \lambda &= 2\sum_{s=1}^{n+1} \mu_s \Delta_{n+1}(\mu_s) c_s e^{\mu_s t},\\ \lambda_k &= \sum_{s=1}^{n+1} \Delta_{n+1+k}(\mu_s) c_s e^{\mu_s t}.\end{aligned} \tag{3.6}$$

Here, the Δ_r are the minors of determinant (3.3) with respect to the elements of r of the first row, and the c_r are constants of integration.

To obtain the controller's equation for the open region, it suffices to take the first n + 2 rows of formulas (3.6) and to eliminate time. This equation has the form

$$\begin{vmatrix} \Delta_1(\mu_1), & \dots, & \Delta_1(\mu_{n+1}), & \eta_1 \\ \dots & \dots & \dots & \dots \\ \Delta_n(\mu_1), & \dots, & \Delta_n(\mu_{n+1}), & \eta_n \\ \Delta_{n+1}(\mu_1), & \dots, & \Delta_n(\mu_{n+1}), & \xi \\ \mu_1\Delta_{n+1}(\mu_1), & \dots, & \mu_{n+1}\Delta(\mu_{n+1}), & \dot{\xi} \end{vmatrix} = 0. \tag{3.7}$$

After expanding the determinant, we find

$$\dot{\xi} = \sum_{\alpha=1}^{n} p_\alpha \eta_\alpha - r\xi \tag{3.8}$$

which is a linear equation with constant coefficients.

We must now convince ourselves of the possibility of determining the arbitrary constants of integration. Formulas (2.4) and (3.6) contain 3n + 3 constants of integration. For their determination we have the n + 1 initial conditions and the 2n + 2 continuity conditions for the functions ξ, $\eta_1, \dots, \eta_n$, $\lambda_1, \dots, \lambda_n$, λ at the point σ_*, and also the continuity condition for the function $f(\sigma)$ which we are seeking. We now show how to find this function and the constant σ_* simultaneously.

Let

$$\frac{1}{h}\left(\sum_{\alpha=1}^{n} p_\alpha \eta_\alpha - r\xi\right) = \sigma, \tag{3.9}$$

where h is some positive constant.

Equation (3.8) gives

$$\dot{\xi} = h\sigma. \tag{3.10}$$

To determine the magnitude of σ_* we find

$$h\sigma_* = \bar{f}. \tag{3.11}$$

Thus, the final form of the controller equation is

$$\dot{\xi} = \begin{cases} +\bar{f} & \text{for } \sigma \geqslant \sigma_*,\\ h\sigma & \text{for } |\sigma| < \sigma_*,\\ -\bar{f} & \text{for } \sigma \leqslant \sigma_*. \end{cases} \tag{3.12}$$

4. Two Problems

What has been presented allows us to formulate two problems. The first of them consists of the following. Given that linear system (1.1), (3.9), (3.10) is stable for any deviations. Consequently, nonlinear optimal system (1.1), (3.9), (3.12) is stable at least for any disturbances with respect to σ which satisfy the inequality $|\sigma| \leq \sigma_*$. By virtue of the continuity property of the region of attraction, this system is extended to the limits $|\sigma| = \sigma_*$. It is required to determine the boundaries of the region of attraction.

Second problem: We consider the functional in (1.3), and remove the term ξ^2 from it. Equations (1.7) of the variational problem then give the solution $f(\sigma) = \bar{f}\operatorname{sign}\sigma$. This solution is compatible with the Weierstrass-Erdmann conditions. It is required to determine the construction of the switching function $\sigma = \sigma(\eta_1, \dots, \eta_n, \xi)$.

5. Example

In the case n = 1, $b_1 = b$, $m_1 = m$, $a_1 = a$, we have the characteristic equation

$$\mu^4 - (b^2 + c)\mu^2 + am^2 + cb^2 = 0, \tag{5.1}$$

and the controller equation in the open region is written in the form

$$\dot{\xi} = -\frac{(\mu_1 - b)(\mu_2 - b)}{m}\eta + (\mu_1 + \mu_2 - b)\xi. \quad (5.2)$$

This equation coincides with Eq. (5.4) which was found in [1, 2].

We easily convince ourselves that, in the general case, Eq. (3.8) coincides exactly with Eq. (4.5) of work [1], which was found for an open region, and with Eq. (3.9) of work [2] for regions bounded with respect to the angle of deviation of the controlling organ.

From this there derives the interesting conclusion that, everywhere in the open region, the formula for the optimal controller is the same, and is determined only by the functional adopted as the criterion.

As in work [2], the question as to the stability of system (1.1), (3.12) must be considered separately.

The author is deeply grateful to N. N. Krasovskii for his very useful remarks and advice in regard to the problem considered here.

INVESTIGATION OF PROBABILITY STABILITY USING EXAMPLE OF AUTOMATIC CONTROL OF AIRCRAFT COURSE

V. S. Novoselov

Leningrad

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 6, pp. 666-673, June, 1960

Definitions are given for weak and strong probability stability of undisturbed motion. The concept of weak stability is a variation, and something of a generalization, of the definition of stability with respect to upper limits of dispersion [1]. The definition of strong stability is close to the concepts of probability stability given in [2-5]. With the example of aircraft course stabilization by means of an autopilot with a constant speed servomotor, the attempt is made to construct a methodology for the investigation of automatic control and regulation systems as regards their probability stability.

1. Let the motion of an automatic regulation or control system be defined by differential equations with random parameters and by random disturbing forces which we shall call, in their totality, random factors.

In the absence of random factors, the system's motion will be called undisturbed. We consider the random process $\{x_i(t)\}$ $(i = 1, 2, \ldots, n)$ of deviations from undisturbed motion by the system, and the n-dimensional band of width ϵ.

We denote by $\tau(\epsilon, T)$ the length of time during which, in a total time interval of duration T, some selected realization of the random process lies within the ϵ-band, i.e., $|x_i(t)| \leq \epsilon$ for $0 \leq t \leq T$.

The relative time spent by the given realization in the ϵ-band during time interval T equals

$$\nu(\epsilon, T) = \tau(\epsilon, T)/T.$$

Since the occurrence of some realization or another is a random phenomenon, then $\nu(\epsilon, T)$ is also a random variable.

Let there exist two positive numbers $Q_1 < 1$ and $Q_2 \leq 1$ such that

$$P\{\nu(\varepsilon, T) > Q_1\} > Q_2, \qquad (1.1)$$

where the symbol P denotes the probability of the event cited within the braces. In this case, we shall say that the random process $\{x_i\}$, during time T, is found in the ϵ-band with relative time Q_1 and with a probability not less than Q_2.

If the following relationship holds:

$$P\{\nu(\varepsilon, T) = 1\} > Q \quad (0 < Q < 1), \qquad (1.2)$$

than the random process $\{x_i\}$ during time interval T lies completely within the ϵ-band with a probability not less than Q.

The quantities ϵ, Q_1, Q_2 and Q give a graphic quantitative estimate in the probabilistic sense of the stability of undisturbed motion during the finite time interval T.

The following definitions of probability stability of undisturbed motion can be put forth.

We call an undisturbed motion weakly probabilistically stable with respect to the admissible set of random factors if, for all $\epsilon > 0$ and for any positive numbers arbitrarily close to unity $Q_1 < 1$, $Q_2 \leq 1$, there exists a subset of random factors for which Relationship (1.2) holds for infinitely large T.

We call an undisturbed motion strongly probabilistically stable with respect to the admissible set of random factors if, for all $\epsilon > 0$ and for a positive number $Q \leq 1$ which is arbitrarily close to unity, there exists a subset of random factors for which relationship (1.2) holds for infinitely large T.

As follows from the definitions, the property of an undisturbed motion to be weakly or strongly probabilistically stable is related to the concept of admissible random factors. A motion which is stable for some admissible random factors may be unstable for another set of them. The adoption of one or another set of admissible random factors will make concrete the concepts of stability just introduced.

Theorem 1. If the process $\{x_i\}$ has zero mathematical expectation and, for all $\delta > 0$, there exists a subset of random factors for which $\tilde{\sigma}_i < \delta$, where $\tilde{\sigma}_i$ is the time average of the dispersion of the process $\{x_i\}$, then the undisturbed motion is weakly probabilistically stable.

We give proof of this theorem, without pretending, however, to complete mathematical rigor.

For the random process $\{x_i(t)\}$ $(i = 1, 2, \ldots, n)$, let there exist a continuous distribution function

$$F(\xi_i, t) = P\{x_i \leqslant \xi_i, t\}.$$

We introduce the random function

$$\varphi(\varepsilon, t) = \begin{cases} 1, \text{ if } \ |x_i| \leqslant \varepsilon, \\ 0, \text{ if, for at least one subscript } j \ |x_j| > \varepsilon, \end{cases}$$

Functions of this type are used in many works [6-8]. For $\nu(\epsilon, T)$ we will have

$$\nu(\varepsilon, T) = \frac{1}{T}\int_0^T \varphi(\varepsilon, t)\,dt.$$

We set up the Chebyshev inequality

$$P\{\mu(\varepsilon, T) \geqslant 1 - Q_1\} \leqslant \frac{M[\mu(\varepsilon, T)]}{1 - Q_1}, \quad (1.3)$$

where M is the symbol for mathematical expectation and $\mu(\epsilon, T(= 1 - \nu(\epsilon, T)(0 < Q_1 < 1)$. We have

$$M[\nu(\varepsilon, T)] = \frac{1}{T}\int_0^T M[\varphi(\varepsilon, t)]\,dt =$$

$$\frac{1}{T}\int_0^T P\{|x_i| \leqslant \varepsilon, t\}\,dt. \quad (1.4)$$

where the symbol ~ denotes an average over the infinite time interval.

Since

$$\widetilde{P}\{|x_i| \leqslant \varepsilon\} > \widetilde{F}(\varepsilon) - \widetilde{F}(-\varepsilon),$$

On the basis of formulas (1.3) and (1.4), we obtain an estimate of the relative time $\nu(\epsilon)$ spent by the process in the ϵ-band during the course of an infinite interval of time:

$$P\{\nu(\varepsilon) > Q_1\} \geqslant \frac{\widetilde{P}\{|x_i| \leqslant \varepsilon\} - Q_1}{1 - Q_1},$$

where $\widetilde{F}(\epsilon)$ and $\widetilde{F}(-\epsilon)$ denote the average distribution function, taken for the values $\xi_i = \epsilon$ and $\xi_i = -\epsilon$ ($i = 1, 2, \ldots, n$) respectively, we then find that

$$P\{\nu(\varepsilon) > Q_1\} > \frac{\widetilde{F}(\varepsilon) - \widetilde{F}(-\varepsilon) - Q_1}{1 - Q_1}.$$

In the case of stationary processes, the probability functions do not depend on time, so that we shall have

$$\widetilde{P}\{|x_i| \leqslant \varepsilon\} = P\{|x_i| \leqslant \varepsilon, 0\};\ \widetilde{F}(\varepsilon) = F(\varepsilon, 0),\ \widetilde{F}(-\varepsilon) = F(-\varepsilon, 0).$$

For the dispersion of a random process with zero mathematical expectation, we have the obvious estimate

$$\sigma_i^2(t) \geqslant \varepsilon^2 P_i(\varepsilon, t),$$

where ϵ is an arbitrarily small positive number. Moreover,

$$P_i(\varepsilon, t) = P\{|x_i| \geqslant \varepsilon, -\infty < x_j < \infty\} \quad (j = 1, 2\ldots, i-1, i+1, \ldots, n).$$

We therefore obtain

$$P\{|x_i| < \varepsilon, t\} \geqslant 1 - \frac{1}{\varepsilon^2}\sum_{i=1}^{n} \sigma_i^2(t).$$

By taking the time average, we find that

$$\widetilde{F}(\varepsilon) - \widetilde{F}(-\varepsilon) > 1 - \frac{1}{\varepsilon^2}\sum_{i=1}^{n} \widetilde{\sigma}_i^2.$$

By virtue of Formula (1.5), we shall have

$$P\{\nu(\varepsilon) \geqslant Q_1\} > 1 - \frac{\sum_{i=1}^{n} \widetilde{\sigma}_i^2}{\varepsilon^2(1 - Q_1)}.$$

Therefore, the random process being considered, during an infinite segment of time, will find itself in the ϵ-band for relative time Q_1 with probability Q_2, these quantities satisfying the relationships

$$Q_2 = 1 - \frac{n\sigma^2}{\varepsilon^2(1 - Q_1)}, \quad \widetilde{\sigma}_i \leqslant \sigma. \quad (1.6)$$

From whence it follows that the undisturbed motion will be weakly probabilistically stable if the time average of the dispersion can be made arbitrarily small. Indeed, for any Q_1 and Q_2 which are arbitrarily close to unity, there exists a sufficiently small σ which satisfies relationships (1.6).

Theorem 1 is thereby proven.

We note that, for stationary processes, the dispersions do not depend on time, so that $\widetilde{\sigma}_i = \sigma_i(0)$.

Let an automatically controlled system be described by the equations

$$\frac{dx_i}{dt} = X_i(x_1, x_2, \ldots, x_n, t) + f_i(t) \quad (i = 1, 2, \ldots, n) \quad (1.7)$$

with random functions $f_i(t)$ and random initial data x_i^0.

We shall study the behavior of the process $\{x_i\}$ for small-size random factors $f_i(t)$ and x_i^0, i.e., for arbitrarily small $\alpha > 0$ and $\beta > 0$ and numbers $A > 0$ and $B > 0$ arbitrarily close to unity in the relationships

$$P\{|f_i(t)| < \alpha\} > A, \quad P\{|x_i^0| < \beta\} > B. \quad (1.8)$$

With such a choice of the random factors, the following theorem is valid.

Theorem 2. If the null solution of system (1.7) is stable for constantly acting disturbances [9], then it will be strongly probabilistically stable with respect to the upper limits of the disturbing functions and the initial data.

To find sufficient conditions for strong probability stability, both for linear and nonlinear control systems, one can use the method of constructing A. M. Lyapunov's functions [9] if the conditions of the corresponding Lyapunov theorems hold for a sufficiently large number of realizations.

It is necessary to mention that stability for constantly acting disturbances is not always decisive in establishing strong probability stability. It can happen that the solution of system (1.7) may turn out to be Lyapunov-stable for some functions $f_i(t)$ and unstable for others. If the probability of finding the realizations $\{f_i(t)\}$ in the first of these sets can be assumed to be sufficiently great, then the solution of system (1.7) will possess strong stability. The bandwidth ϵ can be made arbitrarily small by the proper choice of initial data.

We consider the system of linear differential equations

$$\frac{dx_i}{dt} = \sum_{j=1}^{n} a_{ij}x_j + f_i(t).$$

As is well known [10], the solution of this system is given in the form

$$\left\| \begin{matrix} x_1 \\ x_2 \\ \cdot \\ \cdot \\ \cdot \\ x_n \end{matrix} \right\| = X(t) \left\| \begin{matrix} x_1^0 \\ x_2^0 \\ \cdot \\ \cdot \\ \cdot \\ x_n^0 \end{matrix} \right\| + \int_0^t X_1(t, u) \left\| \begin{matrix} f_1(u) \\ f_2(u) \\ \cdot \\ \cdot \\ \cdot \\ f_n(u) \end{matrix} \right\| du \qquad (1.9)$$

Here, $X(t)$ is the normal fundamental matrix solution of the homogeneous system.and $X_1(t, u) = X(t)X^{-1}(u)$, where $X^{-1}(u)$ is the inverse matrix of $X(u)$.

If, for definite values of α and β, values of A and B satisfying inequalities (1.8) be known, then from formula (1.9), one can determine the quantities $\epsilon > 0$ and $Q > 0$ such that the random process $\{x_i\}$ will be found in the ϵ-band for any time interval T.

The necessary and sufficient condition for stability of a linear system for constantly acting disturbances has the form

$$\int_0^\infty |x_{ij}^1(t, u)|\, du < \infty. \qquad (1.10)$$

where the x_{ij}^1 are elements of the matrix $X_1(t, u)$.

The correlation matrix of the solution of the system of linear differential equations equals [11].

$$R(t, \tau) = X(t+\tau)\, r_1 \overline{X}(t) + \int_0^{t+\tau} du_1 \int_0^t X_1(t+\tau, u_1)\, r_2(u_1, u_2)\, \overline{X}_1(t, u_2)\, du_2, \qquad (1.11)$$

where r_1 is the correlation matrix of the original data, $r_2(u_1, u_2)$ is the correlation matrix of the input process; a superscript bar denotes the conjugate of the function. Let a_{ij} = const and let the roots of the characteristic equation have negative real parts; then, by transforming the equation to canonical variables, one can convince oneself that condition (1.10) holds.

In this case, for all $\mu > 0$, one can find $\nu_1 > 0$ and $\nu_2 > 0$ such that, for $|r_{ij}^1| < \nu_1$ and $|r_{ij}^2| < \nu_2$, we obtain $|R_{ij}(t, \tau)| < \mu$. Here, we have denoted by r_{ij}^1, r_{ij}^2 and R_{ij} the elements of the correlation matrices r_1, r_2 and R, respectively. Further, we have $\sigma_i = R_{ii}(t, 0)$ and, consequently, $\tilde{\sigma}_i < \mu$. From whence, based on Theorem 1, we are led to the proof of the following theorem:

Theorem 3. If the roots of the characteristic equation of a system of linear differential equations with constant coefficients have negative real parts, then its solution, for null initial data and disturbing functions, equal to $M[f_i(t)]$, is weakly probabilistically stable with respect to the upper bounds of the dispersions of the input process and the initial data.

For definite ν_1 and ν_2, one can determine from formula (1.11) the upper bound of the dispersion of the random process deviations of the disturbed motion from the undisturbed. After this, for selected ϵ and Q_1, one easily finds from (1.6) the definite probability of finding this process in the ϵ-band for relative time Q_1 over an infinite interval.

2. We illustrate the results of Section 1 by the example of a system of automatic aircraft course control by means of an autopilot.

With certain simplifying assumptions, the equations of the controlled system are written in the form [12-13]

$$\ddot{\varphi} + M\dot{\varphi} = -N\eta,\ \dot{\eta} = F(\psi),\ \ \psi = \varphi + \beta\dot{\varphi} - \frac{1}{a}\eta. \qquad (2.1)$$

Here, φ is the aircraft's yaw angle, η is the angle of rudder rotation, M and N are constants characterizing, respectively, the aircraft's natural damping and the effectiveness of the rudder device. ψ is the argument of the servomotor, β is the coefficient of artificial damping, $1/a$ is the feedback coefficient. All coefficients in these equations are positive. The servomotor characteristic $F(\psi)$ has the form

$$F(\psi) = \begin{cases} K & \text{for} \quad \psi > \psi_0 \\ 0 & \text{for} \quad |\psi| \leqslant \psi_0 \\ -K & \text{for} \quad \psi < -\psi_0, \end{cases} \qquad (2.2)$$

where $K > 0$ is the servomotor's constant speed, $2\psi_0 > 0$ is the width of the symmetric insensitivity zone.

Let the aircraft's flight, the direction of motion of which is controlled by the autopilot, occur in air layers, the density of which is a random variable. We shall therefore set $M = m\gamma$ and $N = n\gamma$. Here, m and n are positive constants, γ is the air density, taking the form of a piecewise constant random variable.

We introduce the following notation, which is convenient for the problem under consideration [13]:

$$x_1 = \frac{M^2}{N}\dot{\varphi} + M\eta, \quad x_2 = -M\eta,$$

$$x_3 = \frac{M^2}{N\beta}\psi = \frac{M^2}{N}\left(\frac{\varphi}{\beta} + \dot{\varphi} - \frac{\eta}{a\beta}\right), \qquad t' = Mt$$

and the dimensionless coefficients

$$\alpha = \frac{1}{\beta M}, \qquad r = \frac{M}{a\beta N},$$

$$F(\psi) = F\left(\frac{N\beta}{M^2}x_3\right) = F'(x_3).$$

By taking the derivatives with respect to t' of x_1, x_2, and x_3, we get, by virtue of (2.1),

$$\frac{dx_1}{dt'} = -x_1 + F'(x_3), \qquad \frac{dx_2}{dt'} = -F'(x_3),$$
$$\frac{dx_3}{dt'} = (\alpha - 1)x_1 + \alpha x_2 - rF'(x_3). \tag{2.3}$$

The derivative of the positive-definite function

$$V = \frac{|\alpha - 1|}{2}x_1^2 + \frac{\alpha}{2}x_2^2 + \int_0^{x_3} F'(x_3)\,dx_3,$$

computed with account taken of system (2.3), has the form

$$\frac{dV}{dt'} = -|\alpha - 1|x_1^2 + (\alpha - 1 + |\alpha - 1|)x_1F'(x_3) - rF'^2(x_3).$$

We obtain from this dV/dt < 0 if the following condition holds:

$$M\left(\frac{M}{a} + N\beta\right) - N > 0. \tag{2.4}$$

Condition (2.4) is equivalent to the inequality

$$\gamma > \gamma_1, \quad \gamma_1 = \frac{an}{m(m + an\beta)}.$$

The density of air can be considered bounded, so that we find such a sufficiently large number γ_2 that, with probability equal to unity, we get $\gamma < \gamma_2$.

Let the probability be larger than some number Q' that there appear a realization for which, during the entire time of motion, $\gamma_1 < \gamma < \gamma_2$. We denote by l_ϵ the least value of the function $V(x_1, x_2, x_3; \gamma)$ on the set for which $\gamma_1 \leq \gamma \leq \gamma_2$; one of the coordinates x_i is equal in absolute magnitude to ϵ; the remaining ones are less than or equal to ϵ.

Let there be known a quantity Q" such that

$$P\{|x_i^0| < \delta\} > Q'', \tag{2.5}$$

where δ will be less than ϵ, and is defined by the condition

$$\int_0^{\delta} F'(x_3)\,dx_3 + \frac{\alpha}{2}\delta^2 + \frac{|\alpha - 1|}{2}\delta^2 < l_\epsilon$$

for any α which satisfies the inequality

$$\frac{1}{\beta m\gamma_2} \leqslant \alpha \leqslant \frac{1}{\beta m\gamma_1}.$$

By assuming that the choice of initial data and the inhomogeneity of the atmosphere are statistically independent events, we obtain, by virtue of the well-known Lyapunov theorem on stability of motion [9], the expression

$$P\{\nu(\varepsilon) = 1\} > Q,$$

where

$$Q = Q' \cdot Q''. \tag{2.6}$$

Therefore, the random process of deviations of direction of motion of the aircraft from the given course is found completely in the ϵ-band with probability Q.

If the aforementioned events are dependent, then Q" in formula (2.6) must be replaced by the conditional probability of the event defined by formula (2.5), given that the event characterized by the formula $\gamma_1 < \gamma < \gamma_2$ has occurred.

Let $\gamma^* = M[\gamma]$ satisfy the condition $\gamma_1 < \gamma^* < \gamma_2$, which is equivalent to the meeting of condition (2.4) in the absence of random factors. It should be remarked that condition (2.4) is essential, since [12] it will be necessary and sufficient for the Lyapunov stability of the null solution of system (2.1).

In considering the density γ, differing slightly, probabilistically, from γ^*, we arrive at the following conclusion, based on our previous consideration. The aircraft motion with zero initial data and with atmospheric density γ^* is strongly probabilistically stable with respect to the upper bounds of the initial data and to the differences $\gamma - \gamma^*$.

We now turn to the consideration of weak probabilistic stability of the aircraft's course.

We shall assume that the aircraft is acted upon by random gusts of wind, shock waves and other stimuli whose effect on aircraft yaw may be taken into account by the introduction of the random function $f(t)$ in the right member of the first equation of system (2.1). This function equals the ratio of the torque induced by these stimuli to the aircraft's moment of inertia with respect to the yaw axis. We shall also assume that the necessary probabilistic characteristics of the one-dimensional random process $f(t)$ are given.

For action of the disturbance $f(t)$, let the nonlinear element with characteristic given by (2.2) admit the statistical linearization [14]

$$F(\psi) = k_0 M[\psi] + k_1(\psi - M[\psi]), k_0 = \text{const}, k_1 = \text{const}.$$

With this, the coefficient k_1 for the nonlinear characteristic of (2.2) is greater than zero.

The mathematical expectations $M[\varphi]$, $M[\dot{\varphi}]$, $M[\psi]$, and $M[\eta]$ will satisfy system (2.1) if, in the right number of the first equation, one adds the function of time $M[f(t)]$ and, in the right member of the second equation, one replaces the existing function by $k_0 M[\psi]$.

The random process of deviations of the aircraft's motion from the mathematical expectation is defined by the equations

$$\begin{gathered}\ddot{\varphi}' + M\dot{\varphi}' = -N\eta' + f'(t),\\ \dot{\eta}' = k_1\psi',\\ \psi' = \varphi' + \beta\dot{\varphi}' - \frac{1}{a}\eta',\end{gathered} \qquad (2.7)$$

where the primes denote the differences of the corresponding variables from their mathematical expectations.

For the case under consideration, we introduce the notation

$$x_1 = \varphi', \quad x_2 = \dot{\varphi}', \quad x_3 = \eta'.$$

Then, system (2.7) takes the form

$$\frac{dx_1}{dt} = x_2, \quad \frac{dx_2}{dt} = -Mx_2 - Nx_3 + f'(t),$$
$$\frac{dx_3}{dt} = k_1\left(x_1 + \beta x_2 - \frac{1}{a}x_3\right).$$

We find the characteristic equation for the homogeneous system:

$$\lambda^3 + \left(M + \frac{k_1}{a}\right)\lambda^2 + k_1\left(\frac{M}{a} + N\beta\right)\lambda + k_1 N = 0. \qquad (2.8)$$

The coefficients of the third-degree polynomial in (2.8) are positive. Therefore, if the following condition (the second Hurwitz condition) is met:

$$\left(M + \frac{k_1}{a}\right)\left(\frac{M}{a} + N\beta\right) - N > 0 \qquad (2.9)$$

the roots of characteristic Eq. (2.8) have negative real parts.

Relationship (2.9) holds for any positive k_1 if the coefficients of (2.1) satisfy condition (2.4).

On the basis of Theorem 3, we are led to the following conclusion. If condition (2.4) is met, then the undisturbed motion ($M[\varphi]$, $M[\dot{\varphi}]$, $M[\psi]$ and $M[\eta]$) is weakly probabilistically stable with respect to the upper boundaries of the dispersion of the disturbing torque and of the initial data.

We note that, for $M[f(t)] = 0$, the null solution $\varphi = \dot{\varphi} = \psi = \eta = 0$ will be undisturbed.

THE PROBLEM OF SHAPING FILTERS AND OPTIMAL LINEAR SYSTEMS

Yu. P. Leonov

Moscow

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 6, pp. 674-681, June, 1960

It is shown that, under sufficiently general conditions, a nonstationary random process can be formed from "white noise" by means of linear filters. The weight functions of the shaping filters are determined.

1. Posing of the Problem

Given a random function Y(t) ($-\infty < t < +\infty$) which is stationary "white noise" with mathematical expectation $M[Y] = 0$, correlation function $k_y(u) = \delta(u)$ and spectral density function $G(\omega) = 1/2\pi$. It is necessary to show that a nonstationary random function X(t), with $M[X] = 0$, ($0 < t < T$) may, under certain conditions, be presented in the form

$$X = A_x Y \tag{1}$$

where the operator A_x is defined if the function X(t) is given.*

In work [1], expression (1) is called the integral canonical representation of the random function X(t). The problem posed here is also called the problem of constructing a shaping filter.

We shall also consider here the inverse problem of presenting the "white noise" Y(t) in terms of X(t). In this case,

$$Y = A_x^{-1} X. \tag{2}$$

2. Solution of the Problem

Let Y(t) ($-\infty < t < +\infty$) be a stationary random function with correlation function $k_y(u) = \delta(u)$ and spectral density function $G(\omega) = 1/2\pi$ ($-\infty < \omega < +\infty$). The function Y(t) is frequently called "white noise", since it contains all frequencies with identical dispersion density.

It is well known [1] that a random function Z(t) can be presented as a series (canonical expansion)

$$Z(t) = \sum_{k=1}^{\infty} B_k z_k(t), \tag{3}$$

where the random variables satisfy the conditions

$$M[B_j B_i] = \delta_{ji} D_j = \begin{cases} D_j & \text{for} \quad j = i \\ 0 & \text{for} \quad j \neq i \end{cases} \tag{4}$$

and the $z_k(t)$ are some regular (nonrandom) functions [1].

In order that series (3) converge in the mean† to the function Z(t), according to the basic lemma of correlation theory [2], it is necessary and sufficient that the series

$$k_z(t_1, t_2) = \sum_{k=1}^{\infty} D_k^z z_k(t_1) z_k(t_2) \tag{5}$$

converge to the correlation function in the usual sense. With this, the definition of convergence in the mean is meaningful only for random functions with finite dispersion

To solve the basic problem, it is necessary for us to present the function Y(t) in the form of (3). We therefore, consider this problem first. In order to represent the function Y(t) by the series of (3), it is necessary to introduc a new concept of convergence. Convergence in the mean can obviously not be used, since the function Y(t) has infinite dispersion. Specifically, we shall say that the random function $U_n(t)$, as a function now of the parameter n, converges weakly in the mean to the random function U(t) if there exists, in the mean-square sense, the limit of the following integral as $n \to \infty$:

$$a_n(T) = \int_0^T R(t)\, U_n(t)\, dt, \tag{6}$$

where R(t) is an arbitrary "sufficiently smooth"‡ random function, uncorrelated with $U_n(t)$, and such that

$$\int_{-\infty}^{\infty} k_R^2(t, t)\, dt < \infty.$$

The random variable of (6) is basically identical to the generalized random function introduced in [4, 5]. The only difference is that here, as the space of the basic functions, we have choosen the space of random functions while, in [4, 5], the space of nonrandom functions was considered.

---

* For stationary random processes, such a representation is well known (cf., for example, [3]).

† Convergence in the mean is defined by the condition

$$\lim_{n\to\infty} M\left[Z(t) - \sum_{k=1}^{n} B_k z_k(t)\right]^2 = 0.$$

‡ It is assumed that the random function R(t) has a bounded dispersion, is continuous in the mean, and has the necessary number of continuous stochastic derivatives.

Below, we extend the results of correlation theory [2] to generalized random functions. Such an extension is carried out here, since it is lacking in [4, 5].

According to the basic lemma of correlation theory, it is necessary and sufficient for the convergence of (6) that there exist the limit, in the ordinary sense, of the numbers

$$p_{n,n'} = M\,\{a_n,\ a_{n'}\}$$

independently of which sequences $\underline{n}$ and n' run through as n, n' → ∞.

Thus, it is necessary and sufficient that there exist the limit of the numbers

$$p_{n,n'} = \int_0^T\!\!\int_0^T k_R(t_1,\ t_2)\, M\,\{U_n(t_1)\, U_{n'}(t_2)\}\, dt_1 dt_2 \qquad (7)$$

independently of which sequences $\underline{n}$ and n' run through as n, n' → ∞.

We now consider the function $U_n(t)$, defined by the formula

$$U_n(t) = \sum_{k=1}^{n} C_k y_k(t), \qquad (8)$$

where the random variables C_k satisfy the condition

$$M\,\{C_\mu C_\nu\} = \delta_{\nu\mu} N^2 \qquad (9)$$

and $\{y_k\}$'s an arbitrary system of orthonormal functions on the interval (−∞, + ∞), complete in L_2. We then obtain, for the numbers $p_{n,\,n'}$:

$$p_{n,n'} = N^2 \int_0^T\!\!\int_0^T k_R(t_1,\ t_2) \sum_{k=1}^{\min(n,n')} y_k(t_1)\, y_k(t_2)\, dt_1 dt_2. \qquad (10)$$

The numbers $p_{n,\,n'}$, defined by (6), converge in the mean. Indeed,

$$p_{n,n'} = N^2 \int_0^T \sum_{k=1}^{\min(n,n')} \eta_k(t_1)\, y_k(t_1)\, dt_1, \qquad (10a)$$

where $\eta_k = (k_R,\ y_k)$ are the Fourier coefficients of the function $k_R(t_1,\ t_2)$. By virtue of the fact that $k_R \in L_2$** and that the system of functions $\{y_k\}$ is complete in L_2, the sum of the integrand of (10a) converges in the mean as n → ∞ to the function $k_R(t_1,\ t_2)$. With these conditions, we obtain the following for p_∞:

$$p_\infty = N^2 \int_0^T k_R(t,\ t)\, dt. \qquad (11)$$

But formally, on the other hand, we have

$$N^2 \int_0^T\!\!\int_0^T k_R(t_1,\ t_2)\, \delta(t_1 - t_2)\, dt_1 dt_2 = N^2 \int_0^T k_R(t,\ t)\, dt = p_\infty.$$

Thus, the series $N^2 \sum_{k=1}^{\infty} y_k(t_1) y_k(t_2)$, which, formally, is the correlation function of the random function

$$Y(t) = \sum_{k=1}^{\infty} C_k y_k(t), \qquad (12)$$

possesses the properties of a delta-function.

Consequently, it may be said that the random function Y, defined by the series of (12), converges weakly in the mean to white noise.

We now turn to the basic problem. We present the white noise Y(t) by the series in (12), with the assumption that $\{y_k\}$ is a system of orthonormalized functions which is complete in L_2. We then determine the random variables C_k in (12) from the formula

$$C_k = \frac{V_k}{\sqrt{D_k}}, \qquad (13)$$

where the random variables V_k are the coefficients in the expansion of random function X(t) in a series of the form of (3):

$$X(t) = \sum_{k=1}^{\infty} V_k x_k(t) \qquad (14)$$

and $D_k = M[V_k]^2$.

We now consider the linear operator

$$AY = \int_{-\infty}^{+\infty} w_x(t,\ \tau)\, Y(\tau)\, d\tau, \qquad (15)$$

where the weight function is defined by the series

$$w_x(t,\ \tau) = \sum_{k=1}^{\infty} \sqrt{D_k}\, x_k(t)\, y_k(\tau). \qquad (16)$$

The functions $x_k(t)$ are the same as in (14). Then, from (12), (13), (15), and (16), we get

$$AY = \int_{-\infty}^{+\infty} w_x(t,\ \tau)\, Y(\tau)\, d\tau = \sum_{k=1}^{\infty} V_k x_k(t) \qquad (17)$$

and, consequently, we have

$$X = AY = \int_{-\infty}^{+\infty} w_x(t,\ \tau)\, Y(\tau)\, d\tau. \qquad (18)$$

** This follows from the condition

$$\int_{-\infty}^{+\infty} k_R^2(t,\ t)\, dt < \infty.$$

where the integral is taken in the mean, and $w_x(t, \tau)$ is defined by formula (16).

We note that (17) is a generalized random function $X(w_x)$ in the sense of [4, 5] (the notation is the same as in work [5]). Giving the function $w_x(t, \tau)$ is equivalent to defining the space of the basic functions, depending on a continuously varying parameter $\underline{t}$ (the usual functions from the space of basic functions depend on a discretely varying parameter). The necessary requirements on the function $w_x(t, \tau)$ are determined by the finitude of the dispersion of the random function $X(t)$.

The functions $w_x(t, \tau)$ and $Y(\tau)$ in (17) can be defined in infinitely many ways. For this, it suffices to use any other expansion of the function $X(t)$ in a series of the form of (14). As is well known [1], it is always possible to do this.

We also note that if the "white noise" $Y(t)$ is so chosen that (18) holds, then there exists one, and only one, function $w_x(t, \tau)$.

Indeed, if it be assumed that, for one $X(t)$, there exist two functions w_1 and w_2, then from (18), we obtain

$$\int_{-\infty}^{+\infty} \{w_1(t, \tau) - w_2(t, \tau)\}\, Y(\tau)\, d\tau \equiv 0. \qquad (19)$$

By virtue of the completeness of the system of functions $\{y_k\}$, this identity is possible only if $w_1 = w_2$.

After the problem of (1) is solved, there is no difficulty in solving that of (2).

Indeed, we consider the linear operator

$$A_x^{-1}X = \int_{-\infty}^{+\infty} w_x^{-1}(t, \tau)\, X(\tau)\, d\tau, \qquad (20)$$

where the weight function is defined by the series

$$w_x^{-1}(t, \tau) = \sum_{k=1}^{\infty} \frac{y_k(t) a_k(\tau)}{\sqrt{D_k}}, \qquad (21)$$

the functions $a_k(t)$ satisfy the conditions

$$(a_j,\ x_i) = \delta_{ji} \qquad (22)$$

and $\{y_k\}$ is an arbitrary system of orthonormal functions which is complete in L_2.

From (20), (21), and (22) we obtain

$$Y = A_x^{-1}X = \sum_{k=1}^{\infty} \frac{V_k}{\sqrt{D_k}}\, y_k(t). \qquad (23)$$

On the basis of what has been previously stated, the series in (23) converges weakly in the mean to white noise. Consequently, we have

$$Y(t) = \int_{-\infty}^{+\infty} w_x^{-1}(t, \tau)\, X(\tau)\, d\tau, \qquad (24)$$

where the function $w_x^{-1}(t, \tau)$ is defined by relationship (21). Thus, we have obtained the solutions to the problems of (1) and (2).

However, it is sometimes important to know which functional Hilbert space H_B it is in, whose metric, the series of (21), converges to the function $w_x^{-1}(t, \tau)$, and whether, in general, such a space exists. It is obvious that the function $w_x^{-1}(t, \tau)$ itself will also lie in the space H_B since, by definition, it is a complete space.

We now determine the space H_B. We compute the scalar product of any two functions $w_1(t, t_1)$ and $w_2(t, t_2)$ in H_B by the formula

$$(w_1, w_2)_B = \iiint k(t_1, t_2)\, w_1(t, t_1)\, w_2(t, t_2)\, dt_1 dt_2 dt, \qquad (25)$$

where $k(t_1, t_2)$ has the form

$$k(t_1,\ t_2) = \sum_{k=1}^{\infty} D_k^2\, x_k(t_1)\, x_k(t_2). \qquad (26)$$

The domain of integration in (25) is defined as $t, t_1, t_2 \in T$. For simplicity of notation, the limits of integration will always be omitted. The coefficients D_k and the functions $x_k(t)$ in (26) are, respectively, the dispersions of the random variables V_k and the coordinate functions of expansion (14) of the random function $X(t)$. The series in the right member of (26) converges to the function $k(t_1, t_2)$ since the following series converges:††

$$k_x(t_1,\ t_2) = \sum_{k=1}^{\infty} D_k x_k(t_1)\, x_k(t_2). \qquad (27)$$

It is also obvious that the function $k(t_1, t_2)$ is symmetric and positive-definite. As follows from (25), the square of the norm of a function $w(t, \tau)$ in space H_B is defined by the formula

---

†† Indeed, if series (14) converges in the mean to random function $X(t)$ then, in accordance with the basic lemma, series (27) must converge to $k_x(t_1, t_2)$. Consequently, the positive series $\sum_{k=1}^{\infty} D_k$ must converge, and $D_k \to 0$ for $k \to \infty$.

Thus, the series $\sum_{k=1}^{\infty} D_k^2$ is dominated by the convergent series $\sum_{k=1}^{\infty} D_k$ and, consequently, from the convergence of series (27) for any $t_1, t_2 \in T$ follows the convergence of series (25) for the same $t_1, t_2 \in T$.

$$\|w\|_B^2 = \iiint k(t_1, t_2)\, w(t, t_1)\, w(t, t_2)\, dt_1\, dt_2\, dt. \quad (28)$$

It is easily verified that the norm thus defined, by virtue of all symmetry and positive-definiteness of function $k(t_1, t_2)$, satisfies all the necessary axioms for norms.

We now define the functional Hilbert space H_B as a linear set of continuous functions which is closed in the sense of the metric introduced by (28).

We now prove that series (21) converges to the function $w_x^{-1}(t,\tau)$ in the metric of space H_B. For this, we find the square of the norm of a segment of series (21):

$$\left\| \sum_{k=n}^{n+m} \frac{y_k(t) a_k(\tau)}{\sqrt{D_k}} \right\|_B^2 = \sum_{k=n}^{n+m} D_k. \quad (29)$$

Since the series $\sum_{k=1}^{\infty} D_k$ converges, then the sum in the right member of (29) tends to zero as $n \to \infty$. It follows, thus, that series (21) converges in the metric of space H_B and, consequently, the existence of the space in which the function $w_x^{-1}(t,\tau)$ lies is proven. However, it is possible to construct, not just one, but a nondenumerable set of spaces H_B^l in whose metrics series (21) converges. It suffices for this, for example, to substitute for the function $k(t_1, t_2)$ in formulas (26) and (28) the functions

$$k_l(t_1, t_2) = \sum_{k=1}^{\infty} D_k^l x_k(t_1) x_k(t_2) \quad (l = 2, 3, 4, \ldots,). \quad (30)$$

Space H_B is obtained for $l = 2$. In particular cases, it may turn out that function $w_x^{-1}(t,\tau)$ lies in subspace of H_B, for example L_2, or even the set of C of continuous functions. With this, $C \subset L_2 \subset H_B$.

3. Application of Representations (1) and (2) to Optimal Linear System Theory

The problem of determining an optimal linear operator B consists of the following. It is necessary to approximate in the very best way to a given random function Z(t) by a random function BX [an operator on X(t)] by observing the random function $X(\tau)$ on the interval $(-\infty, t)$. It is assumed with this that $M[X] = M[Z] = 0$. The optimal operator B obviously lies in the class of linear operators, namely,

$$\Gamma(t) = BX = \int_{-\infty}^{t} w^*(t, \tau)\, X(\tau)\, d\tau, \quad (31)$$

where $w^*(t,\tau)$ is the weight function corresponding to the optimal operator. The closeness of the function $\Gamma(t)$ to Z(t) is defined by the mean square error

$$M\{\Gamma(t) - Z(t)\}^2. \quad (32)$$

An operator B^* which provides a minimum mean square error is considered to be optimal. It can be shown [1] that the optimal weight function must satisfy an integral equation of the form

$$\int_{-\infty}^{t} w(t, \tau)\, k_x(u, \tau)\, d\tau = k_{xz}(t, u) \quad (-\infty < u < t), \quad (33)$$

where $k_x(t_1, t_2)$ and $k_{zx}(t_1, t_2)$ are, respectively, the autocorrelation function of X(t) and the cross correlation function of X(t) and Z(t), which are assumed to be known.

Here we considered only one variant of the optimal system problem. Other variants lead to integral equations analogous to (33). We therefore limit ourselves to a consideration of the solution of Eq. (33). To solve Eq. (33), we must first make one remark, which is a simple corollary to the results of Section 2.

Let there be given the weight function $\omega(t,\tau)$ of an arbitrary linear system.

It may always be assumed that this linear system forms, from some white noise,

$$Y(t) = \sum_{k=1}^{\infty} \frac{F_k}{\sqrt{D_{F_k}}} y_k(t),$$

at its input, a random function P(t) of the form

$$P(t) = \sum_{k=1}^{\infty} F_k b_k(t).$$

According to (16), the weight function $\omega(t,\tau)$ must have the form

$$\omega(t, \tau) = \sum_{k=1}^{\infty} \sqrt{D_{F_k}}\, b_k(t)\, y_k(\tau) = \sum_{k=1}^{\infty} \eta_k(t)\, y_k(\tau), \quad (34)$$

Then, the weight function $\omega^{-1}(t,\tau)$ of the inverse operator, in accordance with (21), is written in the form

$$\omega^{-1}(t, \tau) = \sum_{k=1}^{\infty} \frac{y_k(t)\, d_k(\tau)}{\sqrt{D_{F_k}}} = \sum_{k=1}^{\infty} y_k(t)\, \zeta_k(\tau), \quad (35)$$

where the functions $b_k(t)$ and $d_k(t)$ satisfy the biorthogonality condition

$$(b_j, d_i) = \delta_{ji}. \quad (36)$$

On the basis of the remark just made, the solution of Eq. (33), if it exists, is determined in an elementary way. Indeed, we present the function $k_x(u, \tau)$, the weight function of the linear operator in Eq. (33), by the series

$$k_x(u, \tau) = \sum_{k=1}^{\infty} \eta_k(u) y_k(\tau), \tag{37}$$

where $\eta_k = (k_x, y_k)$ and $\{y_k\}$ is any complete system of orthonormalized functions in L_2. Then, in accordance with the previous remark, the weight function of the inverse operator has the form

$$k_x^{-1}(\tau, u) = \sum_{1}^{\infty} y_k(\tau) \zeta_k(u). \tag{38}$$

By applying the inverse operator to both members of Eq. (33) and by taking (38) into account, we obtain the solution in the form

$$w^*(t, \tau) = \sum_{k=1}^{\infty} y_k(\tau) \int k_{zx}(t, u) \zeta_k(u)\, du. \tag{39}$$

If we use the expansion of the correlation function in a series such as (5), we then obtain

$$k_x(u, \tau) = \sum_{k=1}^{\infty} D_k x_k(u) x_k(\tau)$$

and, for the inverse operator,

$$k_x^{-1}(\tau, u) = \sum_{k=1}^{\infty} \frac{a_k(\tau) a_k(u)}{D_k}.$$

Then, for the weight function of the optimal operator, we get

$$w^*(t, \tau) = \sum_{k=1}^{\infty} \frac{a_k(\tau)}{D_k} \int k_{zx}(t, u) a_k(u)\, du. \tag{40}$$

If we use the expansion of the correlation function in a series with respect to orthonormalized eigenfunctions, we obtain

$$k_x(u, \tau) = \sum_{k=1}^{\infty} D_k \psi_k(u) \psi_k(\tau),$$

where D_k and $\psi_k(t)$ are, respectively, the eigenvalues and eigenfunctions of the equation

$$\int k_x(u, \tau) \psi(\tau)\, d\tau = D\psi(u). \tag{41}$$

Formula (39) is then written in the form

$$w^*(t, \tau) = \sum_{k=1}^{\infty} \frac{1}{D_k} \psi_k(\tau) \int k_{zx}(t, u) \psi_k(u)\, du. \tag{42}$$

Results (40) and (42) were obtained in [1].

The author thanks V. S. Pugachev and A. M. Yaglom for reviewing the manuscript and for their valuable remarks.

THE OPTIMAL CONTROL OF SYSTEMS WITH DISTRIBUTED PARAMETERS

A. G. Butkovskii and A. Ya. Lerner

Moscow

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 6, pp. 682-691, June, 1960

The paper poses the problem of the optimal control of systems with distributed parameters for certain classes of objects described by systems of first-order partial differential equations and by the heat conduction equation. The solution is adduced for one optimal control problem for an object described by a first-order partial differential equation, and the functional block schematic is given for an optimal control system for objects of this type.

The recently developed optimal system theory allowed new approaches to the solution of the control problem to be developed. The posing of the problem, in all the generally known works on optimal control theory, derived from the tendency to take into account limiting conditions imposed on the controlling stimuli and on the coordinates of the given portions of systems described by systems of ordinary differential equations (for example, [1-4]).

The solutions of these problems can be based on L. S. Pontryagin's maximum principle [3-7], R. Bellman's dynamic programming method [8], or on the use of isosurfaces in phase space [9, 10]. However, in many engineering applications, one has to do with objects with spatially distributed parameters which are impossible to replace by delay lines. This can give rise to the circumstance that the controlling stimuli can be applied to various points or regions of the distributed system or to the position that the control problem is the attainment of a given distribution of object states.

The optimal control problems for such objects cannot be solved by a direct employment of the well-known methods, and require a new approach to their posing and to their solution.

1. Posing of the Problem

We shall consider systems with distributed parameters which are described by partial differential equations.

Many objects of control can be described by systems of first-order partial differential equations:

$$\frac{\partial Q_i}{\partial t} = f_i\Big(x,\ t,\ Q_1 \ldots, Q_n,\ \frac{\partial Q_1}{\partial x}, \ldots \qquad (1)$$

$$\ldots, \frac{\partial Q_n}{\partial x},\ u_1, \ldots, u_k,\ v_{k+1}, \ldots, v_r,\ w_{r+1}, \ldots, w_s\Big)$$

$$(i = 1, 2, \ldots n),$$

where $Q_i = Q_i(x, t)$ $(i = 1, \ldots, n)$ are functions of the two arguments x and t, defined in the rectangle $l_0 \leq x \leq l_1$, $t_0 \leq t \leq t_1$ and characterizing the object's state; $u_j = u_j(t)$ $(j = 1, 2, \ldots, k)$ are controlling functions of the variable t, constrained by the condition

$$F(u_1, \ldots, u_k) \leqslant C. \qquad (2)$$

Here, F is some given functional, and C is a constant.

Further, $v_j = v_j(x, t)$ $(j = k + 1, \ldots, r)$ are controlling functions of two variables, constrained by the conditions

$$\left|\frac{\partial^{\gamma+\delta} v_j}{\partial x^{\gamma}\partial t^{\delta}}\right| \leqslant A_j, \qquad (3)$$

where γ and δ depend on j, $w_j = w_j(x)$ $(j = r + 1, \ldots, s)$ are controlling functions of one variable x, constrained by the condition

$$\left|\frac{d^{\alpha} w_j(x)}{dx}\right| \leqslant B_j, \qquad (4)$$

where α depends on j.

In the given case, we can formulate three optimal control problems.

I. To vary the controlling stimuli u_j, v_j, w_j $(j = 1, \ldots, s)$ constrained by conditions (2), (3), (4), so that, with initial conditions

$$Q_i(x,\ t_0) = Q_{in}(x) \qquad (5)$$

and boundary conditions

$$Q_i(l_0,\ t) = Q_{i0}(t)$$

some functional

$$I = I\left(x,\ t,\ Q_i, \frac{\partial Q_i}{\partial x}, \frac{\partial Q_j}{\partial t}, u_j, v_j, w_j\right)$$

$$(i = 1, \ldots, n;\ j = 1, \ldots, s) \qquad (6)$$

will be minimized. Here, Q_i, u_j, v_j, w_j are vectors with the corresponding coordinates.

II. To vary u_j, v_j, w_j $(j = 1, 2, \ldots, s)$ so that a function of the type of (6), for fixed values of x lying on the segment $[l_0, l_1]$ (for example, for $x = l_1$), attains its minimum value.

III. Finally, to vary u_j, v_j, w_j $(j = 1, 2, \ldots, s)$ so that a functional of the type of (6), for fixed values of t lying on the segment $[t_0, t_1]$, attains its minimum value.

This is the problem with "free ends," i.e., in the case when no limitations are imposed on the functions $Q_i = Q_i(x, t)$ for $t = t_1$ $(i = 1, 2, \ldots, n)$. However, it is meaningful in some cases to require that the state functions $Q_i = Q_i(x, t)$ $(i = 1, 2, \ldots, n)$ differ in some known sense from certain given functions $Q_i^* = Q_i^*(x)$ by a magnitude not exceeding a permissible deviation ϵ. In other words, it is necessary to require that the vector function $Q = Q(x, t) = (Q_1(x,t), \ldots, Q_n(x, t))$, for $t = t_1$, lie in some given ϵ-neighborhood of the vector function $Q^* = Q^*(x) = (Q_1^*(x), \ldots, Q_n^*(x))$, i.e., that the following condition holds:

$$\max |Q_i^*(x) - Q_i(x, t_1)| \leqslant \epsilon \qquad (l_0 \leqslant x \leqslant l_1,\ i = 1, 2, \ldots n). \tag{7}$$

In connection with this, one might also pose the problem: to vary the controlling stimuli u_j, v_j, w_j $(j = 1, 2, \ldots, s)$ so that there shall be minimized, in some sense, the deviation of the vector function $Q(x, t)$ from a given vector function $Q^*(x)$ for a fixed time t_1, for example, to attain

$$\min \max |Q_i^*(x) - Q_i(x, t_1)| \qquad (l_0 \leqslant x \leqslant l_1,\quad i = 1, 2, \ldots, n). \tag{8}$$

Many controlled objects are described by partial differential equations of second and higher orders. Here, we shall consider one of the fundamental problems of mathematical physics, namely, the heat conduction equation. We first consider the one-dimensional heat conduction equation in the simplest case:

$$\frac{\partial Q}{\partial t} = a \frac{\partial^2 Q}{\partial x^2} + g(x, t, u_1(t)) \tag{9}$$

with initial conditions

$$Q(x, t_0) = Q_0(x) \tag{10}$$

and boundary conditions

$$\left.\frac{\partial Q}{\partial x}\right|_{x=l_0} + \beta_0(l_0, t) = \psi_1(t, u_2(t)), \qquad \left.\frac{\partial Q}{\partial x}\right|_{x=l_1} + \beta_1(l_1, t) = \psi(t_3, u_3(t)). \tag{11}$$

Here, g, ψ_1 and ψ_2 are given functions of their arguments; a, β_0 and β_1 are coefficients which, in the general case, depend on x, t and $Q(x, t)$; $Q = Q(x, t)$ is a function of the two arguments x and t, defined in the region $l_0 \leq x \leq l_1$, $t_0 \leq t \leq t_1$ and characterizing the state of the controlled object, and $u_1(t)$, $u_2(t)$ and $u_3(t)$ are controlling functions constrained by conditions (2) for $k = 3$.

The optimal control problem for such objects can consist of the determination of the law of variation of the controlling stimuli $u_1(t)$, $u_2(t)$, and $u_3(t)$, constrained by conditions of the type of (2), for which the functional

$$I = I\left(t, x, Q, \frac{\partial Q}{\partial x}, \frac{\partial Q}{\partial t}, u_1, u_2, u_3\right) \tag{12}$$

attains its minimum value. In other cases, instead of minimizing functional (12) with the same conditions (2), it is necessary to choose the controlling stimuli so that functional (12) will be minimized but, for fixed x from $[l_0, l_1]$ or for fixed t from $[t_0, t_1]$.

Additional conditions, analogous to condition (7) can be imposed on the function $Q = Q(x,t)$, i.e., the function $Q = Q(x, t)$, at time $t = t_1$, must lie in some given ϵ-neighborhood of a given function $Q^* = Q^*(x)$, for example,

$$\max |Q^*(x) - Q(x, t_1)| \leqslant \epsilon \quad (l_0 \leqslant x \leqslant l_1). \tag{13}$$

An analogous problem can be posed for a three-dimensional object, described, for example, by the heat conduction equation

$$\frac{\partial Q}{\partial t} = a\left(\frac{\partial^2 Q}{\partial x^2} + \frac{\partial^2 Q}{\partial y^2} + \frac{\partial^2 Q}{\partial z^2}\right) + \nu_1 \frac{\partial Q}{\partial x} + \nu_2 \frac{\partial Q}{\partial y} + \nu_3 \frac{\partial Q}{\partial z} + g(P, t, u_1, \ldots, u_k) \tag{14}$$

with initial condition

$$Q(P, 0) = Q_0(P) \tag{14'}$$

and boundary condition

$$\left.\frac{\partial Q}{\partial n}\right|_{\Gamma} + \beta Q\Big|_{\Gamma} = \psi(P, t, u_{k+1}, \ldots, u_r)\Big|_{\Gamma}. \tag{15}$$

Here, P is a point of the body D bounded by surface Γ; n is the external normal; a, ν_1, ν_2, ν_3, β are given functions of the point P and time t; g and ψ are given functions of their arguments. Limitations of the type of (2) are imposed on the controlling stimuli $u_1, \ldots, u_r$.

It might be important here to solve the problem of finding such controlling stimuli which, in conjunction with limitations (2), will give the functional

$$I = I(P, t, Q(P, t); u_1, \ldots, u_r) \tag{16}$$

its minimum value.

With this there may still be imposed the further condition that the function $Q = Q(P, t)$ for $t = t_1$ be found in some ϵ-neighborhood of a given function $Q^*(P)$, for example, that the following condition hold:

$$\max_{P\in D} |Q^*(P) - Q(P, t_1)| \leqslant \varepsilon. \qquad (17)$$

Here there might also arise the problem: to so vary the controlling stimuli $u_1, \ldots, u_r$ that the deviation of the function $Q(P, t_1)$ from the given function $Q^*(P)$ is minimal in some sense — for example, that during time $t = t_1 - t_0$ the following integral be a minimum:

$$\iiint_D [Q^*(P) - Q(P, t_1)]^2\, dP.$$

Moreover, the following problem is also of interest: to determine those controlling stimuli $u_1, \ldots, u_r$ so that the functional of (16) will attain a minimum, where the point $P \in \Gamma' \subset \Gamma$, where Γ' is some definite part of the boundary.

It is necessary to mention that here, as in the case when the object is described by equations of the type of (1), the controlling functions may depend, not only on time t, but also on the spatial coordinates x, x and y, or x, y, z, or only on the space coordinates.

A large number of engineering problems, related to the creation of optimal control systems for objects with distributed parameters, lead to the mathematical problems which we have just enumerated.

Such objects, for example, are flow-through furnaces for the heating or thermal processing of materials. If, with this, we are limited to the accuracy of solution which the theory of regular regimens [11] can give, then objects of this type can be described by first-order partial differential equations of the type of (1). In this case, the limitations of (2) flow from the limitations on range of variation of the controlling stimuli, limitations on their speed of variation, etc. Limitations (3) and (4) are imposed on spatially distributed controlling actions as occur, for example, in velocity heating furnaces, deriving from the impossibility of practical implementation in the furnaces of temperature fields with very high gradients. For such objects, functional (6) to be minimized might stand for the time to compensate disturbing stimuli, the mean square deviation of the material's temperature at the furnace output from a given temperature, etc. As disturbing stimuli here, there might be adduced variations of temperature at the input to the furnace (or in one of its zones), variations in the tempo at which the material is fed through the furnace, variations in thickness of the layer of material to be heated. Introducing the quantity Q, which characterizes the material's state, as a vector rather than a scalar, is due to the fact that the requirements on the processing might include, not one, but several indicators, such as, for example, temperature, chemical constitution, crystal structure, etc.

The problem of optimizing a thick body in a flow-through or chamber furnace leads to a posing of the problem wherein the object is described by second-order partial differential equations, such as (9). It might be necessary here to attain a given temperature distribution, in minimal time or with minimal expenditure of energy [functional (12)], in the body to be heated, or to guarantee that the nonuniformity of heating does not exceed some given magnitude.

It is with such types of problems that one has to deal in creating automatic control systems for a broad class of frequently occurring practical production processes. In addition to the aforementioned heating and thermal flow-through and chamber furnaces, this class of objects includes rotating kilns for sintering free-flowing materials, continuous dessicators for ribbon and free-flowing materials, blast and open-hearth furnaces, ribbon-sintering furnaces, machines for continuous plating, etc.

2. Example of an Object with Distributed Parameters

For a certain class of objects, such as continuous furnaces for heating "fine" billets, heat exchangers, and many others, the equations describing the process can be reduced to first-order partial differential equations.

We consider, for example, the one-sided heating of a "fine" lamina (Biot criterion, $Bi \leq 0.25$) which (Fig. 1) moves through the furnace of length L with a velocity of $\nu = \nu(t) \geq 0$ for $0 \leq t \leq T$. We use the notation: thermal capacity of the metal is c, the specific weight is γ, the lamina thickness is s, the heat transfer coefficient to the metal in the given range of temperature variation is α.

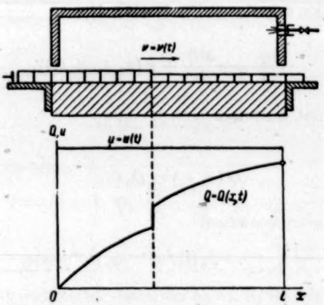

Fig. 1. Single zone flow-through heating furnace. $Q = Q(x, t)$ is the metal temperature as a function of the coordinate x and the time t; u(t) is the furnace temperature as the controlling stimulus; $\nu = \nu(t)$ is the speed at which the metal passes through the furnace.

We assume that the temperature of the furnace's working space (Fig. 1) is the same at all points and that, for $0 \leq t \leq T$, the following limitation is imposed on it:

$$u_1 \leqslant u(t) \leqslant u_2, \tag{18}$$

where u_1 and u_2 are, respectively, the upper and lower admissible or attainable limits of temperature variation of the furnace's working space.

With the aforementioned assumptions taken into account, one can write the equation of the metal heating process in the furnace in the form

$$a\frac{\partial Q}{\partial t} + av\frac{\partial Q}{\partial x} + Q - u = 0. \tag{19}$$

Here, $Q = Q(x, t)$ is the metal temperature at point $\underline{x}$ at time $\underline{t}$; $a = c\gamma s/\alpha$ is the coefficient characterizing the metal's thermal properties. We shall assume that this coefficient depends only on the quantity

$$\xi = x - \int_0^t \nu(p)\,dp.$$

In the case of radiant heat transfer, this equation can be considered the same as an equation in increments.

The initial conditions have the form

$$Q(x,\ 0) = Q_0(x),\ 0 \leqslant x \leqslant L,$$

where $Q_0(x)$ is a given function.

The boundary conditions have the form

$$Q(0,\ t) = 0,\ 0 \leqslant t \leqslant T.$$

In Eq. (19) we carry out the nondegenerate change of variables given by the formulas

$$x = \xi + \int_0^\tau \nu(p)\,dp, \quad t = \tau. \tag{20}$$

The inverse transformation has the form

$$\xi = x - \int_0^t \nu(p)\,dp, \quad \tau = t. \tag{21}$$

After the change of variables, Eq. (19) takes the form

$$a(\xi)\frac{\partial Q(\xi,\ \tau)}{\partial \tau} + Q(\xi,\ \tau) = u(\tau). \tag{22}$$

In this equation, the term with the partial derivative with respect to ξ drops out. By solving this equation for fixed ξ and, thereafter, transforming back to the original variables by means of Formulas (21), we get

$$Q(x,\ t) = e^{-\frac{t}{a}}\left[Q_0\left(x - \int_0^t \nu(p)\,dp\right) + \right. \tag{23}$$
$$\left. + \frac{1}{a}\int_0^t u(p)\,e^{\frac{p}{a}}\,dp\right],$$

where Q_0 and $\underline{a}$ are given functions of the single argument $\xi = x - \int_0^t \nu(p)\,dp$.

3. Optimal Control of Systems with Distributed Parameters

For many objects described by equations of the type of (19), the optimal control problem amounts to finding controlling stimuli, constrained by a condition $u_1 \leq u(t) \leq u_2$ for $0 \leq t \leq T$, such that the functional

$$I = \int_0^T [Q_g - Q(L,\ t)]^2\,dt \tag{24}$$

attains its minimum value. Here, Q_g is some given function of time $\underline{t}$ or is a constant.

For the continuous furnace of the example of Section 2, this requirement signifies the requirement that the mean square deviation of the metal's temperature at the furnace output from a given temperature be minimized.

By setting $x = L$ in formula (23) and substituting in (24), we get

$$I = \int_0^T \left[Q_g - e^{-\frac{t}{a}}Q_0\left(L - \int_0^t \nu(p)\,dp\right) - \right. \tag{25}$$
$$\left. - \frac{1}{a}e^{-\frac{t}{a}}\int_0^t u(p)\,e^{\frac{p}{a}}\,dp\right]^2 dt.$$

With the notation

$$\Theta(t) = Q_g - e^{-\frac{t}{a}}Q_0\left(L - \int_0^t \nu(p)\,dp\right).$$

Expression (25) can be written in the following equivalent form:

$$I = \int_0^T [Q(t) - \Delta(t)]^2\,dt, \tag{26}$$

where $\Delta(t)$ is defined by the equation

$$a\Delta'(t) + \Delta(t) = u(t) \text{ for } \Delta(0) = 0.$$

Here, the optimal control u = u(t) can be found by means of L. S. Pontryagin's maximum principle [6].

The function H has the form

$$H = \psi_0 [\theta(t) - \Delta(t)]^2 - \frac{1}{a}\psi_1 \Delta(t) + \frac{1}{a}\psi_1 u(t), \tag{27}$$

where ψ_0 = const < 0, and ψ_1 satisfies the equation

$$\dot{\psi}_1 = 2[\theta(t) - \Delta(t)]\psi_0 + \frac{1}{a}\psi_1. \tag{28}$$

We determine from (28) that

$$\psi_1(t) = e^{\frac{t}{a}}\left\{C + \int_0^t [\theta(p) - \Delta(p)] e^{-\frac{p}{a}} dp\right\}, \tag{29}$$

where C is an arbitrary constant.

The maximum of the function H is attained for

$$u(t) = \begin{cases} u_2, & \text{if} \quad \psi_1 > 0, \\ u_1, & \text{if} \quad \psi_1 < 0. \end{cases}$$

However, based on the maximum principle, it is impossible to find an optimal control u = u(t) in the case when $\psi_1(t) \equiv 0$ on some segment of the extremals. Such segments, following Rozonoér ([12], Pt. II), we shall call singular. On singular segments, function H does not depend on u, and the control u = u(t) with the condition $u_1 \leq u(t) \leq u_2$ must be so chosen that

$$\theta(t) - \Delta(t) \equiv 0. \tag{30}$$

We assume that condition (30) is met on the portions of the optimal process for $0 \leq t \leq t_1$ and $t_2 \leq t \leq T$. Then, in accordance with [12], Pt. I, in the conditions of problems with "free ends," it is necessary to have $\psi_1(T) = 0$. From this we find that, in expression (29), the constant C equals zero and that, during the course of the optimal process, the following condition must hold:

$$\int_0^T [\theta(t) - \Delta(t)] e^{-\frac{p}{a}} dp = \int_{t_1}^{t_2} [\theta(t) - \Delta(t)] e^{-\frac{p}{a}} dp = 0. \tag{31}$$

Thus, the optimal control has the form

$$u(t) = \begin{cases} u_1 & \text{for} \quad \int_0^t [\theta(p) - \Delta(p)] e^{-\frac{p}{a}} dp > 0, \\ u_2 & \text{for} \quad \int_0^t [\theta(p) - \Delta(p)] e^{-\frac{p}{a}} dp < 0. \end{cases} \tag{32}$$

We now assume that it is necessary to smooth, in some optimum way in the sense of minimizing the functional of (24), step disturbances in the coefficient a. The function a = a(ξ) has the form*

$$a = a(\xi) = \begin{cases} a_1 & \text{for} \quad \xi \leqslant 0, \\ a_2 & \text{for} \quad \xi > 0, \end{cases}$$

where a_1 and a_2 are constants and $\xi = x - \int_0^t \nu(p)\,dp$.

In this case, θ(t), at some moment of time t', $t_1 \leq t' \leq t_2$, will have a jump. Then, in accordance with (32), the optimal control corresponds to the maintenance of u during the interval (t_1, t_2) at one of the limiting levels, the choice of which depends on whether the coefficient a decreased or increased.

The moment t_1 at which there occurs the transition from the singular segment to the nonsingular one is defined by condition (31). The optimal process thus obtained is shown in Fig. 2.

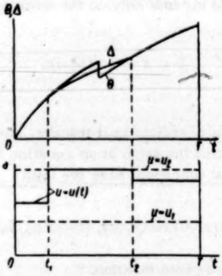

Fig. 2. Optimal process for a disturbance in the coefficient a.

We now determine the optimal control u = u(t) on the singular segments where condition (30) holds. For this, we multiply both members of expression (30) by $ae^{t/a}$ and differentiate them with respect to t. Then, if the function $Q_0(x)_t$ is differentiable with respect to t, we obtain for $0 \leqslant L - \int_0^t \nu(p)\,dp \leqslant L$,

$$u(t) = Q_g + a\nu(t) e^{-\frac{t}{a}} Q_0'\left(L - \int_0^t \nu(p)\,dp\right), \tag{33}$$

where

$$a = \begin{cases} a_1 & \text{for} \quad t \in [0, t_1], \\ a_2 & \text{for} \quad t \in [t_2, T]. \end{cases}$$

---

* This corresponds to a variation in thickness of the billets fed to the continuous furnace.

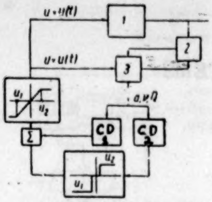

Fig. 3. Block schematic for the optimal control system for an object with distributed parameters. R is a three-position relay: u_1, 0, u_2 as a function of the signal $\delta a = a_2 - a_1$. 1 is the object, 2 is the optimizer, 3 is a model of the object.

It is obvious that condition (33) will also be sufficient for the holding of condition (30). Thus, expression (33) gives the sought-for control on the singular segments of the optimal trajectory.

Implementation of the optimal control process we have found may be achieved, for example, by means of the system whose block schematic is shown on Fig. 3. As is obvious from formulas (31) and (33), it is necessary, for the implementation of the optimal process, to have the function $Q_0 = Q_0(x)$, the coefficient a, and the velocity function $\nu = \nu(t)$.

These data can be obtained from a model of the object, the parameters of which are tuned automatically by means of the optimizer. The initial data, obtained from the model, are fed to computing devices CD1 and CD2. Device CD1 determines the moments for the initial transition from the singular portion of the trajectory to the nonsingular one, and from the nonsingular one to the singular one. With this, there is first opened, and then closed, a key which passes the sign of the increment of coefficient a which is subject to the disturbance. Relay element R has the output values u_2 or u_1 as a function of the sign of the increment of a. Device CD2, using the initial data in correspondence with formula (33), determines the value of controlling parameter u = u(t).

SUMMARY

1. In automating objects with distributed parameters, it is necessary, in seeking an optimal control, to go to a variational problem of a new type, formulated in Section 1 of the present work.

2. The standard works on optimal control theory do not directly give a general method for solving the problem posed here.

3. The characteristic special features of the objects of control considered here are: the presence of both lumped and spatially distributed controlling stimuli and the limitations associated with them, which are imposed, not only on the time derivatives of the controlling stimuli, but also on their derivatives with respect to the spatial coordinates and their combinations. It is an essential point that these controlling stimuli can enter, not only into the equations of the process, but also into the boundary conditions.

4. Control of the objects of the type considered may be directed towards the achievement, either of a minimal deviation of the object's state from a given one, or to a given distribution of object states with certain conditions being met. There becomes very important, with this, the question of the attainability of the given states.

5. In the present paper we cited one of the ways in which the problem posed here can be reduced to a problem which can be solved by means of L. S. Pontryagin's maximum principle.

6. For the optimal control of the objects considered, the control system must contain a sufficiently large operational memory in which there can be stored the disturbing and controlling stimuli for a quite prolonged period of object operation.

THEORY OF CERTAIN INDIRECT CONTROL SYSTEMS WITH SEVERAL ESSENTIAL NONLINEARITIES

R. A. Nelepin

Leningrad

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 6, pp. 692-705, June, 1960

In various domains of technology there are employed single-pulse systems for controlling pressure, level, temperature, speed, etc., with hydraulic, electromechanical or pneumatic amplifiers. The presence of moving parts and linkages in the controllers gives rise to the appearance of dry friction, free play, etc., that is, to factors which occasion essential nonlinearities of the characteristics. As shown both by theoretical investigations and by practical experience, these nonlinearities frequently have a decisive effect on dynamics.

One of the first works devoted to the analysis of the dynamics of nonlinear systems of indirect control is Léauté's classic work [1]. The most significant results in this direction were obtained by A. A. Andronov and his coworkers ([2, 3] and others). These, and many other, investigations explained the influence, principally, of one or another nonlinearity individually. In actual conditions, there are usually several characteristic nonlinearities. The problem thus arises of singling out systems with standard complexes of essential nonlinearities and, on the basis of an analysis of their dynamics, of constructing nomograms or tables which might facilitate the design and adjustment of these systems. The solution of this problem, despite the significant number of investigations, remains in its initial stages [4].

Below, we consider the simplest systems with account taken of nonlinearities of the types of hysteresis loops, dead zones and saturation. Each of these nonlinearities is given a physical interpretation, but other factors can be reduced to them.

The System to Be Considered

For the disturbed motion of the indirect control schemes [5, 6] to be considered, we have:

the equation of the object of control

$$T_a\dot{\varphi} + k\varphi = \mu; \tag{1}$$

the equation of the measurer and valve, with account taken of Coulomb friction in the valve

$$\gamma\eta + b\,\mathrm{sign}\,\dot{\eta} = \varphi + \delta\mu \begin{cases}\text{for} & \dot{\eta} \neq 0\\ \text{for} & \dot{\eta} = 0,\end{cases} \tag{2}$$

$$\text{but } |\gamma\eta - \varphi - \delta\mu| = b,$$

$$\eta = \text{const} \quad \text{for } |\gamma\eta - \varphi - \delta\mu| < b;$$

the equation of the servomotor with a dead zone and power limitations

$$\begin{aligned} T_s\dot{\mu} - c\,\mathrm{sign}\,\eta &= -\eta \quad \text{for} \quad c < |\eta| < c_1\\ \dot{\mu} &= 0 \quad\quad \text{for} \quad |\eta| \leqslant c,\\ \dot{\mu} &= \text{const for} \quad |\eta| \geqslant c_1. \end{aligned} \tag{3}$$

As $c_1 \to \infty$, we have, from (3), the equation of a proportional control servomotor with a dead zone:

$$\begin{aligned} T_s\dot{\mu} - c\,\mathrm{sign}\,\eta &= -\eta \quad \text{for} \quad |\eta| > c,\\ \dot{\mu} &= 0 \quad \text{for} \quad |\eta| \leqslant c. \end{aligned} \tag{4}$$

As $c_1 \to c$ and $(c_1 - c)/T_s = 1/T_C = \text{const}$, we obtain the equation of a constant speed servomotor with a dead zone:

$$\begin{aligned} T_s\mu - c\,\mathrm{sign}\,\eta &= -c_1\,\mathrm{sign}\,\eta \quad \text{for} \quad |\eta| > c,\\ \dot{\mu} &= 0 \quad \text{for} \quad |\eta| \leqslant c, \end{aligned} \tag{5}$$

Here, φ, η, μ are dimensionless coordinates of the object, the valve and the servomotor (the measurer's coordinate is eliminated by means of the valve equation); T_a and T_s are the time constants of the object and servomotor, respectively; k is the self-alignment coefficient; γ is the measurer's nonuniformity coefficient; δ is the feedback factor; b and c are the insensitivity coefficients of the valve and servomotor, respectively; c_1 is the value of coordinate η for which $\dot{\mu}$ attains its greatest magnitude.

We shall consider all the coefficients in Eqs. (1)-(5) to be constant, while of them, in particular cases, b, c, k and δ may be zero, and, moreover, k and δ can be less than zero. For $\delta = 0$, we have a controller without feedback.

As an example, Fig. 1 shows the schemes of controllers whose dynamics, with well-known assumptions, are described by the equations just given. Some of the controllers with such schemes are obtained from the I. I. Polzunov TsKTI, the F. É. Dzerzhinskii VTI, the A. N. Krylov TsNII (SSSR), the English Kent and Bailey companies, the German Askania Company (controllers with jet pipes) and others. It is important to mention that the most widely used schemes in practice of those cited are the controller schemes with feedback of Fig. 1, b and c, in which the measurer and valve are rigidly

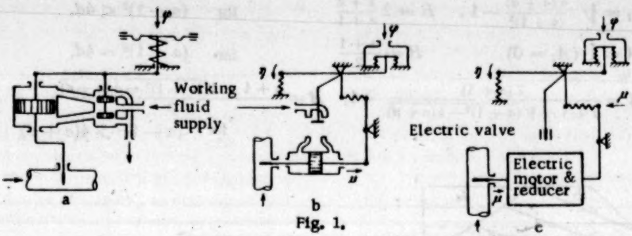

Fig. 1.

connected, and the frictional forces in these elements are inseparable. For such schemes, the foregoing equations take into account the dry friction in all the elements – in the measurer, valve and servomotor.

Method of Investigation

For the investigation of the aforementioned systems, the concept of phase space is applicable, this concept having achieved great popularity in control theory, both in the USSR and other countries, after the well-known works of A. A. Andronov and his school.

We note the specific peculiar features of constructing the phase images of the systems with which we are dealing. First, these systems are piecewise linear, which allows us to obtain the equations of the phase trajectories in the usual form. In considering spaces composed of regions with different trajectories, the concept of virtual singular points is useful [7]. Second, in the three-dimensional phase spaces of the systems under investigation, the trajectories are laid out on a definite form of oriented plane, which permits the investigation of the projections of such spaces on one plane; to eliminate nonsingle-valuedness we employ multisheeted phase surfaces [8, 9] which are analogous to the Riemann surfaces in the theory of functions of a complex variable.

The representation in phase space of a topological map leads, in essential points, to quantitative results by means of the method of point transformations of Poincaré – Brauer – Birkhoff – Andronov. We note that the presence of the Kronecker function in [2] allows the representative point to move only in definite directions on parts of the segments of the characteristics of the equivalent nonlinear link $\dot{\mu} = f(\varphi + \delta\mu)$. We denote these as the basic directions. As the basic directions of the remaining segments, we shall understand such directions in which the representative point can move in its cyclical circuit of the designated characteristic. If the point does not move in a basic direction, then it will either move during a finite time only in basic directions, or fall on a resting segment (or at infinity), without completing an oscillation. Therefore, for an employment of the method of point transformations, it suffices to take into account only those portions of the phase surface sheets which correspond to the aforementioned basic directions which allow one to obtain a simplified multisheet surface with linked (joined) phase trajectories immediately.

Parameter Space of the Systems Considered

For system (1)-(3), the regions corresponding to the different types of motion are located in the space of parameters

$$a = \frac{\delta T'_a}{\gamma k T_s} \gtrless 0, \quad d = \frac{T_a}{\gamma k^2 T_s} > 0 \ (\text{for} \ k > 0),$$

$$d_1 = \frac{T_a}{\gamma k^2 T_s} > 0 \ (\text{for} \ k < 0), \quad G = \frac{\gamma c}{b} \geqslant 0$$

and are defined in the following way. In the region for which $a > -1$, $a + d > 0$, i.e., $\delta T_a + \gamma k T_s > 0$, $1 + \delta k > 0$, $k > 0$ (we call it region I), there lies surface T whose coordinates are determined, after elimination of the parameter V_1, from the equations

$$F_1(V_1) = F(V_1), \quad \left(\frac{\partial F_1}{\partial V}\right)_{V_1} = \left(\frac{\partial F}{\partial V}\right)_{V_1}, \tag{6}$$

where

$$F_1 = G\left(B \ln \frac{B}{B-V} - V\right) + \begin{cases} \sqrt{1 + A_1^2}\exp\left(\frac{1}{A_1} \operatorname{arc\,tg} A_1\right) & \text{for} \quad (a-1)^2 < 4d, \\ e & \text{for} \quad (a-1)^2 = 4d, \\ \exp\left(\frac{A}{A-1} \ln A\right) & \text{for} \quad (a-1)^2 > 4d, \end{cases}$$

$$F = \begin{cases} \sqrt{A_1^2 + (V-1)^2} \exp\left(-\frac{1}{A_1} \operatorname{arc\,tg} \frac{A_1}{V-1}\right) & \text{for} \quad (a-1)^2 < 4d, \\ (V-1)\exp\frac{1}{1-V} & \text{for} \quad (a-1)^2 = 4d, \\ (V-1)\exp\left(\frac{A}{1-A} \ln \frac{V-1}{V-A}\right) & \text{for} \quad (a-1)^2 > 4d, \end{cases}$$

$$A_1 = \sqrt{\frac{4(a+d)}{(a+1)^2} - 1}, \quad B = 2\frac{a+d}{a+1} \qquad \text{for} \quad (a-1)^2 < 4d,$$

$$A = 1 \ (A_1 = 0), \qquad B = \frac{a+1}{2} \qquad \text{for} \quad (a-1)^2 = 4d,$$

$$A = \frac{2(a+1)}{a+1-\sqrt{(a+1)^2 - 4(a+d)}} - 1, \quad B = \frac{a+1+\sqrt{(a+1)^2 - 4(a+d)}}{2}$$

$$\text{for} \quad (a-1)^2 > 4(a+d)$$

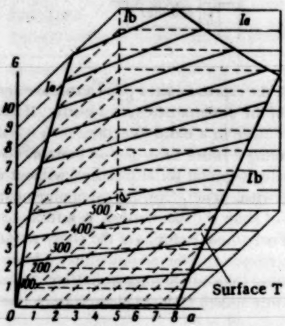

Fig. 2.

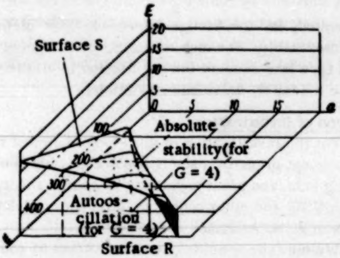

Fig. 3.

Surface T, part of which is shown on Fig. 2, divides region I into the subregions of absolute stability Ia and of rigid autooscillation mode Ib. In subregion Ia lie the points for which $d < d^0$ (for $a = a^0$ = const, $G = G^0$ = const), where a^0, d^0 and G^0 are the coordinates of surface T. For $G = 0$ (i.e., $c = 0$), subregion Ib degenerates to the region of soft autooscillation mode and, for $G = \infty$ (i.e., $b = 0$), disappears entirely due to the coalescence of surface T and the plane $a = -1$.

In the absence of a dead zone of the servomotor ($c = 0$), the boundary of stability coincides with that found previously in [3], and is defined by the trace of surface T on the plane $G = 0$ passing through the points $a = -1$, $d = 1$, and $a = 0$, $d = 3.04$. The remaining regions of the space being considered are of lesser practical interest; without giving the formulas for them, we fall back on Table 1, in which the case $c_1 = \infty$ is referred to system (1)-(3).

For system (1), (2), (4), the corresponding regions are constructed in the space of parameters a, d, d_1, G, $E = b/\gamma\,(c_1 - c) \geq 0$. If the point lies in the aforementioned subregion Ib, the given system, for $G > 0$, can be absolutely stable or autooscillatory (rigid mode). The parameter values on the boundary between stability and autooscillations in subregion Ib are determined by eliminating parameter V_2 from the system

$$F_1(V_2) = F(V_2), \quad \left(\frac{\partial F_1}{\partial V}\right)_{V_2} > \left(\frac{\partial F}{\partial V}\right)_{V_2},$$

$$E = \begin{cases} \dfrac{B}{2(1+A_1^2)}\left(B \ln \dfrac{B}{B-V_2} - V_2\right) & \text{for} \quad (a-1)^2 < 4d, \\ \dfrac{B}{2}\left(B \ln \dfrac{B}{B-V_2} - V_2\right) & \text{for} \quad (a-1)^2 = 4d, \\ \dfrac{B}{2A}\left(B \ln \dfrac{B}{B-V_2} - V_2\right) & \text{for} \quad (a-1)^2 > 4d. \end{cases} \tag{7}$$

When $V_2 = V_1$, the inequality in (7) becomes an equality. Stability corresponds to values of $E > E^0$ (for $a = a^0$ = const, $d = d^0$ = const, $G = G^0$ = const), where a^0, d^0, G^0 and E^0 are defined in accordance with (7). For fixed G, the parameter space of system (1), (2), (4) for region I can be constructed in the coordinates a, d, E. With this, the region of autooscillation will be bounded by the plane $E = 0$, the cylindrical surface R and by some surface S (Fig. 3). An increase in G leads to a decrease in the region of autooscillation. A number of the com-

	$a=2,5\cdot10^3$	d	$50\cdot10^3$	$100\cdot10^3$	$150\cdot10^3$	$200\cdot10^3$	$250\cdot10^3$
		E	0	0	$0,7817\cdot10^3$	$1,244\cdot10^3$	$1,692\cdot10^3$

puted values of the coordinates of surface R are given in Table 2, and those for surface S, in Table 3. The values of parameter E in Table 2 are given for the points of contact of surfaces R and S. Surface T consists of the traces of surface R on the plane $E = 0$, so that Table 1 also contains the boundary values of the parameters for the previous system (1)-(3). For $G = 0$ in subregion Ib, the system (1), (2), (4), will always be autooscillatory (soft mode). With no feedback in the controller ($\delta = 0$), the boundary of stability is defined by the traces of surfaces R and S on the plane $a = 0$, and coincides with that constructed previously in [2]. The behavior of the system in the other regions is clear from Table 1, where the case $c_1 \neq \infty$ (i.e., $E \neq 0$) has been referred to system (1), (2), (4). We note that in region IV, for $k > 0$, $c > 0$, for some initial conditions there is a subregion of attraction of the rest segment. This last remark also applies to system (1)-(3).

In the previously cited cases of rigid modes of autooscillation, the threshold values of the initial deviations, bounding the subregions of stability of systems (1)-(3) and (1), (2), (4) "in the small," may be expressed by the formulas

$$\varphi(0)+\delta\mu(0)=b+\gamma c+\begin{cases}\dfrac{2b\left(1+A_1^2\right)}{B\left(B\ln\dfrac{B}{B-V_2}-V_2\right)} & \text{for}\quad (a-1)^2<4d,\\[2ex] \dfrac{2b}{B\left(B\ln\dfrac{B}{B-V_2}-V_2\right)} & \text{for}\quad (a-1)^2=4d,\\[2ex] \dfrac{2bA}{B\left(B\ln\dfrac{B}{B-V_2}-V_2\right)} & \text{for}\quad (a-1)^2>4d,\end{cases}$$

$$\dot\varphi(0)+\delta\dot\mu(0)=0, \tag{8}$$

where the parameter V_2 is defined by the first equation and inequality in (7).

For $k = 0$, the systems under consideration are autooscillatory only if $\delta > 0$ and $b \neq 0$.

From the spaces constructed it follows that the Coulomb friction in the valve has a negative effect on stability. The servomotor's dead zone and the saturation nonlinearity affect stability positively for stable objects ($k > 0$) and negatively for unstable objects ($k < 0$). On the whole, the effect of the nonlinearities treated here is so significant that, due to them, an absolutely stable linear system may become absolutely unstable, and conversely. In the most important region practically, $k > 0$, $\delta > 0$, the dependence of the boundary of stability on the magnitude of the Coulomb friction and on the magnitude of the saturation nonlinearity parameter c_1 is only observed when several nonlinearities are taken into account jointly. In this region, the deleterious influence on stability of the Coulomb friction in the valve can be compensated by an increase in the servomotor's dead zone, or by limiting its maximum power. These stability requirements are in conflict with requirements for rapidity of system response. Increasing the stability margin at the cost of increasing δ is contrary to the requirement on static accuracy. It is therefore advantageous to have quantities estimates.

For relay system (1), (2), (5), the parameter space was previously constructed in [3]. It follows, from a comparison of the stability boundaries of these three systems, that the region of stability of system (1)-(3) is bounded upon the introduction of a saturation nonlinearity; with a transition from system (1), (2), (4) to a relay system, no increase in the region of stability occurs.

Other Questions of Dynamics

In analyzing a system by our designated method, the "amplitudes" of autooscillations are defined by the coordinates of the stable fixed points of the corresponding point transformations, and the periods of autooscillations are defined by the sums of the times spent by the representative point on the segments of the trajectories making up closed cycles. Thus, for system (1)-(3), in subregion Ib, the "amplitude" of the autooscillation $x_n = (\varphi + \delta\mu)_{\max}$ is expressed by formulas (8) with V_3 replacing V_2 in them, where the parameter V_3 is determined from the system

$$F_1(V_3)=F(V_3),\quad \left(\frac{\partial F_1}{\partial V}\right)_{V_3}<\left(\frac{\partial F}{\partial V}\right)_{V_3}. \tag{9}$$

With this, the period of autooscillation, for example, for $(a-1)^2 > 4d$, will be

$$T_{\mathrm{p}}=\frac{2T_a}{k}\left[\frac{A}{B(A-1)}\ln A\,\frac{V_3-1}{V_3-A}+\frac{A/B\,\dfrac{2b}{x_{\mathrm{p}}-b-\gamma c}+V_3}{B}+\right.$$
$$\left.+\ln\frac{(V_3-A)\exp\left(\dfrac{1}{1-A}\ln\dfrac{V_3-1}{V_3-A}\right)}{(V_3-A)\exp\left(\dfrac{1}{1-A}\ln\dfrac{V_3-1}{V_3-A}\right)-\dfrac{A}{B}\,\dfrac{2\gamma c}{x_{\mathrm{p}}-b-\gamma c}}\right] \tag{10}$$

Autooscillations are ordinarily not the working modes of the systems being considered, so that we shall not give all the corresponding formulas here. But, for $k = 0$, $\delta > 0$, $b > 0$, all three systems are autooscillatory, and may be used as stabilization systems of certain processes only under the condition that the maximum deviation $\varphi_{\max}$ of the controlled quantity be small in the autooscillatory mode. In this case, the relative "amplitudes"

of the autooscillation $\Phi = (\varphi_{\max} - \gamma c_1)/\gamma(c_1 - c)$, defining the value of $\varphi_{\max}$, are expressed by the formulas:
for system (1)-(3)

$$\Phi_1 = E + E\frac{1-2h}{E^*} - 1, \tag{11}$$

for system (1), (2), (4),

$$\begin{aligned} \Phi_2 &= E + 2h\left(\frac{U_p^2}{4} - 1\right) \quad \text{for} \quad E > E^*, \\ \Phi_2 &\equiv \Phi_1 \qquad\qquad\qquad\quad \text{for} \quad E < E^*, \end{aligned} \tag{12}$$

for system (1), (2), (5),

$$\Phi_3 = \frac{E^2}{8h} - 1. \tag{13}$$

Here, $h = a^2/4d$; E^* and U_p are defined by the equations

$$(L)_{U=0,\, E=E^*} = 0, \quad (L)_{U=U_p} = 0,$$

$$L = \sqrt{A_1^2 + \left[\sqrt{U^2 + 4E(1 + A_1^2)} - 1\right]^2} \exp\left[-\frac{1}{A_1} \operatorname{arc\,tg} \frac{A_1}{\sqrt{U^2 + 4E(1 + A_1^2)} - 1} - \right.$$

$$\left. - \sqrt{A_1 + (U + 1)^2} \exp\left(\frac{1}{A_1} \operatorname{arc\,tg} \frac{A_1}{U + 1}\right) \right. \qquad \text{for} \quad h < 1,$$

$$L = \left(\sqrt{U^2 + 4E} - 1\right) \exp\left(-\frac{1}{\sqrt{U^2 + 4E} - 1}\right) - (U + 1) \exp \frac{1}{U + 1} \quad \text{for} \quad h = 1,$$

$$L = \left(\sqrt{U^2 + 4AE} - 1\right) \exp\left(\frac{A}{1 - A} \ln \frac{\sqrt{U^2 + 4AE} - 1}{\sqrt{U^2 + 4AE} - A}\right) -$$

$$- (U + 1) \exp\left(\frac{A}{A - 1} \ln \frac{U + A}{U + 1}\right) \quad \text{for} \quad h > 1,$$

where, in accordance with our previous notation,

$$A_1 = \sqrt{\frac{1}{h} - 1}, \quad A = \frac{1 + \sqrt{1 - 1/h}}{1 - \sqrt{1 - 1/h}}.$$

Formulas (11)-(13) isolate, in coordinates E, h, the regions for which one of the inequality signs $\Phi_1 \gtrless \Phi_3$, $\Phi_2 \gtrless \Phi_3$, is valid, and it follows from them, that systems (1)-(3) and (1), (2), (4), when compared with system (1), (2), (5) in terms of the magnitude of Φ, gain with a decrease in h and an increase in E, and lose for the inverse changes of the parameters.

Analysis of phase spaces permits one to establish the conditions for monotonic (without overshoot) flow of the transient response. We note that the region of monotonicity of System (1)-(3) is broadened upon the introduction of a saturation nonlinearity. For system (1), (2), (4), the region in which the transient response, with initial conditions $-\infty < \varphi(0) + \delta\mu(0) < \infty$, $\dot{\varphi}(0) + \delta\dot{\mu}(0) = 0$, occurs without overshoot and which lies in parameter space inside the region of stability, is defined by the inequalities

$$\sqrt{A_1^2 + (B - 1)^2} \exp\left(-\frac{1}{A_1} \operatorname{arc\,tg} \frac{A_1}{B - 1}\right) \leqslant \frac{2(1 + A_1^2)}{B} GE \quad \text{for} \quad (a - 1)^2 < 4d,$$

$$B \leqslant 1 + \frac{2}{B} GE \exp \frac{1}{B - 1} \quad \text{for} \quad (a - 1)^2 = 4d,$$

$$B \leqslant A + \frac{2A}{B} GE \exp\left(\frac{1}{A - 1} \ln \frac{B - 1}{B - A}\right) \quad \text{for} \quad (a - 1)^2 > 4d.$$

Practical Applications of the Theory

An important assumption in the theory presented is the neglect of inertial forces in the controlling devices. However, as was shown by experimental investigation of a number of control schemes for naval steam energy stands, this assumption was justified in the corresponding cases (low inertia measuring system, hydraulic piston servomotor).

As an example of the use of the results presented, we determine the magnitude of the feedback factor necessary for stabilizing the steam pressure regulator [10] of the A. N. Krylov TsNII system, one of which was demonstrated at the All-Union Industrial Exhibition in 1957. For this example, it was determined that: $T_a = 60$ seconds; $k = 0.25$; $\gamma = 0.03$; $T_s = 40$ seconds; $c = 0.2$; $b = 0.001$; $c_1 = 0.9$; i.e., $a = 200\delta$; $d = 800$; $G = 6$; $E = = 0.0476$. From the tables we find that, for stability, the adjustment must provide $\delta > 0.09$, which is borne out by practical testing.

The data given are applied in an analogous way to some other practical problems.

ON THE THEORY OF OSCILLATIONS OF QUASI-LINEAR SYSTEMS WITH CONSTANT LAGS

S. N. Shimanov

Sverdlovsk

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 6, pp. 706-709, June, 1960

The conditions are given for the existence and stability of almost periodic oscillations in quasi-linear systems with time delays.

The problem of studying the conditions for the appearance of autooscillations, and also forced oscillations, in control systems is of significant interest. The study of oscillations in control systems described by ordinary differential equations was the subject-matter of works by B. V. Bulgakov [1], A. M. Letov [2], A. I. Lur'e [3], M. A. Aizerman, Ya. Z. Tsypkin, and others. In particular, very effective use was made in the works cited of the method of small parameters in the study of oscillations in certain controlled systems.

It is of interest to develop the method of small parameters in the direction of its use in the study of the appearance and stability of periodic and almost periodic modes in nonlinear control systems. The present paper presents the author's results in the theory of almost periodic oscillations in general quasi-linear systems with constant lags.

The method of N. N. Bogolyubov [4] is used in this work. The paper is a development of results obtained by I. G. Malkin [5] in solving the problem of the existence of almost periodic modes in quasi-linear systems whose motions are described by ordinary differential equations.

In clearing up the question of stability, the methods of A. M. Lyapunov, developed in the works of N. G. Chetaev [6], N. N. Krasovskii [7], and others, turned out to be very useful.

1. We consider a system whose motions are described by a set of differential-difference equations of the form

$$\frac{dx_s(t)}{dt} = a_{s1}x_1(t) + \ldots + a_{sn}x_n(t) + b_{s1}x_1(t-\tau) + \ldots + b_{sn}x_n(t-\tau) + f_s(t) + \mu F_s[t;\ x_1(t), \ldots, x_n(t);\ x_1(t-\tau), \ldots, x_n(t-\tau);\ \mu] \quad (s = 1, \ldots, n) \tag{1}$$

Here, a_{si}, b_{si} are constant coefficients; τ is a constant which characterizes the temporal delay; $f_s(t)$ are finite trigonometric sums; $F_s(t, x_1, \ldots, x_n, x'_1, \ldots, x'_n, \mu)$ are polynomials in $x_1, \ldots, x_n, x'_1, \ldots, x'_n$ and trigonometric finite sums in t with frequencies which do not depend on the variables x, x', and μ is a small parameter on which the coefficients of the F_s depend analytically; $[x'_1 = x_1(t-\tau), \ldots, x'_n = x_n(t-\tau)]$.

We consider the characteristic equation

$$\Delta(\lambda) \equiv |a_{si} - \delta_{si}\lambda + b_{si}\exp(-\lambda\tau)| = 0. \tag{2}$$

Theorem 1. If Eq. (2) has no roots on the imaginary axis of the λ plane, then system (1) admits a unique almost periodic solution $x_s^*(t, \mu)$ for sufficiently small $|\mu|$.

The proof of this theorem is carried out by the method of successive approximations on the basis of the following lemma.

Lemma 1. We consider the system of linear differential-difference equations

$$\frac{dx_s(t)}{dt} = a_{s1}x_1(t) + \ldots + a_{sn}x_n(t) + b_{s1}x_1(t-\tau) + \ldots + b_{sn}x_n(t-\tau) + f_s(t) \quad (s = 1, \ldots, n). \tag{3}$$

This system is obtained from (1) for $\mu = 0$.

If characteristic Eq. (2) has no roots on the imaginary axis of the λ plane, then Eq. (3) admits one, and only one, almost periodic solution $x_s^*(t)$, and this solution has the estimate

$$|x_s^*(t)| < AM, \tag{4}$$

where A does not depend on the f_s, and is determined only by the coefficients a, b and the lag τ.

We construct the solution $x_s^*(t)$ by Bückner's method in the following way. Let $\Delta_{jk}(i\lambda)$ be the cofactor of the element in the kth column and jth row of the matrix $\|\Delta(i\lambda)\|$. We introduce the notation $\Gamma_{kj}(i\lambda) = \Delta_{jk}(i\lambda)/\Delta(i\lambda)$.

Let
$$K_{js}(t) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} e^{i\lambda t}\Gamma_{js}(i\lambda)\,d\lambda.$$

It can be shown that the integral

$$\int_{-\infty}^{+\infty} |K_{js}(t)|\,dt \tag{5}$$

has a finite value.

Then the almost periodic solution of system (3) is determined by the formulas

$$x_s^* = \sum_{j=1}^{n}\int_{-\infty}^{+\infty} f_j(\xi)\,K_{sj}(\xi - t)\,d\xi \equiv \sum_{j=1}^{n}\int_{-\infty}^{+\infty} f_j(t+\xi)\,K_{sj}(\xi)\,d\xi \quad (s = 1, \ldots, n).$$

From this expression, for the solutions x_s^*, with account taken of (5), the estimate of (4) is rapidly obtained.

In the course of the proof of convergence of the successive approximations for the almost periodic solution of system (1), a rough estimate is obtained for the region of existence of an almost periodic solution in terms of the parameter μ.

Theorem 2. If all the roots of Eq. (2) have negative real parts, then the solution $x_s^*(t, \mu)$ of system (1) will be asymptotically stable for $t \to +\infty$ and for sufficiently small, by modulus, initial functions, characterizing the disturbance μ for sufficiently small $|\mu|$.

2. We consider the case when, among the roots of Eq. (2), there are m purely imaginary ones: $\omega_1 i, \omega_2 i, \ldots, \omega_m i$. We assume that to these roots there will correspond m periodic solutions $\varphi_{s1}, \varphi_{s2}, \ldots, \varphi_{sm}$ of homogeneous system (3). The periods of these solutions will be, respectively: $2\pi/|\omega_1|, \ldots, 2\pi/|\omega_m|$. In case some of the ω equal zero, the periods of the solutions will be arbitrary, and we shall take them as equal to, for example, 2π. We assume that $\omega_m \neq 0$.

We again consider system (3), in which we shall assume the $f_s(t)$ to be arbitrary, almost periodic functions.

Lemma 2. We consider the auxiliary system

$$\begin{aligned}\frac{dx_s(t)}{dt} &= a_{s1}x_1(t) + \ldots + a_{sn}x_n(t) + b_{s1}x_1(t-\tau) + \ldots + b_{sn}x_n(t-\tau) + \\ &+ f_s(t) + \varphi_{s1}W_1(t) + \ldots + \varphi_{sm}W_m(t) \quad (s = 1 \ldots, n)\end{aligned} \tag{6}$$

No matter what the almost periodic functions $f_s(t)$, it is always possible to construct almost periodic functions $W_1, \ldots, W_m$ with frequencies whose moduli do not exceed 2ϵ (ϵ is an arbitrarily small positive number) such that system (6) will admit an almost periodic solution of the form

$$x_s^* = M_1\varphi_{s1} + \ldots + M_m\varphi_{sm} + \varphi_s(t), \tag{7}$$

where $M_1, \ldots, M_m$ are arbitrary constants, and $\varphi_s(t)$ is an almost periodic function. The functions $\varphi_s(t)$ will be completely uniquely defined if it is required that, for example, frequencies equal to the frequencies $\omega_1, \ldots, \omega_m$ not enter in φ_n. The functions φ_s admit estimates of the type of (4).

Lemma 3. We consider an auxiliary system of the form

$$\begin{aligned}\frac{dx_s(t)}{dt} &= a_{s1}x_1(t) + \ldots + a_{sn}x_n + b_{s1}x_1(t-\tau) + \ldots + b_{sn}x_n(t-\tau) + f_s(t) + \\ &+ \mu F_s[t, x_1(t), \ldots, x_n(t-\tau), \mu] + \varphi_{s1}W_1 + \ldots + \varphi_{sm}W_m \quad (s = 1, \ldots, n).\end{aligned} \tag{8}$$

System (8) permits almost periodic solutions of the form

$$x_s^*(t, M_1, \ldots, M_m, \mu) = \varphi_{s1}M_1 + \ldots + \varphi_{sm}M_m + \varphi_s + \mu\bar{x}_s^*(t, M, \mu) \quad (s = 1, \ldots, n). \tag{9}$$

where $M_1, \ldots, M_m$ are arbitrary parameters, defined in some neighborhood of the point $\bar{M}_1, \ldots, \bar{M}_m$, $\mu = 0$, and the $\bar{x}_s^*$ are analytical functions of the parameters $M_1, \ldots, M_m$, in the neighborhood of the point $\bar{M}_1, \ldots, \bar{M}_m$, $\mu = 0$.

With respect to t, the function x_s^* is almost periodic. Solution (9) exists for completely determined functions $W_1, \ldots, W_m$ with low frequencies, less than some 2ϵ, and are analytic with respect to the parameters $M_1, \ldots, M_m$ and μ in the neighborhood of the same point $\overline{M}_1, \ldots, \overline{M}_m, 0$. With our assumptions as to F_s and as to the polynomials $\underline{x}$, the point $\overline{M}_1, \ldots, \overline{M}_m$ is arbitrary.

The proof is carried out on the basis of Lemma 2 by the method of successive approximations.

The lemma generalizes a result of the author [8] obtained earlier for ordinary equations and functions F_s which are periodic in $\underline{t}$.

3. We assume that we have found the almost periodic solutions of auxiliary system (8) and the corresponding slowly varying functions $W_1, \ldots, W_m$. We note that, for the sequel, it suffices to find, for example, only several terms in the series expansions of these functions in powers of μ.

Thanks to the fact that the F_s are assumed to be polynomials in $\underline{x}$ and finite trigonometric sums in $\underline{t}$, it is always possible to choose a number ϵ sufficiently small that the functions W_i will have the expressions

$$W_i \equiv \mu Q_i(M_1, \ldots, M_m) + \\ + \mu^2 W_i'(t, M_1, \ldots, M_m, \mu) \quad (i = 1, \ldots, m),$$

where the Q_i are determined in the following manner.

Let $\psi_{s1}, \ldots, \psi_{sm}$ be periodic solutions of the linear homogeneous system "adjoint" to system (3):

$$\frac{dx_s(t)}{dt} = -a_{1s}x_1(t) - \ldots - \\ - a_{ns}x_n(t) - b_{1s}x_1(t+\tau) - \ldots - b_{ns}x_n(t+\tau).$$

Let $\lim\limits_{t \to +\infty} (1/t) \int\limits_0^t \sum\limits_{s=1}^n \varphi_{sj} \psi_{sk} \, dt = d_{jk}$. It can be shown that $|d_{jk}| \neq 0$. Then

$$d_{j1}Q_1 + \ldots + d_{mj}Q_m + P_j = 0 \quad (j = 1, \ldots, m),$$

where

$$P_j \equiv \lim_{t \to +\infty} \frac{1}{t} \int\limits_0^t \sum_{s=1}^n F_s[t, x_1^0(t), \ldots, \\ x_n^0(t), x_1^0(t-\tau), \ldots, x_n^0(t-\tau), 0] \, \psi_{sj}(t) \, dt. \\ (j = 1, \ldots, m).$$

In the last expression,

$$x_s^0 = M_1\varphi_{s1} + \ldots + M_m\varphi_{sm} + \varphi_s \quad (s = 1, \ldots, n)$$

are solutions of system (1) with $\mu = 0$.

Theorem 3. Let the system of equations

$$P_j(M_1, \ldots, M_m) = 0 \quad (j = 1, \ldots, m) \qquad (10)$$

admit the solutions $M_j = \overline{M}_j$, and let system (1), for $\mu = 0$, admit almost periodic solutions.

If the equation

$$\left| \frac{\partial (P_j(\overline{M}))}{\partial \overline{M}_k} - \delta_{jk}\lambda \right| = 0 \qquad (11)$$

has roots with negative real parts, and the roots of (2), not lying on the imaginary axis, have negative real parts, then system (1) has an almost periodic solution in a sufficiently small region $|\mu| \leq \mu^*$, asymptotically stable for $t \to \infty$ and initial disturbances of sufficiently small moduli. This solution, to a first approximation, is defined by the formulas

$$x_s = \overline{M}_1\varphi_{s1} + \\ + \ldots + \overline{M}_m\varphi_{sm} + \varphi_s(t) \quad (s = 1, \ldots, n). \qquad (12)$$

SUMMARY

It was shown in this work that, for quasi-linear systems with time delays, it is possible to establish the conditions for existence and stability of almost periodic motions analogous to the well-known conditions for systems described by ordinary differential equations.

TRANSIENT RESPONSES IN CONTROL SYSTEMS WITH LAGS

Z. Sh. Blokh

Moscow

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 6, pp. 710-719, June, 1960

A method is given for constructing the transient response in systems with lags. Transfer functions are found for systems with lags, where these lags may be in the forward circuit, in the basic feedback path and in auxiliary feedback paths. For the transient response under consideration, an integral equation is set up and solved, its solution being given in the form of a series which converges absolutely and uniformly on any given finite interval of time.

Estimates of overshoot and control time (duration of the transient response) are given, based on the parameters of the real and imaginary frequency characteristics of the system with lags.

Relationships are derived which permit one to compare different integral criteria of control quality for systems with, and without, lags.

1. Representation and Construction of the Transient Response

We consider a model of a control circuit with a lag (Fig. 1), where $\Phi(z)$ is the link's transfer function when the lag is not taken into account, and θ is the lag time which, in the sequel, we shall take to be constant. By assuming that, to construct the representation function $\varphi_{\text{out}}(t)$, we should take into account the initial function $\varphi^{*}_{\text{in}}(t)$, given in the interval $-\theta \leq t \leq 0$, which precedes the initial moment of time,* we may write

$$L[\varphi_{\text{out}}(t)] = \Phi(z)e^{-\theta z}L[\varphi_{\text{in}}(t)] + \Phi(z)\varepsilon(\theta, z), \quad (1)$$

where L is the symbol of the Laplace transform,

$$\varepsilon(\theta, z) = e^{-\theta z}\int\limits_{-\theta}^{0}\varphi^{*}_{\text{in}}(t)e^{-zt}\,dt.$$

Formula (1) shows that, for nonzero initial functions, the representation of the transient response output signal consists of two terms, whereby the effect of the initial functions can be taken into account independently by assuming that, at the input of the ordinary link with transfer function $\Phi(z)$, there acts an external disturbance, given by the representation $\varepsilon(\theta, z)$. By taking this circumstance into account, we shall henceforth consider a standard representation of the transient response in a closed linear control system with lags (Fig. 2) in the form

$$W(z) = \frac{W_0(z)e^{-\theta_1 z}}{1 + W_k(z)e^{-\theta_2 z}}, \quad (2)$$

where $W_0(z) = \Phi_1(z)L[\varphi_{\text{in}}(t)]$, $W_k(z) = \Phi_1(z)\Phi_2(z)$, $\theta_2 = \theta_1 + \theta_3$. It is assumed with this that the functions $\Phi_1(z)$ and $\Phi_2(z)$ must take into account the lags in the auxiliary feedback paths in those cases when this is necessary.

In work [2], for representations of the type given in (2), there is given a method of constructing the transient response based on the expansion of W(z) in an infinite series in powers of $W_k(z)$ which converges for $|W_k(z)| < 1$, i.e., for small values of the gains.

It is preferable to give a method of constructing the transient response which does not entail the investigation of convergences of an infinite series. Directly from formula (2) we obtain

$$W(z) = W_0(z)e^{-\theta_1 z} - W(z)W_k(z)e^{-\theta_2 z}. \quad (3)$$

Fig. 1.

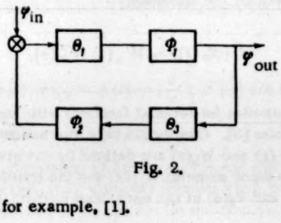

Fig. 2.

---

*Cf., for example, [1].

By applying the convolution and lag theorems [3] to expression (3), we obtain an integral equation for the transient response being sought:

$$\varphi_{out}(t) = \tag{4}$$

$$= \varphi_0(t-\theta_1) - \int_0^t \varphi_{out}(\tau)\varphi_k(t-\theta_2-\tau)\,d\tau,$$

where $\varphi_{out}(t)$, $\varphi_0(t)$, and $\varphi_k(t)$ are the time domain functions corresponding to the transforms W(z), $W_0(z)$, and $W_k(z)$. The solution of Eq. (4) is written in the form of a series:

$$\varphi_{out}(t) = \varphi_0(t-\theta_1) - \varphi_1(t-\theta_1-\theta_2) +$$

$$+ \varphi_2(t-\theta_1-2\theta_2) - \ldots + \tag{5}$$

$$+ (-1)^n \varphi_n(t-\theta_1-n\theta_2),$$

which converges absolutely and uniformly in t on any finite interval of time. The sufficient conditions which are imposed on the initial function $\varphi_0(t)$ and the kernel $\varphi_k(t)$ of integral Eq. (4) amount, as is well known [4], to the holding of the conditions

$$|\varphi_0(t)| < Ae^{at}, \quad |\varphi_k(t)| < Be^{bt},$$

where A, B, a, b are positive constants.

In computing by formula (5), it must be taken into account that all the functions entering into it, $\varphi_m(t-\theta_1-m\theta_2)$ (m = 0, 1, 2, . . . n), equal zero for negative values of the argument. This important circumstance allows one to find the values of $\varphi_{out}(t)$ exactly for any previously given finite interval of time t which, at the same time, can be considered as an approximation for a large interval.

To construct the time domain functions entering into formula (5), we take into account that the transform of any of them,

$$L[\varphi_m(t-\theta_1-m\theta_2)] = \tag{6}$$

$$= W_0(z) W_k^m(z) e^{-(\theta_1+m\theta_2)t},$$

is easily obtained if we apply the ordinary Laplace transformation to the formulas for the successive determinations of the $\varphi_m(t-\theta_1-m\theta_2)$ by integral Eq. (4). In practice, the problem reduces to the determination of the functions $\varphi^*_m(t)$, given by the transforms

$$L[\varphi^*_m(t)] = W_0(z) W_k^m(z), \tag{7}$$

from the formulas for rational fractions with known multiple poles [3]. One should take into account with this that $W_0(z)$ and $W_k(z)$ are defined by the given transform of the input stimulus $W_{in}(z)$ and the transfer functions $\Phi_1(z)$ and $\Phi_2(z)$ of the open-loop circuits (Fig. 2).

As an example of the application of the formulas we have derived, we construct the transient response for the representation

$$W(z) = \frac{ke^{-\theta z}}{z[(T_1z+1)(T_2z+1)+ke^{-\theta z}]}.$$

Since

$$\lim_{z\to\infty} zW(z) = \varphi_{out}(0) = 0,$$

we shall find it preferable to consider the transform of the transient response's velocity,

$$L\varphi'_{out}(t) = zW(z) = \frac{ke^{-\theta z}}{(T_1z+1)(T_2z+1)+ke^{-\theta z}}.$$

In accordance with our notation $\theta_1 = \theta_2 = \theta$,

$$W_0(z) = W_k(z) = \frac{k}{(T_1z+1)(T_2z+1)}.$$

The transforms of the successive functions, in accordance with formula (7), are found from the expression

$$L[\varphi^*_m(t)] =$$

$$= \frac{k^{m+1}}{(T_1z+1)^{m+1}(T_2z+1)^{m+1}} \quad (m = 0, 1, 2, \ldots, n). \tag{8}$$

Since

$$L^{-1}\left[\frac{1}{(T_kz+1)^{m+1}}\right] = \frac{t^m e^{-\frac{t}{T_k}}}{T_k^{m+1}m!} \quad (k = 1, 2),$$

then all the functions given by the transforms of (8) are defined by the convolution formula

$$\ddot{\varphi}_m(t) = \frac{k^{m+1}e^{-\frac{t}{T_2}}}{(m!)^2(T_1T_2)^{m+1}}\int_0^t \tau^m(t-\tau)^m e^{-\left(\frac{\tau}{T_1}-\frac{\tau}{T_2}\right)}d\tau.$$

Consequently,

$$\dot{\varphi}_m(t) = \tag{9}$$

$$\frac{k^{m+1}}{(m!)^2(T_1T_2)^{m+1}}\int_0^t e^{-\frac{t}{T_2}}dt\int_0^t \tau^m(t-\tau)^m e^{-\left(\frac{\tau}{T_1}-\frac{\tau}{T_2}\right)}d\tau.$$

The solution being sought is written in the form

$$\varphi_{out}(t) = \varphi_0(t-\theta) - \varphi_1(t-2\theta) + \ldots +$$

$$+ (-1)^{n-1}\varphi_n(t-n\theta),$$

where all the functions φ^*_m are computed from formula (9).

For representations of more general types, the method just presented for constructing the transient responses leads to arduous computations, particularly when the gains are large.

2. Frequency Characteristics of Systems with Lags

By taking into account that, in representation (2), the factor $e^{-\theta_1 z}$ leads only to a shift of the corresponding time domain characteristic by the amount θ_1, we shall find it more advantageous in the sequel to consider the following function as the representation of a transient response with lags:

$$W(z) = \frac{W_0(z)}{1 + W_k(z)\, e^{-\theta z}}. \tag{10}$$

As will be shown later, the frequency characteristics corresponding to representation (10) ordinarily have a finite number of points of intersection with the frequency axis, and do not differ essentially in their main features from the analogous characteristics of systems without lags. This allows us to carry over to systems with lags the estimating methods which have been previously developed for systems without lags (5, 6, 7).

If all the poles of representation (10) lie in the left half-plane, then the abscissa of convergence of the integral

$$W(z) = \int_0^\infty \varphi(t)\, e^{-zt}\, dt,$$

is $\sigma < 0$, and we can set $z = i\omega$ in it. Then,

$$W(i\omega) = S(\omega) + iQ(\omega) = \int_0^\infty \varphi(t)\, e^{-i\omega t}\, dt.$$

Consequently,

$$S(\omega) = \int_0^\infty \varphi(t) \cos \omega t\, dt. \tag{11}$$

$$Q(\omega) = -\int_0^\infty \varphi(t) \sin \omega t\, dt. \tag{12}$$

The functions $S(\omega)$ and $\varphi(t)$, $Q(\omega)$ and $\varphi(t)$ are Fourier transform pairs. Based on their duality property [8], one can write

$$\varphi(t) = \frac{2}{\pi} \int_0^\infty S(\omega) \cos t\omega\, d\omega, \tag{13}$$

$$\varphi(t) = -\frac{2}{\pi} \int_0^\infty Q(\omega) \sin t\omega\, d\omega. \tag{14}$$

If representation (10) has a simple pole at the origin:

$$W(z) = \frac{\Phi(z)}{z},$$

we then set

$$\Phi(i\omega) = R(\omega) + iI(\omega)$$

and find the transient response corresponding to W(z) from the convolution formula, taking into account that the transient response for $\Phi(z)$ is determined from formulas (13) and (14):

$$\varphi(t) = \frac{2}{\pi} \int_0^t \int_0^\infty R(\omega)\, 1(t-\tau) \cos \tau\omega\, d\omega\, d\tau.$$

By changing the order of integration, we get

$$\varphi(t) = \frac{2}{\pi} \int_0^\infty \frac{R(\omega)}{\omega} \sin t\omega\, d\omega. \tag{15}$$

Analogously,

$$\begin{aligned} \varphi(t) &= -\frac{2}{\pi} \int_0^t \int_0^\infty I(\omega)\, 1(t-\tau) \sin \tau\omega\, d\omega\, d\tau = \\ &= \frac{2}{\pi} \int_0^\infty \frac{I(\omega)}{\omega} \cos t\omega\, d\omega - \frac{2}{\pi} \int_0^\infty \frac{I(\omega)}{\omega}\, d\omega. \end{aligned} \tag{16}$$

Since the first of these integrals equals zero for $t \to \infty$, then

$$\varphi(\infty) = \varphi_v = -\frac{2}{\pi} \int_0^\infty \frac{I(\omega)}{\omega}\, d\omega = \frac{2}{\pi} \int_0^\infty S(\omega)\, d\omega, \tag{17}$$

where

$$S(\omega) = -\frac{I(\omega)}{\omega}, \tag{18}$$

and φ_s is the steady-state value of the output coordinate.

Consequently,

$$\varphi(t) = -\frac{2}{\pi} \int_0^\infty S(\omega) \cos t\omega\, d\omega + \varphi_v. \tag{19}$$

By shifting the origin of coordinate, we shall henceforth consider as the transient response the time domain function

$$\psi(t) = \varphi_v - \varphi(t) = \frac{2}{\pi} \int_0^\infty S(\omega) \cos t\omega\, d\omega. \tag{20}$$

A comparison of formulas (13) and (20) shows that the function $S(\omega)$, given by formula (18), is the frequency characteristic of the system for the transient response $\psi(t)$.

3. Some Properties of the Frequency Characteristics W(z)

We limit our consideration to the case when the representation has a simple pole at the origin. Since, for linear systems and a broad class of disturbing actions $W_0(z)$ and $W_k(z)$ are rational fractions, then, by introducing the following notation into formula (10):

$$zW_0(z) = \frac{d_0(z)}{d_1(z)}, \quad W_k(z) = \frac{d_2(z)}{d_3(z)},$$

$$D_0(z) = d_0(z)\,d_3(z),$$

$$D_1(z) = d_1(z)\,d_3(z), \quad D_2(z) = d_1(z)\,d_2(z),$$

where $d_k(z)$ and $D_k(z)$ are polynomials in z, we present the function $\Phi(z)$, for $z = i\omega$, in the form

$$\Phi(i\omega) = \frac{D_0(i\omega)}{D_1(i\omega) + D_2(i\omega)\,e^{-i\theta\omega}} = R(\omega) + iI(\omega).$$

By setting $D_k(i\omega) = x_k + iy_k$ $(k = 0, 1, 2)$, we get

$$R(\omega) = \frac{Ax_0 + By_0}{A^2 + B^2},$$

$$I(\omega) = \frac{Ay_0 - Bx_0}{A^2 + B^2},$$

$$A = x_1 + x_2\cos\theta\omega + y_2\sin\theta\omega,$$

$$B = y_1 + y_2\cos\theta\omega - x_2\sin\theta\omega.$$

The zeros of the frequency characteristics $R(\omega)$ and $I(\omega)$ are defined, respectively, by the roots of the transcendental equations:

$$\begin{gathered} x_0x_1 + y_0y_1 + (x_0x_2 + y_0y_2)\cos\theta\omega + \\ + (x_0y_0 - y_0x_2)\sin\theta\omega = 0, \\ y_0x_1 - x_0y_1 + (y_0x_2 - x_0y_2)\cos\theta\omega + \\ + (y_0y_2 + x_0x_2)\sin\theta\omega = 0. \end{gathered} \tag{21}$$

Let the stimulus $\varphi_{in}(t) = 1(t)$ be applied to the measuring device, and let $W_k(z) = zW_0(z)$. Then $D_0(z) = D_2(z)$ and Eqs. (21) for $R(\omega)$ and $I(\omega)$ are rewritten in the form, respectively,

$$\cos\theta\omega = -\frac{x_1x_2 + y_1y_2}{x_2^2 + y_2^2}, \quad \sin\theta\omega = \frac{y_1x_2 - x_1y_2}{x_2^2 + y_2^2}. \tag{22}$$

Let the polynomials $D_2(z)$ and $D_1(z)$ be of degrees m and n, respectively, where $m \leq n$. Then, a detailed analysis of formulas (22) leads to the following results.

The frequency characteristic $R(\omega)$ has a finite number of points of intersection with the ω axis for $m < n-1$, independently of the system parameters and the lag θ. For $m \geq n-1$, the number of points of intersection with the ω axis will be finite only if the following inequality holds:

$$\lim_{\omega\to\infty}\left|\frac{x_1x_2 + y_1y_2}{x_2^2 + y_2^2}\right| > 1. \tag{23}$$

Frequency characteristic $I(\omega)$, and with it frequency characteristic $S(\omega)$, has a finite number of points of intersection with the ω axis for $m < n$ independently of the system parameters and the lag θ. Since the case $m = n$ is not possible for $\varphi(0) = 0$, the characteristics $I(\omega)$ and $S(\omega)$, for sufficiently large ω, do not change sign, and tend to zero for $\omega \to \infty$. The same behavior occurs for characteristic $R(\omega)$ for $m < n-1$ or, if inequality (23) holds, for $m < n$. Consequently, for the particular case being investigated, one can neglect the high-frequency parts of the characteristics $R(\omega)$, $I(\omega)$ and $S(\omega)$ and can estimate the errors thus introduced by means of the formulas derived in [5, 6], for characteristics without lags. For the characteristics of systems with lags we thereby establish the concept of the essential interval of frequency on which they should be constructed. Thus, for example, considering $S(\omega) > 0$, for definiteness, in the high-frequency interval $\omega_c \leq \omega \leq \infty$, and by then discarding this segment of the characteristic, we obtain, by using the results of [6], the following estimate of the transient response error:

$$|\Delta\psi| \leqslant \psi(0) - \frac{2}{\pi}F, \tag{24}$$

where F is the area bounded by the frequency characteristic $S(\omega)$ in the chosen essential interval of frequency $0 \leq \omega \leq \omega_c$, $\psi(0) = \varphi_s$. Since φ_s is easily computed from the given representation of the transient response, then formula (24) allows the essential frequency interval (by area) to be so chosen that the error in the transient response will not exceed the previously given quantity $|\Delta\psi|$.

4. Estimate of Overshoot and Control Time

To determine overshoot and control time from frequency characteristics, we construct these latter from a large number of computed ordinates in the essential frequency interval, and then replace them by the sum of standard characteristics for which the formulas of the corresponding transient responses have been previously obtained. After this, one computes the ordinates of the transient response being investigated and, from the curve thus constructed, one fins the overshoot and the control time. If one takes as standards the natural frequency characteristics of simple systems without lags, then the constructions and computations involved in estimating overshoot and control time are significantly simplified [7]. We limit ourselves to the consideration of just two standard cases, referring the reader to the literature [7] for a more complete analysis. As standards, we shall choose the frequency characteristics corresponding to the representation

$$W(z) = \frac{b_1 z + a_2}{z(z^2 + a_1 z + a_2)}. \tag{25}$$

By setting z = iω in (25) we obtain, for zW(z),

$$R(\omega) = \frac{c_2\omega^2 + c_4}{\omega^4 + d_2\omega^2 + c_4}, \tag{26}$$

where $c_2 = a_1b_1 - a_2$, $c_4 = a_2^2$, $d_2 = a_1^2 - 2a_2$ are three new essential parameters of characteristic R(ω) by which it is completely defined. Among the various possible types of curves for R(ω), we consider in detail the characteristic which is nonnegative in the essential frequency interval (Fig. 3). Let the characteristic R(ω) of the system with lags under investigation be nonnegative in the essential interval $0 \leq \omega \leq \omega_2$ and have one maximum $R = R_1$ for $\omega = \omega_1$. We choose the parameters c_2, c_4 and d_2 such that the characteristic of the system with lags shall coincide with that given by (26) in the three points for $\omega = 0$, $\omega = \omega_1$ and $\omega = \omega_2$ (Fig. 3). Since, by (26), R(0) = = 1, then coincidence of the ordinates at the point ω = 0 is attained by a simple change of scale for the investigated characteristic of the system with lags. After this, the parameters being constructed are determined from the system of equations

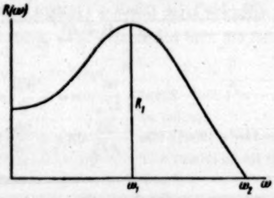

Fig. 3.

$$R_1 = \frac{c_2\omega_1^2 + c_4}{\omega_1^4 + d_2\omega_1^2 + c_4} = \frac{c_2}{2\omega_1^2 + d_2}, \tag{27}$$

$$c_2\omega_2 + c_4 = 0$$

by the formulas

$$c_2 = \frac{R_1\omega_1^4}{\omega_2^2(1 - R_1)}, \quad c_4 = \frac{R_1\omega_1^4}{R_1 - 1}, \tag{28}$$

$$d_2 = \frac{\omega_1^4}{\omega_2^2(1 - R_1)} - 2\omega_1^2.$$

We then compute the initial parameters:

$$a_2 = \sqrt{c_4}, \quad a_1 = \sqrt{d_2 + 2a_2}, \quad b_1 = \frac{a_2 + c_2}{a_1}. \tag{29}$$

By the formulas derived in [9], the quantities just found permit one to compute the overshoot and control time exactly for the transient response corresponding to the representation of (25).

We now give the computational scheme:

$$\Delta\phi = \sqrt{\frac{F(-b_1)}{a_2}}\, e^{-\frac{\alpha}{\beta}\gamma}, \tag{30}$$

$$\operatorname{tg}\gamma = -\frac{\beta b_1}{a_2 - \alpha b_1}, \quad e^{\alpha T} = s\sqrt{\frac{F(-b_1)}{a_2}}.$$

In the formulas just given, $\Delta\psi$ is the overshoot, T is the control time, s is a parameter defining the zone of admissible deviations (s = 10 to 20), $2\alpha = a_1$, $\beta = \sqrt{a_2 - \alpha^2}$, $F(-b_1) = b_1^2 - a_1b_1 + a_2$.

As an example, we estimate the quality of control in a static system with lags by setting, in the representation of (10),

$$W_k(z) = zW_0(z) = \frac{k(T_1z + 1)}{(T_2z + 1)(T_3z + 1)}$$

and by taking $T_1 = 0.1$ second, $T_2 = 1$ second, $T_3 = 0.2$ second, k = 4.

By using the method developed in [2], we can determine that the system is stable if the lag time is θ < 0.48 second. For the following computations, we take θ = 0.3 second.

The closed system's real frequency characteristic is

$$R(\omega) = \frac{(400 + 4\omega^2)\cos\theta\omega + 100 - 8\omega^2}{A^2 + B^2}, \tag{31}$$

where $A = 5 - \omega^2 - 20\cos\theta\omega + 2\omega\sin\theta\omega$, $B = 6\omega + 2\omega\cos\theta\omega - 20\sin\theta\omega$.

The points of intersection of characteristic R(ω) with the ω axis are defined by the equation

$$\cos\theta\omega = \frac{2\omega^2 - 25}{\omega^2 + 100},$$

which has the sole real solution $\omega_2 = 4.7$.

In addition, we find from formula (31) that R(0) = 0.8 and $R_1 = 1.7$ for ω = 4 at the maximum point. We change the scale of the axis of ordinates, setting R(0) = 1, R_1 = = 2.12. Then, by formulas (28) and (29), we find: $a_1 = 2$, α = 1.3, $a_2 = 22$, $b_1 = 0.069$, $\beta^2 = 21.6$. By substituting

TABLE 1

k	1.6	1.2	1.0	0.8	T_i	5	4	3	2
S_0	8	6	5	4	S_0	8.0	6.4	4.8	3.2
ω_2	0.54	0.64	0.74	0.82	ω_2	0.54	0.54	0.57	0.6
ω_1	0.27	0.32	0.37	0.41	ω_1	0.27	0.27	0.285	0.3
S_1	1.05	1	0.97	0.95	S_1	1.05	1.25	1.7	2.0

these values in formulas (30), we obtain: $\tan\gamma = -0.0145$, $\gamma = \pi - 0.01 = 3.13$, $\Delta\psi = 0.64$, $T = 4.6$ seconds for $s = 20$. From the exact curve of the transient response, constructed by the method presented in Section 1 to verify our example, $\Delta\psi = 0.6$ (with the scales of the variables taken into account), which differs little from the estimated value. In astatic systems with variable loads, $\varphi_s = 0$, and formulas (18) to (30) cannot be applied. For such systems, one may take as standard the frequency characteristics corresponding to the representation

$$W(z) = \frac{b_1}{z^2 + a_1 z + a_2}.$$

By setting $z = i\omega$, we obtain, for the real frequency characteristic,

$$S(\omega) = \frac{b_1(a_2 - \omega^2)}{(a_2 - \omega^2)^2 + a_1^2\omega^2}. \qquad (32)$$

The three essential parameters b_1, a_1 and a_2 of the characteristic of (32) are defined by the ordinates in three chosen points of the analogous characteristic of the system with lags under investigation as a function of its behavior. If it be required that the characteristics coincide for $\omega = 0$, $\omega = \omega_1$ and $\omega = \omega_2$ for $S(\omega_2) = 0$, then the parameters being sought are determined from the formulas

$$a_2 = \omega_2^2,\ b_1 = S_0 a_2 = S_0\omega_2^2,\ a_1^2 = \frac{S_0\omega_2^2(\omega_2^2 - \omega_1^2) - S_1(\omega_2^2 - \omega_1^2)^2}{S_1\omega_1^2}, \qquad (33)$$

where S_0 and S_1 are the ordinates of the investigated system's frequency characteristic at the points $\omega = 0$ and $\omega = \omega_1$, respectively.

As an example of the use of formulas (33), we take the analysis of the control quality of concentrating sulfur dioxide (SO_2) for an external disturbance $\varphi_{in} = 1(t)$ applied to the object of control. With some simplifying assumptions, we give the basic functions entering into the representation of (2):

$$W_0(z) = \frac{k_1k_2k_3}{z(T_1z+1)(T_2z+1)(T_3z+1)},$$

$$W_k(z) = \frac{(T_iz+1)k_1k_2k_3k_6k_8}{(T_1z+1)(T_2z+1)(T_3z+1)(T_6z+1)(T_8z+1)kT_iz} \qquad (34)$$

In the sequel, we shall measure time in minutes, taking into account the corresponding scale changes in representation of the transient response. Taking the controller adjustment parameters T_i and k as variables, we present the analysis for the following values of the remaining system parameters: $\theta_1 = 0.25$ minutes, $\theta_2 = 1$ minute, $T_1 = 0.25$ minutes, $T_2 = 0.5$ minutes, $T_3 = 0.33$ minutes, $T_8 = 0.25$ minutes, $T_6 = 1$ minute, $k_1k_2k_3 = 1$, $k_6k_8 = 1$.

By substituting the parameters' numerical values in formulas (34) and discarding the factor $e^{-0.25z}$, the effect of which is taken into account by shifting the time domain characteristic by $\theta = 0.25$ minutes, we obtain

$$W(z) = \frac{24(z+1)(z+4)}{z(z+4)^2(z+3)(z+2)(z+1) + \frac{96}{k}\left(z + \frac{1}{T_i}\right)e^{-z}}.$$

By setting $z = i\omega$ in this representation, we find that

$$W(i\omega) = \frac{(96-24\omega^2)A + 120\omega B + i[1200A - B(96-24\omega^2)]}{A^2+B^2},$$

where

$$A = -\omega^6 + 75\omega^4 - 224\omega^2 + \frac{96}{kT_i}\cos\omega + \frac{96\omega}{k}\sin\omega,$$

$$B = -14\omega^5 - 190\omega^3 + 96\omega - \frac{96}{kT_i}\sin\omega + \frac{96\omega}{k}\cos\omega.$$

We separate out, for the further computations, the real frequency characteristic

$$S(\omega) = \frac{(96-24\omega^2)A + 120\omega B}{A^2+B^2}. \qquad (35)$$

Analysis of stability, carried out in [2], showed that the system is stable in the following range of parameter variations: $1.8 \le T_i \le 5$, $0.8 \le k \le 1.6$.

Since, within the given limits of parameter variation, the characteristics $S(\omega)$, found from formula (35), do not increase in the interval $0 \le \omega \le \omega_2$, then, for the subsequent estimates, we took $\omega_2 = 2\omega_1$. The values of the ordinates of $S(\omega_k)$, computed from formula (35) for $T_i = 5$ in the range $0.8 \le k \le 1.6$, and for $k = 1.6$ in the range $2 \le T_i \le 5$, are given in Table 1.

Substitution of the values thus found into formulas (33) allowed the computation of a_1, a_2 and b_1 for the accepted values of controller adjustment, T_i and k. After this, the greatest deviation of the controlled coordinate, and the control time, were computed by the

TABLE 2

k	1.6	1.2	1.0	0.8	T_1	5	4	3	2
ψ max	0.83	0.85	0.89	0.87	ψ max	0.83	0.82	0.85	0.82
T	19	14	11	8.3	T	19	15	10.3	7.4

formulas derived in [9]. If $a_1^2-4a_2 > 0$, then

$$\psi_{\max}=S_0\omega_2 e^{-\alpha t_{el}},\ t_{el}=\frac{1}{\alpha^2-\omega_2^2}\ln\frac{\alpha+\sqrt{\alpha^2-\omega_2^2}}{\omega_2}, \quad (36)$$

where $2\alpha = a_1$. The control time T was defined by the transcendental equation

$$\frac{S_0\omega_2^2}{2\sqrt{\alpha^2-\omega_2^2}}\left(e^{-z_1T}-e^{-z_2T}\right)=\frac{1}{s} \quad (37)$$

for $s = 10$, $z_1 = \alpha - \sqrt{\alpha^2-\omega_2^2}$, $z_2 = \alpha + \sqrt{\alpha^2-\omega_2^2}$.

If $z_2 \gg z_1$, we may then use the following formula for the determination of the control time:

$$T\approx\frac{1}{z_1}\ln\frac{sS_n\omega_2^2}{2\sqrt{\alpha^2-\omega_2^2}}. \quad (38)$$

In the case $a_1^2-4a_2 < 0$, the greatest deviation, and the control time, were determined from the formulas

$$\psi_{\max}=S_0\omega_2 e^{-\frac{\alpha}{\beta}\gamma}, \quad \operatorname{tg}\gamma=\frac{\beta}{\alpha}, \quad (39)$$

$$T=\frac{1}{\alpha}\ln\left(sS_0\omega_2\right),$$

where $2\alpha = a_1$, $\beta^2 = \omega_2^2-\alpha^2$. The results of all these computations are given in Table 2.

Analysis of the results obtained shows that the isodrome controller time T_1 and the parameter k, corresponding to the range of the throttled controller, have very little influence on the greatest deviation of the controlled parameter. The control time is essentially decreased by decreases in T_1 and k. The optimal adjustment of the controller corresponds to the lowest values of k and T_1 which are compatible with the stability requirements. Verification of the computations made by more exact methods showed that the deviations of the estimated values from the more exact ones did not go beyond the limits of computational accuracy.

LYAPUNOV FUNCTIONS FOR RELAY CONTROL SYSTEMS

Yu. I. Alimov

Sverdlovsk

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 6, pp. 720-728, June, 1960

The idea of a trajectory is introduced, and the stability in the large is investigated of the equilibrium state of one class of relay control systems.

1. In many cases, the dynamic properties of automatic-control relay systems are well described by a mathematical model consisting of a combination of a linear part having a transfer function

$$W(p) = \frac{\sigma(p)}{y(p)} = \frac{b_n p^{n-1} + b_{n-1} p^{n-2} + \cdots + b_1}{a_{n+1} p^n + a_n p^{n-1} + \cdots + a_1} k_p \qquad (1)$$

$$(a_1, \ldots, a_{n+1}, b_1, \ldots, b_n = \mathrm{const}, b_1, a_{n+1}, k_p > 0)$$

and a relay element without a zone of insensitivity having the characteristic form $y = \varphi(\sigma)$.

In actual fact, both the input $\sigma(t)$ and the output $\varphi(\sigma(t))$ of any real unit approximating such a relay element (a kinematic couple with dry friction, an amplifier with a small zone of linearity, a relay, etc.) are continuous functions of the time. If the coordinate $\sigma(t)$ passes rapidly through its threshold value $\sigma = 0$, the function $\varphi(\sigma)$ can be assumed to be discontinuous, and we can set $\varphi(\sigma) = \operatorname{sign}\sigma$, for example. Such an idealization becomes unsatisfactory for the investigation of those relay systems (sliding and partially sliding regimes, motion with stops [1-4]) for which $\sigma(t)$ remains for long periods of time near to its change-over value. The continuous character of the function $\varphi(\sigma)$ is taken into account most simply in the description of such motions by the Coulomb characteristic:

$$y = \varphi(\sigma) = \begin{cases} -(1-\varphi_0) & \text{for } \sigma < 0, \\ \xi & \text{for } \sigma = 0, \\ +(1+\varphi_0) & \text{for } \sigma > 0, \end{cases} \qquad (2)$$

where $\varphi_0 = \mathrm{const}$, $|\varphi_0| < 1$, and ξ can be any number from the interval $[-(1-\varphi_0), 1+\varphi_0]$, and with $\xi = \xi(t)$ expressed as in [3], so that the equations (1)-(2) for $y(t) = \varphi(0) = \xi(t)$ are compatible with the equality $\sigma(t) = 0$.

In order to derive and investigate the phase space of the system (1)-(2), we write its equations in the normal Cauchy form

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{b}\varphi(\sigma), \quad \sigma = \mathbf{k}'\mathbf{x}, \qquad (3)$$

using for brevity of notation the usual vector-matrix notation of [5]: **A** is a square matrix, and **x**, **b**, and **k** are n-dimensional column matrices. The prime indicates the transpose of a matrix, so that, according to the rule for multiplying matrices ([5], p. 14) $\mathbf{k}'\mathbf{x}$ is a scalar, and $\mathbf{k}\mathbf{b}'$ is a square matrix. The transformation of the equations (1)-(2) to the normal form is particularly simple, and yields

$$\begin{aligned} \dot{x}_k &= x_{k+1} \quad (k = 1, \ldots, n-1), \\ \dot{x}_n &= -a_{n+1}^{-1}\left(\sum_{i=1}^{n} a_i x_i + k_p \varphi(\sigma)\right), \\ \sigma &= \sum_{i=1}^{n} b_i x_i. \end{aligned} \qquad (4)$$

In several works (for example, see [1]) the trajectories of the system (2)-(3) have been considered close to a certain periodic motion with simple switching conditions, and in [6], close to the origin. In [1, 3, and 4] sliding regimes of relay systems were investigated in detail. Many authors have laid out the whole **x** phase space of the system (2)-(3) in trajectories for n = 2, 3. This is done below for any n under the assumption that

$$a_{n+1}^{-1} k_p b_n = -\mathbf{k}'\mathbf{b} > 0 \qquad (5)$$

(the case

$$b_n = 0, \quad b_{n-1} > 0 \qquad (6)$$

was considered in [7], the violation of the conditions (5)-(6) is connected [1, 6] with the loss of stability). The second Lyapunov method is applied to the dynamic system obtained. Effective algorithms are obtained for deriving a wide class of sufficient conditions for stability in the large of the equilibrium of the system (2)-(3) with a stable or unstable linear part. The stability criteria given in this paper are expressed in terms of the coefficien of the transfer function (1), but the method of constructing the Lyapunov functions is described in invariant form, and it can be applied in obtaining criteria expressed in terms of the elements of the matrices **A**, **b**, and **k** in the usual form. In the case

$$\operatorname{Re}\lambda_i < 0 \quad (i = 1, \ldots, n), \tag{7}$$

where λ_i are the roots of the equation det $(\mathbf{A} - \lambda\mathbf{E}) = 0$, the Lyapunov functions are obtained by the interlacing method, and can be used to estimate the control time. The case

$$\lambda_1 = 0,\ \operatorname{Re}\lambda_k < 0 \quad (k = 2, \ldots, n). \tag{8}$$

is also discussed briefly.

It should be mentioned that the unsymmetric characteristic (2) must also be considered [1] in the investigation of systems

$$\dot{\mathbf{z}} = \mathbf{A}\mathbf{z} + \mathbf{b}\varphi\ (\mathbf{k}'\,\mathbf{z}),\quad \varphi(\sigma) = \begin{cases} -1 & \text{for } \sigma < 0, \\ +1 & \text{for } \sigma > 0 \end{cases} \tag{9}$$

with a symmetric relay link when, for example, in the case (7) we are investigating the effect of a discontinuous external action:

$$\sigma(t) = \mathbf{k}'\,\mathbf{z}(t) + \mathbf{1}(t)\,\sigma_0, \tag{10}$$

and in the case (8) for motion with a linear input:

$$\sigma(t) = \mathbf{k}' z(t) + \mathbf{1}(t)\,(\sigma_0 + \sigma_1 t). \tag{11}$$

The system (9)-(10) and (11) reduces to the form (2)-(3) by a nonsingular linear transformation of the coordinates **z**. The value of φ_0 is determined here from the parameters σ_0 and σ_1 of the external disturbance.

2. We denote by $\mathbf{x}_+(\mathbf{x}^0, t)$, and $\mathbf{x}_-(\mathbf{x}^0, t)$ the trajectories of the systems

$$\dot{\mathbf{x}} = \mathbf{f}_+(\mathbf{x}) = \mathbf{A}\mathbf{x} + \mathbf{b}\,(1 + \varphi_0), \tag{12}$$

$$\dot{\mathbf{x}} = \mathbf{f}_-(\mathbf{x}) = \mathbf{A}\mathbf{x} - \mathbf{b}\,(1 - \varphi_0), \tag{13}$$

passing for t = 0 through the point $\mathbf{x}^0$ of the space **x**. For the investigation of the system (2)-(3) and (7), it is convenient to write Equations (12) and (13) in the form

$$\dot{\mathbf{x}}_+ = \mathbf{A}\mathbf{x}_+,\ \mathbf{x}_+ = \mathbf{x} + \mathbf{A}^{-1}\mathbf{b}\,(1 + \varphi_0), \tag{12'}$$

$$\dot{\mathbf{x}}_- = \mathbf{A}\mathbf{x}\ ,\ \mathbf{x}\ = \mathbf{x} - \mathbf{A}^{-1}\mathbf{b}\,(1 - \varphi_0). \tag{13'}$$

We denote by $\dot{\sigma}_+(\mathbf{x})$ and $\dot{\sigma}_-(\mathbf{x})$ the derivatives with respect to time of the function $\sigma(\mathbf{x}) = \mathbf{k}'\mathbf{x}$ according to the systems (12) and (13). Thus,

$$\sigma_+(\mathbf{x}) = \mathbf{k}'\mathbf{A}\mathbf{x} + \mathbf{k}'\mathbf{b}\,(1 + \sigma_0),$$

$$\dot{\sigma}_-(\mathbf{x}) = \mathbf{k}'\mathbf{A}\mathbf{x} - \mathbf{k}'\mathbf{b}\,(1 - \varphi_0),$$

and, according to (5), we have

$$\dot{\sigma}_+(\mathbf{x}) < \dot{\sigma}_-(\mathbf{x}). \tag{14}$$

Using the method in [1-4, 6, 7], we give the determination of the trajectory $\mathbf{x}(\mathbf{x}^0, t)$ of system (2)-(3) satisfying the condition (5).

(a) In the space $\sigma(\mathbf{x}) > 0$ $(\sigma(\mathbf{x}) < 0)$ we assume that $\mathbf{x}(\mathbf{x}^0, t) = \mathbf{x}_+(\mathbf{x}^0, t)$. $(\mathbf{x}(\mathbf{x}^0, t) = \mathbf{x}_-(\mathbf{x}^0, t))$.

(b) At any point $\mathbf{q}_1$ of the set $\sigma(\mathbf{x}) = 0$, $\dot{\sigma}_+(\mathbf{x})\,\dot{\sigma}_-(\mathbf{x}) > 0$, representing two half-planes $(\mathbf{k}'\mathbf{b})^{-1}\,\mathbf{k}'\mathbf{A}\mathbf{x} < -(1 + \varphi_0)$, $\mathbf{k}'\mathbf{x} = 0$ and $(\mathbf{k}'\mathbf{b})^{-1}\mathbf{k}'\mathbf{A}\mathbf{x} > (1 - \varphi_0)$, $\mathbf{k}'\mathbf{x} = 0$, the trajectories $\mathbf{x}_+(\mathbf{q}_1, t)$, $\mathbf{x}_-(\mathbf{q}_1, t)$ intersect the switching surface $\sigma(\mathbf{x}) = 0$ in the same direction. We determine $\mathbf{x}(\mathbf{q}_1, t)$ by linking continuously at $\mathbf{q}_1$ those half-trajectories $\mathbf{x}_+(\mathbf{q}_1, t)$ and $\mathbf{x}_-(\mathbf{q}_1, t)$ which lie close to $\mathbf{q}_1$ in the regions $\sigma(\mathbf{x}) > 0$ and $\sigma(\mathbf{x}) < 0$, respectively.

(c) According to (14), at every point $\mathbf{q}_0$ of the set $\sigma = 0$, $\dot{\sigma}_+(\mathbf{x})\,\dot{\sigma}_-(\mathbf{x}) < 0$ the trajectories $\mathbf{x}_+(\mathbf{q}_0, t)$, and $\mathbf{x}_-(\mathbf{q}_0, t)$ intersect the surface $\sigma(\mathbf{x}) = 0$ in the same direction. In accord with what was said in Sec. 1, we will assume that in the set consisting of the zone

$$(1 - \varphi_0) > (\mathbf{k}'\mathbf{b})^{-1}\mathbf{k}'\mathbf{A}\mathbf{x} > -(1 + \varphi_0),\ \mathbf{k}'\mathbf{x} = 0, \tag{15}$$

the representative point of the system (2)-(3) moves according to the equations

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{b}\varphi\ (0) = \mathbf{A}\mathbf{x} + \mathbf{b}\xi(t). \tag{16}$$

where $\xi(t)$ is chosen so that the derivative with respect to time $\dot{\sigma}_0(\mathbf{x})$ of the function $\sigma(\mathbf{x})$ obtained as in (16), satisfies the equality

$$\dot{\sigma}_0(\mathbf{x}) = \mathbf{k}'\mathbf{A}\mathbf{x}(t) + \mathbf{k}'\mathbf{b}\xi(t) = 0. \tag{17}$$

If we combine (16) and (17), we obtain

$$\sigma(\mathbf{x}) = \mathbf{k}'\mathbf{x} = 0,$$

$$\dot{\mathbf{x}} = \mathbf{f}_0(\mathbf{x}) = \mathbf{B}\mathbf{x},\ \mathbf{B} = \mathbf{A} - (\mathbf{k}'\mathbf{b})^{-1}\mathbf{b}\mathbf{k}'\mathbf{A}. \tag{18}$$

Various forms of the scalar representation of (18) are given in [1, 3, and 4]. For trajectories of the system (18) we will use the notation $\mathbf{x}_0(\mathbf{x}^0, t)$.

(d) We consider finally the boundary $\sigma(\mathbf{x}) = 0$, $\dot{\sigma}_+(\mathbf{x})\,\dot{\sigma}_-(\mathbf{x}) = 0$ of the zone (15) of the sliding regime, represented by the two hyperlines

$$\mathbf{k}'\mathbf{x} = 0,\ \dot{\sigma}_+(\mathbf{x}) = \mathbf{k}'\mathbf{A}\mathbf{x} + \mathbf{k}'\mathbf{b}\,(1 + \varphi_0) = 0 \tag{19}$$

and

$$\mathbf{k}'\mathbf{x} = 0,\ \dot{\sigma}_-(\mathbf{x}) = \mathbf{k}'\mathbf{A}\mathbf{x} - \mathbf{k}'\mathbf{b}\,(1 - \varphi_0) = 0. \tag{20}$$

According to (12), (13), (14), and (18), for all the points q_+ and q_-, belonging, respectively, to the straight lines (19) and (20), the relations

$$\mathbf{f}_+(\mathbf{q}_+) = \mathbf{f}_0(\mathbf{q}_+),\ \ \mathbf{f}_-(\mathbf{q}_-) = \mathbf{f}_0(\mathbf{q}_-), \tag{21}$$

and

$$\dot{\sigma}_-(\mathbf{q}_+) > 0,\ \ \dot{\sigma}_+(\mathbf{q}_-) < 0, \tag{22}$$

are valid, so that, for example, for the straight line (19), we have

$$\frac{d^m}{dt^m}[\sigma_+(\mathbf{q}_+)]_+ = \frac{d^m}{dt^m}[\dot{\sigma}_+(\mathbf{q}_+)]_0,\ \ m \geqslant 1, \tag{23}$$

where $\frac{d^m}{dt^m}[\dot{\sigma}_+(\mathbf{q}_+)]_+$ and $\frac{d^m}{dt^m}[\dot{\sigma}_+(\mathbf{q}_+)]_0$ are the derivatives of order m with respect to the time of the function $\dot{\sigma}_+(\mathbf{x})$, evaluated at the point $\mathbf{q}_+$ by (12) and (18). It is evident from (23) that in a sufficiently small neighborhood of the point $\mathbf{q}_+$ the positive half-trajectories $\mathbf{x}_+(\mathbf{q}_+, t)$, and $\mathbf{x}_0(\mathbf{q}_+, t)$ lie simultaneously either in the region $\dot{\sigma}_+(\mathbf{x}) \geqslant 0$, or in the region $\dot{\sigma}(\mathbf{x}) < 0$. In this neighborhood for t > 0, in the first case of the similar location of the trajectories $\mathbf{x}_+(\mathbf{q}_+, t)$, and $\mathbf{x}_0(\mathbf{q}_+, t)$, we set $\mathbf{x}(\mathbf{q}_+, t) = \mathbf{x}_+(\mathbf{p}_+, t)$; in the second $\mathbf{x}(\mathbf{q}_+, t) = \mathbf{x}_0(\mathbf{q}_+, t)$. The positive half-trajectory $\mathbf{x}(\mathbf{p}_+, t)$ will be unique since, according to (22), the trajectories $\mathbf{x}_-(\mathbf{q}_+, t)$ for t > 0 start in the half-space $\sigma(\mathbf{x}) < 0$. The straight line (20) can be considered similarly.

3. The solution $\mathbf{x}(\mathbf{x}^0, t)$ of the system (2)-(3), determined as above, is also a generalized solution of this system in the sense of the definition of A. F. Filippov [8].

(We mention that the essence of A. F. Filippov's definition is precisely the definition of the discontinuous right-hand sides, including infinite valued functions, continuous in the same sense as the characteristic (2)). The fact that the solution $\mathbf{x}(\mathbf{x}^0, t)$ can be continued for t → + ∞, its uniqueness, and the property $\mathbf{x}((\mathbf{x}^0, t_1), t_2) = \mathbf{x}(\mathbf{x}^0, t_1 + t_2)$ for t ≥ 0 are obvious; the continuity relative to $\mathbf{x}^0$ and t can easily be proved by using (21).

Thus, for the reflection of $\mathbf{x}(\mathbf{x}^0, t)$ for t ≥ 0, we can apply all the results of the general theory of dynamic systems [9], and this, in turn, makes it possible to use a series of results formulated for classical systems of differential equations, but permitting obvious generalizations to abstract dynamic systems – for example, the theorems of E. A. Barbashin and N. N. Krasovskii [10] concerning stability in the large.

4. We will form the Lyapunov function V(x) for the system (2)-(3) and (5) in the case (7) by linking on the surface $\sigma(\mathbf{x}) = 0$ the Lyapunov functions

$$V_+(\mathbf{x}) = \mathbf{x}_+\mathbf{H}\mathbf{x}_+,\ \ \mathbf{x}_+ = \mathbf{x} + \mathbf{A}^{-1}\mathbf{b}(1 + \varphi_0), \tag{24}$$

$$V_-(\mathbf{x}) = \mathbf{x}_-\mathbf{H}\mathbf{x}_-,\ \ \mathbf{x}_- = \mathbf{x} - \mathbf{A}^{-1}\mathbf{b}(1 - \varphi_0) \tag{25}$$

(H is a symmetric matrix of the nth order) for the systems (12') and (13'), respectively:

$$V(\mathbf{x}) = \begin{cases} V_+(\mathbf{x}) - V_+(0) & \text{for } \sigma(\mathbf{x}) \geqslant 0, \\ V_-(\mathbf{x}) - V_-(0) & \text{for } \sigma(\mathbf{x}) \leqslant 0. \end{cases} \tag{26}$$

The continuity of V(x) is ensured if $V_+(\mathbf{x})$ and $V_-(\mathbf{x})$ are chosen so that the equality

$$V_+(\mathbf{x}) - V_+(0) = V_-(\mathbf{x}) - V_-(0) \text{ for}$$
$$\sigma(\mathbf{x}) = \mathbf{x}'\mathbf{k} = 0. \tag{27}$$

holds. Since the relation $V_+(\mathbf{x}) - V_+(0) = V_-(\mathbf{x}) - V_-(0)$ is equivalent to $\mathbf{x}'\mathbf{H}\mathbf{A}^{-1}\mathbf{b} = 0$, the condition (27) used in the linking can be written in the form

$$\mathbf{H}\mathbf{A}^{-1}\mathbf{b} = \mu\mathbf{k}\ \ (\mu = \text{const} \neq 0). \tag{28}$$

It is evident from the relation

$$V(\mathbf{x}) = \mathbf{x}'\mathbf{H}\mathbf{x} + 2\mu\sigma\cdot\varphi(\sigma), \tag{29}$$

that follows from (26) and (28), that if the function $\mathbf{x}'\mathbf{H}\mathbf{x}$ satisfying condition (28) is positive-definite, then the function V(x) will also be positive-definite for μ > 0.

For any solution $\mathbf{x}(\mathbf{x}^0, t)$ everywhere except possibly at points of intersection of $\mathbf{x}(\mathbf{x}^0, t)$ with the surface $\sigma(\mathbf{x}) = 0$, the derivative $\dot{V}(\mathbf{x})$ with respect to time of the function (29) along $\mathbf{x}(\mathbf{x}^0, t)$ exists and satisfies the relations

$$\dot{V}(\mathbf{x}) = \begin{cases} \dot{V}_+(\mathbf{x}) & \text{for } \sigma(\mathbf{x}) > 0, \\ \dot{V}_-(\mathbf{x}) & \text{for } \sigma(\mathbf{x}) < 0, \\ \dot{V}_0(\mathbf{x}) & \text{for } \sigma(\mathbf{x}) = 0,\ \dot{\sigma}_+(\mathbf{x})\cdot\dot{\sigma}_-(\mathbf{x}) < 0, \end{cases} \tag{30}$$

where $\dot{V}_+(\mathbf{x}) = \mathbf{x}_+'(\mathbf{H}\mathbf{A} + \mathbf{A}'\mathbf{H})\mathbf{x}_+$ and $\dot{V}_-(\mathbf{x}) = \mathbf{x}_-'(\mathbf{H}\mathbf{A} + \mathbf{A}'\mathbf{H})\mathbf{x}_-$ are the derivatives with respect to time of the functions $V_+(\mathbf{x})$ and $\dot{V}_-(\mathbf{x})$ according to (12') and (13'), and $\dot{V}_0(\mathbf{x}) = \mathbf{x}'(\mathbf{H}\mathbf{B} + \mathbf{B}'\mathbf{H})\mathbf{x}$ is the derivative with respect to time of the function (29) according to (18).

Let the form $-\mathbf{x}'\mathbf{G}\mathbf{x}$ (G is a symmetric matrix of the nth order) be positive-definite. Then when the condition (7) is satisfied, there exists one, and only one, form $x'Hx$, related to $x'Gx$ by

$$G = HA + A'H, \tag{31}$$

where the form $x'Hx$ is positive-definite (A. M. Lyapunov). It is evident, in addition, that the function $V_+(x)$ or the function $V_-(x)$ will be negative everywhere, except at the point x_+^0, where $x_+ = x_+^0 + A^{-1}b(1 + \varphi_0) = 0$, or the point x_-^0, where $x_- = x_-^0 - A^{-1}b(1 - \varphi_0) = 0$). If

$$a_1^{-1}k_p b_1 = k'A^{-1}b > 0, \tag{32}$$

corresponding to negative feedback in the system (1)-(2), then $\sigma(x_+^0) < 0$ and $\sigma(x_-^0) > 0$, so that

$$\begin{aligned} \dot{V}_+(x) &< 0 \quad \text{for} \quad \sigma(x) \geqslant 0, \\ \dot{V}_-(x) &< 0 \quad \text{for} \quad \sigma(x) \leqslant 0. \end{aligned} \tag{33}$$

If the inequalities (33) are satisfied, the function $V(x)$ decreases along any trajectory $x(x^0, t)$, while the point representing the system (2)-(3) moves according to Equations (12) or (13). It remains to show that $V(x)$ also decreases for motion according to (18). We now turn to the proof of this fact, and formulate the final results in the following theorem:

Theorem I. If the conditions (5), (7), and (32) are satisfied for the system (2)-(3), and if there exists a negative-definite form $x'Gx = x'(HA + A'H)x$, satisfying (28), then the equilibrium solution $x = 0$ of this system is asymptotically stable in the large.

In accordance with the equality $H = GA^{-1} - A'HA^{-1}$ we write the relation

$$Hbk'A = GA^{-1}bk'A - A'HA^{-1}bk'A. \tag{34}$$

Further, according to the linking conditions (28) we have

$$A'HA^{-1}bk'A = \mu A'kk'A. \tag{35}$$

If we substitute (34) and (35) in the expression

$$\begin{aligned} \dot{V}_0(x) &= x'(HB + B'H)x = \\ &= x'(G - (b'k)^{-1}(Hbk'A + A'kbH))x, \end{aligned}$$

we obtain the identity

$$\dot{V}_0(x) = f_0'(x)A'^{-1}GA^{-1}f_0(x),$$

from which it follows that $\dot{V}_0(x)$ is zero only at points x_0 of the set $f_0(x) = 0$. This set and the surface $\sigma(x) = 0$ have only one common point – the origin 0.

Actually, we have [see (16)-(18)], the equality

$$f_0(x) = Ax + b\xi,$$

so that $x_0 = -\xi A^{-1}b$. According to (32) the relation $\sigma(x_0) = -\xi k'A^{-1} \cdot b = 0$ can hold only for $\xi = 0$, i.e., only at the point 0. At the remaining points of the surface $\sigma(x) = 0$, the function $\dot{V}_0(x)$ is negative.

Thus, when the conditions of Theorem I are satisfied, the infinitely large positive-definite function (29) strictly decreases along any nonzero trajectory $x(x^0, t)$. The system (2)-(3) will satisfy all the essential conditions of Theorem I of [10].

We have reduced the investigation of the equilibrium stability of the system (2)-(3) in the case considered to a study of conditions that are sufficient for the compatibility of the equality (28) and the Sylvester criterion for the sign-definiteness of the form $x'Gx$. The limitation (5) appears [7] to be a necessary condition for this compatibility. It is now clear, that in its final part, the method of obtaining the Lyapunov functions is a modification of the method of I. G. Malkin [2] (p. 163), [11, 12], of investigating absolute stability.

5. Let it be possible to choose a negative-definite form $x'Gx = x'(HA + A'H)x$, satisfying (28). If we use the results in [5], p. 251, and consider a pencil of forms

$$x'Gx + \nu \cdot x'Hx, \tag{36}$$

we obtain the inequality

$$\nu_1 x'Hx \leqslant -x'Gx \leqslant \nu_n x'Hx, \tag{37}$$

where ν_1 and ν_n are the least and greatest roots of the characteristic equation of the pencil (36), respectively. From (37) we obtain

$$\nu_1 \cdot V(x) \leqslant -\dot{V}(x) \leqslant \nu_n \cdot V(x) \tag{38}$$

for the rate of change $\dot{V}(x)$ of the function (29) for the motion by using (12) and (13).

For the forms $x'Hx$ and $\dot{V}_0(x) = x'(HB + B'H)x$ on the surface $k'x = 0$ the relation

$$x'Hx = V(x), \quad \nu_1^0 x'Hx \leqslant -\dot{V}_0(x) \leqslant \nu_{n-1}^0 x'Hx, \tag{39}$$

holds, where ν_1^0, ν_{n-1}^0 are the smallest and largest roots, respectively, of the characteristic equation of the form $x^{0\prime}(HB + B'H)^0 x^0 + \nu^0 x^{0\prime} H^0 x^0$, obtained from the pencil

$$x'(HB + B'H)x + \nu x'Hx$$

on applying the relation $k'x = 0$.

The time taken for the distance $r^2 = V(x)$, from a representative point of the system (2)-(3) to the origin, to decrease from the value r_1 to the value r_2, can be given its coarsest estimate by using the inequalities (38) and (39) in a way similar to that in [13] for a linear system. The frequency method [14] is applied to calculate the roots $\nu_1, \nu_n, \nu_1^0, \nu_{n-1}^0$.

6. We now consider the case when the equations of motion of the relay system considered above have the form (2) and (4), i.e., when they are actually given in the form (1)-(2), which is the most common in control theory. The relation (31) between the matrix $\mathbf{G} = -\|\beta_{ij}\|_1^n$ and $\mathbf{H} = \|\alpha_{ij}\|_1^n$ (the abbreviated notation is borrowed from [5]) and the condition (28) for $\mu = k_p$ can be written

$$\beta_{ij} = a_{n+1}^{-1}(\alpha_{in}a_j + \alpha_{jn}a_i) - \\ - \alpha_{ji-1} - \alpha_{ij-1}\,(b_0 = \alpha_{i0} = \alpha_{0i} = 0), \tag{40}$$

$$\alpha_{1k} = a_1 b_k \quad (k = 1, \ldots, n), \tag{41}$$

and the Lyapunov function (29) takes the form

$$V(\mathbf{x}) = \sum_{i,\,j=1}^{n} \alpha_{ij} x_i x_j + 2k_p \varphi(\sigma)\sigma. \tag{42}$$

The investigation of the conditions under which the form $-\mathbf{x}'\mathrm{G}\mathbf{x} = \sum\limits_{i,\,j=1}^{n} \beta_{ij} x_i x_j$, which satisfies the conditions (40) and (41), can be positive-definite is more convenient if it is reduced to a consideration not of the matrix $\|\beta_{ij}\|_1^n$, but of the matrix $\|\gamma_{ij}\|_1^n$ congruent to it [5] (p. 240), for which

$$\begin{aligned} &\gamma_{11} = \beta_{11}, \quad \gamma_{i1} = \gamma_{1i} = \beta_{i1} - \beta_{11} a_i, \\ &\gamma_{ij} = \gamma_{ji} = \beta_{ij} - \beta_{i1} a_j - \beta_{1j} a_i + \beta_{11} a_i a_j, \end{aligned} \tag{43}$$

since the quantities γ_{ij} can be expressed more simply in terms of α than the quantities β_{ij}.

A relatively uncomplicated calculation shows that the components of α satisfy condition (41) if, and only if, the components of γ satisfy

$$\gamma_{11} = 2a_{n+1}^{-1} b_n, \quad \gamma_{kk} = \\ = 2\Big(B_{kn} + \sum_{r=0}^{k-3} (-1)^r \gamma_{k+r+1,\,k-r-1}\Big) \\ (k = 2, \ldots, n), \tag{44}$$

where

$$B_{kn} = b_{k-1} a_k - \\ - \sum_{r=0}^{k-2} (-1)^r (b_{k+r} a_{k-r-1} + b_{k-r-2} a_{k+r+1}), \tag{45}$$

$$b_{n+l} = a_{n+l+1} = \alpha_{i,\,n+l} = \gamma_{n+l+1,\,i} = 0,$$

$$\gamma_{n+1,\,i} = -\gamma_{1i} a_{n+1} \quad (l \geqslant 1).$$

We now denote by D_n the determinant of the matrix $\|\gamma_{ij}\|_1^n$, and write Theorem I in a concrete form.

Theorem II. If the elements of the determinant D_n satisfy the relations (44) and (45), and if the quantities γ_{ij} $(i \neq j)$ can be chosen so that all the diagonal minors D_{kn} of the determinant D_n are positive, then the equilibrium state of the system (1)-(2) is asymptotically stable as a whole if its linear part is asymptotically stable for $b_n > 0$.

7. If the condition (8) is satisfied, then the Lyapunov function for the system (2), (4) can be taken to have the form

$$V(\mathbf{x}) = \sum_{i,\,j=2}^{n} \alpha_{ij} x_i x_j + 2k_p \varphi(\sigma)\sigma, \tag{46}$$

obtained from (41) and (42) for $a_1 \to 0$. By calculations and reasoning similar to that in Sec. 4, and with the derivative of $V(\mathbf{x}(\mathbf{x}^0, t))$ [2, 11, 12] taken as the n-variable form,

$$x_1' = \varphi(\sigma), \quad x_k' = x_k \quad (k = 2, \ldots, n).$$

it is easy to show that Theorem II is valid in this case. The construction of the Lyapunov function, however, loses its elegant geometric interpretation. The stability criteria obtained from Theorem II with the assumption (7) tend for $a_1 \to 0$ to a sufficient condition for stability of the system (2), (4) when its linear part is neutral for one coordinate. We note here that these criteria, for $b_n \to 0$, tend to the stability criteria obtained in [7] for $b_n = 0$.

The method of obtaining Lyapunov functions proposed in 4 and 6 thus becomes, for $a_1 \to 0$, an extension of the method of L. G. Malkin to relay systems.

Below (in 8 and 9 we obtain the minimum limitations for n = 3, 4 stability criteria which can be obtained by using Theorem II. These criteria are equivalent to the stability conditions that follow from the theorem of A. I. Lur'e as given by A. M. Letov in [2] (p. 124). Consequently, the assumption [11] that I. G. Malkin's method will give more precise stability conditions than the Lur'e algorithm for control systems with one nonlinear link is, generally speaking, not justified. This method is, however, [2, 12] suitable for obtaining simplified criteria for the stability of systems of high order (n ≥ 5). In Sec. 10 of the present paper, an effective algorithm is proposed for obtaining such criteria.

8. For n = 3 the determinant D_n has the form

$$D_3 = \begin{vmatrix} 2a_4^{-1} b_3 & \gamma_{12} & \gamma_{13} \\ \gamma_{21} & 2B_{23} & \gamma_{23} \\ \gamma_{31} & \gamma_{32} & 2(B_{33} - a_4\gamma_{12}) \end{vmatrix} \tag{47}$$

The simultaneous validity of the inequalities

$$B_{23} > 0. \quad B_{33} - a_4\gamma_{12} > 0, \qquad D_{22} = 4a_4^{-1}b_3B_{23} - \gamma_{12}^2 > 0 \tag{48}$$

is a necessary condition that all the principal minors of the determinant (47) be positive. For $\gamma_{13} = \gamma_{23} = 0$ this condition is also sufficient.

From (48) we obtain the relation

$$\gamma_{12} < a_4^{-1} B_{33},$$

$$-2\sqrt{a_4^{-1} b_3B_{23}} < \gamma_{12} < -2\sqrt{a_4^{-1} b_3B_{23}}$$

and this can be used to obtain necessary and sufficient conditions for the solvability of (48) for γ_{12}:

$$B_{23} = b_1a_2 - b_2a_1 > 0, \qquad B_{33} = b_2a_3 - b_3a_2 - b_1a_4 > -2\sqrt{b_3a_4B_{23}}. \tag{49}$$

According to Theorem II, the conditions (49) are sufficient for the stability in the large of the system (2), (4) that we are considering.

9. For n = 4

$$D_4 = \begin{vmatrix} 2a_5^{-1}b_4 & \gamma_{12} & \gamma_{13} & \gamma_{14} \\ \gamma_{21} & 2B_{24} & \gamma_{23} & \gamma_{24} \\ \gamma_{31} & \gamma_{32} & 2(B_{34} + \gamma_{24}) & \gamma_{34} \\ \gamma_{41} & \gamma_{42} & \gamma_{43} & 2(B_{44} - a_5\gamma_{13}) \end{vmatrix} \tag{50}$$

The simultaneous validity of the inequalities

$$B_{24} > 0, \quad 4a_5^{-1} b_4(B_{34} + \gamma_{24}) - \gamma_{13}^2 > 0, \qquad 4B_{24}(B_{44} - a_5\gamma_{13}) - \gamma_{24}^2 > 0 \tag{51}$$

is a necessary condition that all the principal minors of the determinant (50) be positive. For $\gamma_{12} = \gamma_{14} = \gamma_{23} = \gamma_{34} = 0$, if

$$D_{24} = 4a_5^{-1} b_4B_{24}, \quad D_{34} = 2B_{24}(4a_5^{-1} b_4(B_{34} + \gamma_{24}) - \gamma_{13}^2).$$
$$D_{44} = [4B_{24}(B_{44} - a_4\gamma_{13}) - \gamma_{24}^2]\,[4a_5^{-1} \cdot b_4(B_{34} + \gamma_{24}) - \gamma_{13}^2].$$

this condition also appears to be sufficient. If we use the results of [15] (p. 95), we arrive at the following necessary and sufficient conditions for the solvability of the inequality (51) for γ_{13} and γ_{24}:

$$B_{24} > 0, \tag{52}$$

$$M^3 + N^3 - M^2N^2 - \frac{9}{8}MN + \frac{27}{956} > 0, \tag{53}$$

where

$$M = 0.25\, B_{44}B_{24}^{-\frac{1}{3}}b_4^{-\frac{2}{3}}a_5^{\frac{2}{3}}, \tag{54}$$

$$N = 0.24\, B_{34}B_{24}^{-\frac{2}{3}}b_4^{-\frac{1}{3}}a_5^{\frac{1}{3}}.$$

According to Theorem II, the conditions (52)-(54) are sufficient for stability in the large for the system (2), (4).

10. For $n \geq 5$, the most precise criteria that can be obtained from Theorem II involve calculations that make them practically inapplicable in their general form. In order to obtain simplified stability criteria, the method can be recommended of insisting that only one or two elements γ_{ij} $(i \neq j)$ be exactly equal to zero, and of reducing the condition that the main minors of the determinant D_n be positive to inequalities similar to the relations (46) and (51).

Thus, for example, the simple inequalities

$$B_{55} + \gamma_{53} + a_6\gamma_{12} > 0. \quad 4a_6^{-1} b_5B_{25} - \gamma_{12}^2 > 0, \qquad 4B_{35}B_{45} - \gamma_{53}^2 > 0 \tag{55}$$

are obtained for n = 5, when the values of the elements γ_{12} and γ_{35} of the determinant D_5 are left as variable quantities. Calculations similar to those in 8, applied to the system (55), yield the criteria

$$B_{25}, \quad B_{35}, \quad B_{45} > 0,$$

$$B_{55} > -2(\sqrt{B_{34}B_{45}} + \sqrt{a_6b_5B_{25}})$$

for the stability of the relay system considered. If we do not assume that the elements γ_{24} and γ_{53} are equal to zero, we obtain

$$D_5 = 2a_6^{-1}b_5 \begin{vmatrix} 2B_{25} & 0 & \gamma_{24} & 0 \\ 0 & 2(B_{35} + \gamma_{24}) & 0 & \gamma_{35} \\ \gamma_{24} & 0 & 2(B_{45} + \gamma_{53}) & 0 \\ 0 & \gamma_{53} & 0 & 2B_{55} \end{vmatrix}.$$

The reasoning applied in 9 leads to stability conditions given by the relations $B_{25} > 0$, $B_{55} > 0$, and (53), where $M = 0.25\, B_{25}^{-1/3} B_{35}B_{55}^{-2/3}$, $N = 0.25\, B_{25}^{-2/3}B_{45}B_{55}^{-1/3}$.

In conclusion, we note that the very simple stability criterion

$$B_{kn} > 0$$

can be obtained from Theorem II for any $n \geq 2$, if we set $\gamma_{ij} = 0$, for $i \neq j$, in the determinant D_n.

The author wishes to thank E. A. Barbashin for his guidance and help in the work involved in preparing the present paper.

THE APPLICATION OF THE METHOD OF SMALL PARAMETERS IN THE INVESTIGATION OF SYSTEMS OF AUTOMATIC CONTROL WITH DELAY

Yu. A. Ryabov

Moscow

Translated from Avtomatika i Telemekhanika, Vol. 21, No. 6, pp. 729-739, June, 1960

A method of investigation of systems of automatic regulation (SAR) with retardation is presented, based on the consideration of retardation as a small parameter and the application of the Lyapunov-Poincaré method of small parameters. The case is considered of a SAR expressed as a linear equation with constant coefficients and with a single constant retardation.

In many problems of automatic control, the delay is small and plays the role of a type of interference causing a distortion in that "undisturbed" process which would occur in the absence of any delay. It is therefore completely natural in such problems to consider the delay as a small parameter, and to attempt to apply the Poincaré-Lyapunov method of small parameters. One method of investigation of automatic control systems with delay is to seek the solution of the relevant differential equations by using successive approximations, with the first approximation taken to be the solution of these equations with a zero delay. We will consider here linear equations with constant coefficients and a single constant delay, although this method can also be used with known restrictions in the case of equations with variable coefficients with delay, and also in the case of quasi-linear equations.

1. In the general case, the equations we will consider have the form

$$\dot{x}_s(t) = \sum_{j=1}^{n} [a_{sj} x_j(t) + b_{sj} x_j(t-\mu)] \quad (s = 1, \ldots, n), \tag{1}$$

where a_{sj} and b_{sj} are constant coefficients and μ is the constant delay.

Let the functions $x_1^{(0)}, \ldots, x_n^{(0)}$ form a solution of the system (1) for $\mu = 0$ (we will call this solution undisturbed) and for the initial conditions $x_s(0) = x_{s0}$ ($t = 0$ being the initial instant of time). If we rewrite (1) in the form

$$\dot{x}_s(t) = \sum_{j=1}^{n} \bar{a}_{sj} x_j(t) + \sum_{j=1}^{n} b_{sj} [x_j(t-\mu) - x_j(t)], \quad \bar{a}_{sj} = a_{sj} + b_{sj}, \tag{2}$$

then we can consider the difference $x_j(t-\mu) - x_j(t)$ in these equations as a type of nonlinearity depending on the small parameter μ and becoming zero for $\mu = 0$. Then for obtaining the solution of the system (2), it is natural to consider the method that is applied in the theory of differential equations with small parameters (see, for example, [1]). If we take $x_s^{(0)}$ for the zeroth approximation, then, for the first approximation, we use $x_s^{(1)}$, $s = 1, \ldots, n$, which is the solution of the system

$$\dot{x}_s(t) = \sum_{j=1}^{n} \bar{a}_{sj} x_j^{(1)}(t) + \sum_{j=1}^{n} b_{sj} [x_j^{(0)}(t-\mu) - x_j^{0}(t)], \tag{3}$$

for the same initial conditions $x_s^{(1)}(0) = x_{s0}$. Since the functions $x_j^{(0)}(t)$ are already known, then the differences $x_j^{(0)}(t-\mu) - x_j^{(0)}(t)$ are known functions of t and the delay μ, where μ plays the part of a parameter. The equations (3) are ordinary linear inhomogeneous equations. Their solutions, defined uniquely for all $-\infty < t < \infty$, are obtained in the form $x_s^{(1)} = x_s + \bar{x}_s^{(1)}$, where the functions $\bar{x}_s^{(1)} = \bar{x}_s^{(1)}(t, \mu)$ become zero for $t = 0$ or $\mu = 0$. The second approximation $x_s^{(2)}$ is obtained in a similar way as the solution of the inhomogeneous linear system

$$\dot{x}_s^{(2)}(t) = \sum_{j=1}^{n} \bar{a}_{sj} x_j^{(2)}(t) + \sum_{j=1}^{n} b_{sj} [x_j^{(1)}(t-\mu) - x_j^{(1)}(t)] \tag{4}$$

with the initial conditions $x_s^{(2)}(0) = x_{s0}$. As a result we obtain $x_s^{(2)} = x_s^{(0)} + \bar{x}_s^{(1)} + \bar{x}_s^{(2)}$, where the functions $\bar{x}_s^{(2)} = \bar{x}_s^{(2)}(t, \mu)$ are of the second order of smallness relative to μ, (and so on. For the kth approximation we obtain $x_s^{(k)} = x_s^{(0)} + \bar{x}_s^{(1)} + \ldots + \bar{x}_s^{k}$. In the limit (for $k \to \infty$) the solution of the system (1) can be written as a series:

$$x_s = x_s^{(0)} + \sum_{k=1}^{\infty} \bar{x}_s^{(k)} \quad (s = 1, \ldots, n), \tag{5}$$

where the functions $\bar{x}_s^{(m)}$, $m = 1, 2, \ldots$ are of order m relative to μ. Each term of this series is a function that is analytic in $\underline{t}$ and μ for $-\infty < t < \infty$ and any finite μ. It can be shown, that, if μ does not exceed a certain bound μ_0 which depends on the coefficients of the system (1), then the series (5) is convergent and is uniformly convergent relative to $\underline{t}$ in any finite interval of $\underline{t}$. The sum of this series for $\mu < \mu_0$ is consequently an analytic function of $\underline{t}$, and the above iteration process, in all cases when μ is sufficiently small, can be used to obtain a solution of the equations (1) in $-\infty < t < \infty$ having continuous derivatives of all orders at every point and satisfying the given initial conditions $x_s(0) = x_{s0}$.

2. It follows from the general theory of differential equations with delay that the solution of the system (1) depends not only on the initial values x_{s0} of the functions sought at the initial instant of time $t = 0$, but also on the so-called initial functions $\varphi_1, \ldots, \varphi_n$. The functions $x_1, \ldots, x_n$ are set equal to the respective initial functions in the interval $-\mu \leq t < 0$. These initial functions express the "previous history" or the "hereditary properties" of the dynamic system being considered that is described by the equations (1). The solution obtained by our proposed method is uniquely determined by a single set of initial values x_{s0}. This solution does not exhibit the so-called "hereditary properties," and is only one particular solution among the infinite number of solutions determined by the same initial conditions but with different initial functions. The question arises of the position of this solution of the system (1) among the other solutions.

We will consider as an example the equation

$$\dot{x}(t) = ax(t-\mu), \tag{6}$$

where $\underline{a}$ is a positive number, and we denote by $\psi(t)$ the solution of this equation corresponding to some initial function $\varphi(t)$ that is defined, continuous, and bounded for $-\mu \leq t < 0$. By using the "step" method we obtain successively the values of $\psi(t)$ in each of the intervals $[t_{k-1}, t_k]$, $t_k = k\mu$, $k = 1, 2, \ldots$ As is known (see [2], for example), we can be sure that the function $\psi(t)$ will possess in the interval $t_{k-1} \leq t < t_k$ continuous derivatives up to and including the $(k-1)$th order, and a continuous $\underline{k}$th derivative in the interval $t_{k-1} \leq t < t_k$. It is therefore possible to express this function in the interval $t_{k-1} \leq t \leq t_k$ in the form of a Taylor series with a remainder as

$$\psi(t) = \psi_k + \bar{t}\dot{\psi}_k + \ldots + \frac{\bar{t}^{k-1}}{(k-1)!}\psi_k^{(k-1)} + \frac{\bar{t}^k}{k!}\psi^{(k)}(\theta_k), \tag{7}$$

where $\bar{t} = t - t_k$, $\psi_k = \psi(t_k)$, $\psi_k^{(\sigma)} = \psi^{(\sigma)}(t_k)$, $\sigma = 1, 2, \ldots, k-1$, $t_{k-1} < \theta_k < t_k$, where $\psi^{(k)}(\theta_k) = a^k\varphi(\bar{\theta})$, $\mu < \bar{\theta} < 0$. Moreover, by using the condition of continuity of the derivatives of the function $\psi(t)$ at $t = t_k$ up to and including the $(k-1)$th order (derivatives from the left, of course), we arrive at the following relations between the values of the function $\psi(t)$ at the points $t = t_k$, $t = t_{k-1}$ and its derivatives at the point $t = t_{k-1}$:

$$\begin{aligned} u_0 &= \psi_k - \mu a u_0 + \frac{\mu^2}{2} a u_1 - \ldots + (-1)^{k-1}\frac{\mu^{k-1}}{(k-1)!} a u_{k-1} + \delta_k, \\ u_1 &= a u_0 - \mu a u_1 + \ldots + (-1)^{k-2}\frac{\mu^{k-2}}{(k-2)!} a u_{k-2} + \delta_{k-1}, \\ &\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \\ u_{k-1} &= a u_{k-2} + \delta_1, \end{aligned} \tag{8}$$

where $u_j = \psi^{(j)}(t_{k-1})$, $j = 1, \ldots, k-1$, $u_0 = \psi(t_{k-1})$, $\delta_\sigma = (-1)^\sigma a^k \mu^\sigma/\sigma!\ \varphi(\theta_\sigma)$, $-\mu < \theta_\sigma < 0$.

These equations are linear algebraic equations in $u_0, \ldots, u_{k-1}$. If we solve them for $u_0, \ldots, u_{k-1}$, and then express $\dot{\psi}_k, \ddot{\psi}_k, \ldots$ by the formulas $\dot{\psi}_k = au_0$, $\ddot{\psi}_k = au_1, \ldots$ and substitute these expressions in (7), we obtain $\psi(t)$ in the interval $t_{k-1} \leq t \leq t_k$ in the form $\psi(t) = \tilde{\psi}_k(t) + \Delta\psi_k(t)$, where the function $\tilde{\psi}_k(t)$ corresponds to the solution of Equations (8) for $\delta_1 = \ldots = \delta_k = 0$, and the function $\Delta\psi_k(t)$ depends linearly on $\delta_1, \ldots, \delta_k$ and is of the order $\underline{k}$ relative to μ. Thus,

$$\Delta\psi_2(t) = \bar{t}\,\frac{\delta_2}{A} + \frac{\bar{t}^2}{2}a^2\varphi(\bar{\theta}_2),\ \Delta\psi_3(t) =$$

$$= \bar{t}\left(\frac{\mu^2}{2}\delta_2 + A\delta_3\right)\frac{1}{\Delta_2} + \frac{\bar{t}^2}{2}(A\delta_2 + \delta_3)\frac{1}{\Delta_2} + \frac{\bar{t}^3}{3!}a^3\varphi(\bar{\theta}_3),$$

where $A = 1 + \mu a/a$, $\Delta_2 = A^2 - \mu^2/2$, and the arguments $\bar{\theta}_2, \bar{\theta}_3$ of the function φ are in the interval $(-\mu, 0)$. If $|\varphi(t)| \leq \gamma$, then we can obtain the inequality

$$|\Delta\psi_2(t)| \leqslant \frac{|a\mu|^2}{2}\left(1 + \frac{\mu}{|A|}\right)\gamma,\ |\Delta\psi_3(t)| \leqslant$$

$$\leqslant \frac{|a\mu|^3}{3!}\left[1 + \left(2\mu^2 + \frac{5}{2}|A|\mu\right)\frac{1}{\Delta_2}\right]\gamma$$

$$t_1 \leqslant t < t_2, \quad t_2 \leqslant t < t_3$$

and similar formulas for $\Delta\psi_4, \Delta\psi_5, \ldots$. These inequalities show that for small values of μ, or, more correctly, for small values of the product $|a|\mu$, the functions $\Delta\psi_k$ decrease very rapidly in absolute value for increasing k. For all values of k we have $|\Delta\psi_k(t)| \le Q_k(\mu)\gamma$, where $Q_k(\mu)$ is of order k relative to μ.

We will now consider the solution $\overline{x}(t, t_k)$ of Eq. (6) obtained by the method of iterations for the initial condition $x(t_k) = \psi_k$. Since this solution has continuous derivatives of any order at $t = t_k$, a relation similar to (7) and (8) can be obtained for it. As a result, we find that, in the interval $t_{k-1} \le t < t_k$,

$$\overline{x}(t, t_k) = \widetilde{\psi}_k(t) + \Delta\overline{x}_k(t),$$

where the function $\Delta\overline{x}_k(t)$ consists of terms of order k and higher relative to μ for $t_{k-1} \le t < t_k$. For the difference between the functions $\overline{x}(t, t_k)$ and $\psi_k(t)$ in this interval, we obtain the inequality

$$|\psi(t) - \overline{x}(t, t_k)| \leqslant |\Delta\psi_k(t)| + |\Delta\overline{x}_k(t)|.$$

For values of μ for which the solution $\overline{x}(t, t_k)$ exists and for all values of t, we have $\lim\limits_{k\to\infty} \Delta\overline{x}_k = 0$. This is clear from the fact that if we expand $\overline{x}(t, t_k)$ in a double series of powers of $t - t_k$ and μ, then $\Delta\overline{x}_k$ is part of the remainder term of this series. It can be shown that for these values of μ we have $\lim\limits_{k\to\infty} Q_k(\mu) = 0$, so that $\Delta\psi_k \to 0$, and also $|\psi(t) - \overline{x}(t, t_k)| \to 0$ for $k \to \infty$.

If we denote by $\varphi_k(t)$ and $\overline{\varphi}_k(t)$ functions given in the interval $t_{k-1} \le t < t_k$, and coinciding in this interval with $\psi(t)$ and $\overline{x}(t, t_k)$, respectively, then these functions can be considered as initial functions determining the solution $\psi(t)$ and $\overline{x}(t, t_k)$ for $t > t_k$. Since the difference $\varphi_k(t) - \overline{\varphi}_k(t)$ tends to zero for $k \to \infty$, and in view of the continuous dependence of the solutions of differential equations with delay on the initial functions, the solution $\psi(t)$ will be a more accurate approximation to the solution $\overline{x}(t, t_k)$ for $t > t_k$, for larger t_k. The following theorem can be proved rigorously.

Let two arbitrary positive numbers ϵ and L be given, where ϵ can be as small as we wish and L can be as large as we wish. Then, in every case, if $\mu < 1/(|a|e)$, there is an instant of time T such that if $t_* > T$, then in the interval $[t_*, t_* + L]$, where $t_* > T$, the inequality $|\psi(t) - \overline{x}(t, t_k)| \le \epsilon$, will hold where $\psi(t)$ is the solution of Equation (6) determined by the initial function $\varphi(t)$, and $x(t, t_k)$ is the solution of this equation obtained by the method described above for the initial condition $x|_{t=t_k} = \psi(t_*)$. The time T depends on ϵ, a, μ, and on the upper limit of the absolute value of $\varphi(t)$.

This theorem can easily be extended to cover the case of the equation

$$\dot{x}(t) = ax(t) + bx(t-\mu),$$

where a, b, μ are constants, and also the case of the system

$$\dot{x}_s(t) = a_{s1}x_1(t-\mu) + \ldots + a_{sn}x_n(t-\mu) \qquad (s = 1, \ldots, n), \tag{8*}$$

where $a_{s\sigma}$ and μ are constant. In the latter case the theorem holds if $\mu < 1/(|\overline{\lambda}|e)$, where $\overline{\lambda}$ is the root of the characteristic equation with the largest absolute value for $\mu = 0$. In the general case of a system of type (1), we have not proved this theorem rigorously, but it is evident that it is valid.

Thus, in all cases of equations with a delay of a certain type, when the delay is sufficiently small, a phenomenon takes place that can be called the relaxation of "heredity," i.e., the weakening of the influence of the "heredity" with time.

In fact, let us consider a dynamic system described by the equations (1). Because of the dependence of the solution of these equations on the initial functions, the state of the system at any instant of time $t > 0$ will depend not only on its state of the system at any instant $t = 0$, but also, on its state in the preceding interval of time from $t = -\mu$ to $t = 0$. We will consider a certain instant t_*, that is sufficiently far from the origin, and will assume that the state of the system at this instant is fixed. Then, in view of the above-stated theorem, the state of the system for a reasonably large interval of time beginning with t_* will depend mainly on its state at the instant of time $t = t_*$, and can be adequately predicted. The influence of the state of the system in the interval of time preceding t_* becomes smaller as the time t_* becomes larger. The behavior of the system in this case corresponds to a certain extent to a so-called Markoff process.

The question is very intersting as to whether this phenomenon also occurs for systems described by more complex equations with delay—for example, in the case of variable coefficients with delay, and in the case of nonlinear systems.

On the basis of what has been said, the solutions obtained by the proposed method can be called "limiting" solutions. For linear systems of the type (1) when the above-stated theorem holds, it can be proven that certain characteristics of the asymptotic behavior are the same (for $t \to \infty$) for the limiting solutions and for any solution of the system corresponding to arbitrary initial functions. Thus, it can be shown that if the functions $x_1, \ldots, x_n$ in the "limiting" solution constructed for any initial conditions $x_s(0) = x_{s0}$ tend to zero for $t \to \infty$, then any solution of the system (1) has the same property. Also, if the initial conditions are such that the functions $x_1, \ldots, x_n$ in the "limiting" solution increase without limit in absolute value, then, for arbitrary initial functions (if they are not specially chosen – a case that will be considered below), the functions $x_1, \ldots, x_n$ in the corresponding solution also increase without limit (in absolute value). If all the roots of the characteristic equation for the system (1) for $\mu = 0$ have negative real parts, and if μ does not exceed a certain bound μ_0, then the functions $x_1, \ldots, x_n$ in any "limiting" solution tend to zero as $t \to \infty$, and so do the solutions for arbitrary initial functions. In other words, the zero solution of the system (1) possesses asymptotic stability both for $\mu = 0$ and for $\mu < \bar{\mu}$, and this property does not depend either on the initial conditions or on the initial functions. If, among the roots $\lambda_1, \ldots, \lambda_n$ of the characteristic equation, there are roots with positive real parts, then the zero solution ceases to be stable both for $\mu = 0$ and for any other value of μ. This conclusion concerning the equivalence in a certain sense of the solutions of a system of the type (1) for $\mu = 0$ and $\mu \neq 0$ agrees with the results of [3]. Nothing that has been said in this section contradicts the results of A. D. Myshkis ([4], §§ 11, 23) on the classification of solutions of equations with delay. Let us assume, for example, that all the roots $\lambda_1, \ldots, \lambda_n$ of the characteristic equation for the system (1) for $\mu = 0$ have negative real parts. Then, according to this classification, all the solutions can be separated for sufficiently small μ into two categories: 1) the weakly damped solutions, tending to zero not more rapidly than $e^{\rho t}$, where ρ is the least of the absolute values of the real parts of the roots $\lambda_1, \ldots \lambda_n$; 2) the strongly damped solutions, tending to zero as rapidly as we please according to the law $e^{\alpha t}$, where $\alpha \to -\infty$ for $\mu \to 0$. If the solution of the system (1) is sought by using Euler's method in the form of exponential functions $x_s = c_s e^{\lambda t}$, then the solutions of the first type correspond to those roots of the characteristic equation

$$\| a + be^{-\lambda\mu} - E\lambda \| = 0, \qquad (9)$$

of the system (1) that, for $\mu \to 0$, tend to the corresponding roots $\lambda_1, \ldots, \lambda_n$ of the characteristic equation $\| a + b - E\lambda \| = 0$. The solutions of the second type correspond to those complex roots $\alpha \pm \beta_i$ of Equation (9) for which $\alpha \to -\infty$ for $\mu \to 0$. For arbitrary initial functions we obtain a solution that can be represented as some combination of the two types of solution. The terms corresponding to solutions of the second type decrease very rapidly, and, after a relatively short time interval starting at the initial instant, they cease to influence the further behavior of the solution, which is thereafter determined by the main terms corresponding to a combination of solutions of the first type. The "limiting" solution corresponds to this latter combination of solutions of the first type.

If among the roots $\lambda_1, \ldots, \lambda_n$ there are roots with positive real parts, then for arbitrary initial functions we obtain a solution in which the functions $x_1, \ldots, x_n$ increase in absolute value without limit. It is, of course, possible to choose the initial functions in such a way that they correspond to solutions of the form $x_s = c_s e^{\alpha t} \cos \beta t$ or to a combination of such solutions, where $\alpha + \beta i$ is a root of Equation (9) that is discontinuous for $\mu = 0$, i.e., $\alpha \to -\infty$ for $\mu \to 0$. In other words, for the zero solution of the system (1) for sufficiently small μ, as for $\mu = 0$, the so-called stability condition is satisfied.

3. We will consider a system of equations arising in a problem on the stabilization of a rocket relative to its yaw angle γ by an automatic pilot with rigid inverse coupling, and a delay μ in the argument of the controlling parameter of the rudder mechanism:

$$\ddot{\gamma}(t) + b_1 \dot{\gamma}(t) + b_3 \delta(t) = 0, \quad \delta(t) + \delta(t) = \sigma(t - \mu), \quad \sigma(t) = p_1 \gamma(t) + p_2 \gamma(t). \qquad (10)$$

Here b_1 and b_3 are positive constant coefficients characterizing the object being controlled, and p_1 and p_2 are positive constant parameters of the regulator. Since the regulator does not act until $\gamma = \dot{\gamma} = 0$, and then $\delta = 0$, the initial functions must be assumed to be zero, i.e., we set $\sigma = 0$ for $-\mu \leq t < 0$, and the initial values are $\gamma(0) = \gamma_0$, $\dot{\gamma}(0) = \dot{\gamma}_0$, $\delta(0) = 0$.

We will give the formulas that can be used in the iteration method to construct the "limiting" solution $\bar{\gamma}(t, t_0)$ of this system for the arbitrary initial conditions $\gamma(t_0) = \gamma_0$, $\dot{\gamma}(t_0) = \dot{\gamma}_0$, $\delta(t_0) = \delta_0$. Here we are interested only in the regulated coordinate γ, and so we transform the system (10) into a single equation for γ:

$$\dddot{\gamma}(t) + (1 + b_1)\ddot{\gamma}(t) + b_1\dot{\gamma}(t) + b_3[p_1\gamma(t - \mu) + p_2\dot{\gamma}(t - \mu)] = 0. \qquad (10^*)$$

If we set $\mu = 0$ and assume for simplicity that $t_0 = 0$, then we obtain the "undisturbed" solution $\gamma^{(0)}(t)$ of this equation in the form

$$\gamma^{(0)} = A_1 e^{\lambda t} + (A_2 \cos \omega t + A_3 \sin \omega t) e^{at}, \qquad (11)$$

where

$$A_1 = \frac{1}{s}[\ddot{\gamma}_0 - 2a\dot{\gamma}_0 + (a^2 + \omega^2)\gamma_0],$$

$$A_2 = \frac{1}{s}[-\ddot{\gamma}_0 + 2a\dot{\gamma}_0 + (\lambda^2 - 2a\lambda)\gamma_0],$$

$$A_3 = \frac{1}{\omega^2 s}[(a - \lambda)\ddot{\gamma}_0 + (\lambda^2 + \omega^2 - a^2)\dot{\gamma}_0 + \lambda(a^2 - \omega^2 - a\lambda)\gamma_0], \quad s = (a - \lambda)^2 + \omega^2.$$

Here λ, a ± iω are the roots of the characteristic equation for the system (10) for $\mu = 0$:

$$k^3 + (1 + b_1)k^2 + (b_1 + b_3p_2)k + b_3p_1 = 0. \quad (12)$$

This equation has one real root and two complex (or purely imaginary) roots. Our main interest, of course, is to find the region of values of the coefficients of the system, for which λ and a are negative, i.e., the region of asymptotic stability of the zero solution of the system (10) for $\mu = 0$.

The first approximation of the "limiting" solution is obtained in the form $\gamma^{(1)} = \gamma^{(0)} + \bar{\gamma}^{(1)}$, where $\bar{\gamma}^{(1)}$ is the solution of the linear homogeneous equation

$$\dddot{\bar{\gamma}}^{(1)} + (1 + b_1)\ddot{\bar{\gamma}}^{(2)} + (b_1 + b_3p_2)\dot{\bar{\gamma}}^{(1)} + b_3p_1\bar{\gamma}^{(1)} = \\ = -b_3p_1[\gamma^{(0)}(t-\mu) - \gamma^{(0)}(t)] - b_3p_2[\dot{\bar{\gamma}}^{(0)}(t-\mu) - \\ - \gamma^{(0)}(t)]$$

for zero initial conditions. This solution is found from the formula

$$\bar{\gamma}^{(1)} = \frac{b_3}{s}\int_0^t f(t-\tau)[p_1\Delta\gamma^{(0)}(\tau) + p_2\Delta\dot{\gamma}^{(0)}(\tau)]\,d\tau, \quad (13)$$

where

$$\Delta\gamma^{(0)}(t) = \gamma^{(0)}(t-\mu) - \gamma^{(0)}(t),$$

$$\Delta\dot{\gamma}^{(0)}(t) = \frac{d}{dt}\Delta\gamma^{(0)}(t),$$

$$f(t) = -e^{\lambda t} + \left(\cos\omega t + \frac{\lambda - a}{\omega}\sin\omega t\right).$$

The function $\Delta\gamma^{(0)}$ can be written according to (11) in the form

$$\Delta\gamma^{(0)}(t) = A_1\chi_1e^{\lambda t} + [(A_2\chi_2 - A_3\chi_3)\cos\omega t + \\ + (A_2\chi_3 + A_3\chi_2)\sin\omega t]e^{at}, \quad (14)$$

where the quantities $\chi_1 = e^{-\lambda\mu} - 1$, $\chi_2 = e^{-a\mu}\cos\omega\mu - 1$, $\chi_3 = e^{-a\mu}\sin\omega\mu$ are of the first order relative to μ. If we differentiate this equation with respect to t, we obtain $\Delta\dot{\gamma}^{(0)}(t)$.

A calculation leads to the formula

$$\bar{\gamma}^{(1)} = (M_1^{(1)} + M_2^{(1)}t)e^{\lambda t} + \\ + [(N_1^{(1)} + N_2^{(1)}t)\cos\omega t + \\ + (L_1^{(1)} + L_2^{(1)}t)\sin\omega t]e^{at}, \quad (15)$$

where

$$M_2^{(1)} = -\chi_1\frac{A_1b_3}{s}(p_1 + p_2\lambda), \quad N_2^{(1)} = \frac{1}{2}(l_2A_2 + l_3A_3),$$

$$L_2^{(1)} = \frac{1}{2}(-l_3A_2 + l_2A_3).$$

$$M_1^{(1)} = \frac{2(a-\lambda)}{s}M_2^{(1)} - \frac{2\omega}{s}L_2^{(1)},$$

$$L_1^{(1)} = \frac{(\lambda-a)^2 - \omega^2}{\omega s}M_2^{(1)} - \frac{1}{\omega}N_2^{(1)} + \frac{2(\lambda-a)}{s}L_2^{(1)}.$$

$$l_2 = \frac{b_3}{s}[(p_1 + p_2a)\bar{\chi}_2 + p_2\omega\bar{\chi}_3],$$

$$l_3 = \frac{b_3}{s}[p_2\omega\bar{\chi}_3 + (p_1 + p_2a)\bar{\chi}_2],$$

$$\bar{\chi}_2 = \chi_2 - \frac{\lambda - a}{\omega}\chi_3, \quad \bar{\chi}_3 = \chi_3 - \frac{\lambda + a}{\omega}\chi_2.$$

All the approximations can be obtained similarly in the form

$$\gamma^{(k)} = \gamma^{(0)} + \bar{\gamma}^{(1)} + \ldots + \bar{\gamma}^{(k)},$$

where
